At the same altitudes, the sun, moon, and stars all undergo the same refraction: for at equal altitudes the incident rays have the same inclinations; and the sines of the refracted angles are as the sines of the angles of inclination, &c.

Ptolemy, Albazen, and Vitello, were all acquainted with this refraction, having given many observations on it, though imperfect on the score of accuracy. But Tycho Brahé, who deduced the refractions of the sun, moon, and stars from good observations, and whose table of the refractions of the stars is not much different from those of Flamsteed and Newton, except near the horizon, makes the solar refractions about 4′ greater than those of the fixed stars, and the lunar refractions also sometimes greater than those of the stars, and sometimes less. But the theory of refractions discovered by Snell, was not fully understood in his time.

The horizontal refraction, being the greatest, is the cause that the sun and moon appear of an oval form at their rising and setting; for the lower edge of each being more refracted than the upper edge, the perpendicular diameter is shortened, and the under edge appears more flatted also.—Hence also, if we take with an instrument the distance of two stars when they are in the same vertical and near the horizon, we shall find it considerably less than if we measure it when they are both at such a height as to suffer little or no refraction; because the lower star is more elevated than the higher. There is also another alteration made by refraction in the apparent distance of stars: when two stars are in the same almacantar, or parallel of declination, their apparent distance is less than the true; for since refraction makes each of them higher in the azimuth or vertical in which they appear, it must bring them into parts of the vertical where they come nearer to each other; because all vertical circles converge and meet in the zenith. This contraction of distance, according to Dr. Halley (Philos. Trans. numb. 368) is at the rate of at least one second in a degree; so that, if the distance between two stars in a position parallel to the horizon measure 30°, it is at most to be reckoned only 29° 59′ 30″.

The quantity of the refraction at every altitude, from the horizon, where it is greatest, to the zenith where it is nothing, has been determined by observation, by many astronomers; those of Dr. Bradley and Mr. Mayer are nearly alike, and have been used by most astronomers. Doctor Bradley, from his observations, deduced this very simple and general rule for the refraction r at any altitude a whatever; viz, as rad. 1 : cotang. $a + 3r$ :: 57″ : r'' the refraction in seconds; that is, refr. $r = 57'' \times$ cot. $(a+3r)$, or, which is the same, refr. $r = 57'' \times$ tan. $(z-3r)$, where z is the zenith distance.

This rule, of Dr. Bradley's, is adapted to these states of the barometer and thermometer, viz,

either 29·6 inc. barom. and 50° thermometer,
or 30 — barom. and 55 thermometer,

for both which states it answers equally the same. But for any other states of the barometer and thermometer, the refraction above-found is to be corrected in this manner, viz, by either of the two following rules, the first of them given by Dr. Maskelyne, and the 2d by Dr. Brinkley.

$$\text{Refrac.} = \frac{b}{29\cdot6} \times \text{tan.}\,(z-3r) \times 57'' \times \frac{400}{350+t}.$$

$$\text{Refrac.} = \frac{b}{29\cdot6} \times \text{tan.}\,(z-3\cdot2r) \times 56''\cdot9 \times \frac{500}{450+t}.$$

Where b = altitude of barometer in inches,
t = height of Fahrenheit's thermometer in deg.
$r = 57''$ tan. z the appar. zenith dist.

From Dr. Bradley's rule, $r = 57'' \times$ cot. $(a+3r)$ was computed the table of mean astronomical refractions, given in pa. 1 of Dr. Maskelyne's requisite tables.

M. Laplace gave also a rule for the refractions, in vol. 4 of his Mecanique Celeste. He first assumed it of the same form as Dr. Bradley's, viz, $r = m \times$ cot. $(a+nr)$ $= m \times$ tan. $(z-nr)$, with general coefficients m and n, to be determined by comparing this general formula with two observations; where a denotes the true altitude, or z the true zenith distance, and r the refraction. Besides determining these co-efficients, m, n, more accurately, than in Dr. Bradley's rule, he also reduced the result to a more convenient form for use, which is expressed by this general equation, $\cdot99765175 \sin z = \sin (z - 8r)$. But by computation I find that the first numeral co-efficient ought more correctly to be ·997684, and then the rule will be $\cdot997684 \sin z = \sin (z - 8r)$. That is, to use it, multiply the sine of the true zenith distance by ·997684, or add their logarithms, the result will be the sine of the other arc $(z - 8r)$; therefore subtract this last arc from z, the remainder will be $8r$, which therefore divided by 8, gives r the fraction sought. By this rule then the numbers in the following table have been calculated, though the apparent altitudes are set down in the table, in order to adapt it to the purposes of observation.

TABLE OF REFRACTIONS.—*Barom.* 29·92. *Therm.* 54°.

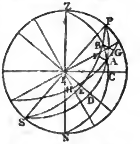
Mr. Mayer says his rule was deduced from theory, and when reduced from French measure and Reaumur's thermometer, to English measure and Fahrenheit's thermometer, it is this,

$r = \frac{74\cdot4h \times \cos. a \times \text{tang.} \frac{1}{2}A}{(1 + \cdot00245t)\frac{1}{2}}$ the refraction in seconds, corrected for both barometer and thermometer: where the letters denote the same things as before, except A, which denotes the angle whose tangent is $\frac{\sqrt{(1 + \cdot00245t)}}{17\cdot14 \sin. a}$.

Mr. Simpson too (Dissert. pa. 46 &c) ingeniously determined by theory the astronomical refractions, from which he formed this rule, viz, As 1 to ·9986 or as radius to sine of 86° 58′ 30″, (or rather 4″,) so is the sine of any given zenith distance, to the sine of an arc; then $\frac{2}{11}$ of the difference between this arc and the zenith distance, is the refraction sought for that zenith distance. And by this rule Mr. Simpson computed a table of the mean refractions, which are not much different from those of Dr. Bradley and Mr. Mayer, being uniformly a few seconds less in every case.

Besides the above, the public have been favoured with other rules, deduced from numerous observations, made by Ste. Groombridge, esq. of Blackheath, a gentleman of fortune, who very laudably amuses himself, and benefits science, by cultivating the practice of astronomy. The results of extensive series of observations on astronomical refractions, he has given in two volumes of the Philos. Trans. both in general rules and large tables of results, differing but very little from those above inserted, and that chiefly in the refractions very near the horizon. In the former volume, viz that for the year 1810, Mr. Groombridge's rule for the mean refraction is $58''\cdot1192 \times \text{tang.} (z - 3\cdot3625r)$, where z is the zenith distance, and r an assumed near value of the refraction. But after numerous other observations, especially on stars at very low altitudes, in the vol. for 1814, Mr. G. by further corrections, reduces the rule to this form, viz, the mean refraction $= 58\cdot132967 \times \text{tang.} (z - 3\cdot6342956)$; from which he has calculated an extensive table of refractions, for every 10′ of altitude; accompanied with other tables, showing the corrections on account of the difference of the barometer and thermometer from their mean states.

It is evident that all observed altitudes of the heavenly bodies ought to be diminished by the numbers taken out of the foregoing tables. It is also evident that the refraction diminishes the right and oblique ascensions of a star, and increases the descensions: it increases the northern declination and latitude, but decreases the southern: in the eastern part of the heavens it diminishes the longitude of a star, but in the western part it increases the same.



REFRACTION *of Altitude*, is an arc of a vertical circle, as AB, by which the altitude of a star AC is increased by the refraction.

REFRACTION *of Ascension and Descension*, is an arc DE of the equator, by which the ascension and descension of a star, whether right or oblique, is increased or diminished by the refraction.

REFRACTION *of Declination*, is an arc BF of a circle of declination, by which the declination of a star DA or EF is increased or diminished by refraction.

REFRACTION *of Latitude* is an arc AG of a circle of latitude, by which the latitude of a star AH is increased or diminished by the refraction.

REFRACTION *of Longitude*, is an arc IH of the ecliptic, by which the longitude of a star is increased or diminished by means of the refraction.

Terrestrial REFRACTION, is that by which terrestrial objects appear to be raised higher than they really are, in observing their altitudes. The quantity of this refraction is estimated by Dr. Maskelyne at one-tenth of the distance of the object observed, expressed in degrees of a great circle. So, if the distance be 10000 fathoms, its 10th part 1000 fathoms, is the 60th part of a degree of a great circle on the earth, or 1', which therefore is the refraction in the altitude of the object at that distance. (Requisite Tables, 1766, pa. 134).

But M. Legendre is induced, he says, by several experiments, to allow only $\frac{1}{14}$th part of the distance for the refraction in altitude. So that, on the distance of 10000 fathoms, the 14th part of which is 714 fathoms, he allows only 44" of terrestrial refraction, so many being contained in the 714 fathoms. See his Memoir concerning the Trigonometrical operations, &c.

Again, M. Delambre, an ingenious French astronomer, makes the quantity of the terrestrial refraction to be the 11th part of the arch of distance. But the English measurers, Col. Edw. Williams, Capt. Mudge, and Mr. Dalby, from a multitude of exact observations made by them, determine the quantity of the medium refraction to be the 12th part of the said distance. The quantity of this refraction, however, is found to vary considerably, with the different states of the weather and atmosphere, from the 15th part of the distance, to the 9th part of the same; the medium of which is the 12th part, as above mentioned.

Some whimsical effects of this refraction are also related, arising from peculiar situations and circumstances. Thus, it is said, that any person standing by the side of the river Thames at Greenwich, when it is high-water there, can see the cattle grazing on the Isle of Dogs, which is the marshy meadow on the other side of the river at that place; but when it is low water, he cannot see any thing of them, as they are hid from his view by the land wall or bank on the other side, which is raised higher than the marsh, to keep out the waters of the river. This curious effect is probably owing to the moist and dense vapours, just above and rising from the surface of the water, being raised higher or lifted up with the surface of the water at the time of high tide, through which the rays pass, and are the more refracted.

In like manner, Calais sometimes is seen from the sea side at Dover.

And other more extraordinary circumstances have been communicated in the following letter from an ingenious friend, Mr. John Andrews.

An account of some remarkable appearances arising from Terrestrial Refraction.

In the year 1792, at Traine, near Modbury, in Devon, for the purpose of obtaining an improved prospect from the garden, a railed platform was erected among the branches of a large spreading laurel-tree, to which was given the name of The Laurel Mount.—It was furnished with chairs, &c, and had moveable staffs, made convenient for resting a telescope at different elevations, so as to form a kind of observatory, for viewing both celestial and terrestrial objects.—Some time after its erection, it was unexpectedly discovered that the pinnacles and flag-staff, on the tower of Maker Church, west of Plymouth Sound, (where signals are made of the ships which pass by that harbour,) might be seen with a telescope, just appearing above the horizon, distance from hence about 12 miles. This object, being frequently looked at, was perceived to appear at certain times higher than usual; and some of the parapet of the tower (below the pinnacles) was evidently seen above the horizon, which was not the case in general; and which, being considered as a curious and remarkable circumstance, occasioned the object to be more frequently and more attentively observed. It was found that the morning was the time best suited for these appearances, which in certain instances were much more remarkable and striking than in others; and that not only the tower, but the scenery of the country, at different distances between it and the place of observation, was in like manner affected by the peculiar state of the atmosphere.—The figures on the plate (plate 30), with the references underneath, will help to explain the following descriptions.

The first instance of this sort occurred on the 9th of January 1794, a little after sunrise; the weather bright, with hard frost, and thick hoary incrustations.—At this time half or more of the shaft of the tower appeared conspicuously above the horizon; its height and appearance frequently varying; sometimes the pinnacles were scarce discernible, and the whole body seemed to be solid; when presently the pinnacles would begin to appear again, as if growing suddenly out of the body of the tower, and shooting up to a greater length than they are of in reality. The horizon itself was also subject to the like mutations, and the trees in Mount Edgcumbe Park, (which is just below the tower,) were sometimes more and sometimes less elevated, and sometimes not visible at all. The intervening scenery assumed the appearance represented in the 3d figure on the plate; objects before concealed by the horizon were elevated considerably above it. Among these was a conical object, supposed then to be a large edifice; and which was, in two journeys for that purpose, searched for in vain; but, being afterwards seen again, from the Mount, altered in size and shape, was found, on a third journey, to be a mow of hay, and was the means of ascertaining the situation of the range of ground at CC, whereon it stood, which might not have been easily done otherwise. It was therefore an object of some importance, and is shown in the 3d drawing at *g*. The enlargement of the prospect was so very singular and striking, as to seem almost as if produced by enchantment.

At this time another phenomenon was observed, which I could scarce believe to be real, till on the 27th of September following it was confirmed by another instance. This was a fluctuating appearance of two horizons, one above the other, with a complete vacancy between them, like what is sometimes observed in looking through an uneven pane of glass. On the day last mentioned, about 6 in the morning, the horizon being perfectly clear, the pinnacles of the tower were observed to have a taller appearance than ordinary; and at about half an hour past 6, a flag being hoisted on the staff, (which is considerably higher than the pinnacles,) the latter appeared to reach farther up towards the flag than they usually did. They also continually varied their appearance, being sometimes longer and sometimes shorter, and sometimes of unequal lengths; and at other times they could not be seen at all, though the flag still continued visible, and was seemingly unaffected. In one of these intervals (of the pinnacles disappearing), the horizon at *c c* being perfectly clear, I began to discern over it a faint stratum of vapour, the upper boundary of which (unevenly terminated) passed just below the flag, which seemed as if in a kind of insulated state. Soon afterwards the stratum extended itself higher, and the flag also became invisible; but in a little while the whole appeared again, when the parapet, pinnacles, and staff, seemed all to have a long and tall appearance, and the flag also to be altered in form from what it had before the extension of the stratum. Not long after this I observed the intervening horizon *c c* begin to be somewhat obscured, the wind probably wafting the stratum of vapour over it, and this obscurity increasing extended itself over all the ground at *c c*, which, (as well as the tower, &c) I then conceived to have a higher elevation than before. The vapour continuing to increase, it became so dense at 40 minutes after 7, as to hide all those objects from my sight, though the hill *b*, and other parts of the horizon, remained exceeding clear.

Another very remarkable instance was observed on the 6th of January 1795, at which time the elevation of the objects was equal to that represented in the 3d drawing, and the phenomenon of the double horizon very distinctly observed both by my brother and myself. The appearances were continually varying and intermitting, but not rapidly, so that sufficient time was afforded for ascertaining their reality beyond a doubt. The vacant line of separation (having the appearance of a whitish stratum of vapour), would often increase its breadth, so as to efface entirely the uppermost of the two horizons; forming then a kind of dent or gap in the remaining horizon; which horizon, at the extremities of the vacancy, seemed to be of the same height as the upper horizon was before its being effaced. This vacancy (continually varying in length as well as breadth), was several times seen to approach and take in the tower, and immediately to admit an apparent view of the whole or the most part of its body (like that in the third drawing), which was not the case before; exactly, to all appearance, as if it had opened a gap for that purpose in the intercepting ground. This phenomenon excited great surprise, and seemed to be inexplicable.

A great many other observations were made in the year 1794 and 1795, and minutes thereof taken, but the above were the most remarkable. The certainty of the phenomena being fully confirmed, less attention was thought necessary, and no further memorandums have been made. After some years the observatory getting into decay, and becoming dangerous, it was taken down, and hath not been since renewed.

In the course of these observations it was remarked that a hoar frost, or that kind of dewy vapour which in a sufficient degree of cold occasions a hoar frost, accompanied by an air rather calm than otherwise, seemed requisite for the elevation of the objects; and that a dry frost, however intense, especially if attended with wind, had no tendency to produce it. Indeed, in several instances of that sort, I have observed the objects very sensibly depressed below their usual pitch. I know at present no other instance of the double horizon having been observed, except by Mr. Isaac Dalby; who (as appears by Phil. Trans. for 1795, pa. 587) noticed an appearance of that sort about nine months before I did.

The telescope made use of was a 3-foot refractor of Dollond's, of the sort with long polygonal tubes of wood. What served me for a micrometer (and from which the scale on the plate was deduced) was a notched bar, made of a piece of fine screw, filed flat, and laid across the focus of the eye-glass.—Its value was ascertained by computing the distance of the stars γ and δ Coronæ, which was found to be the extent of the telescope's field of view. The quantities of elevation are to be understood as judged of by comparing the objects among each other; for having no graduated instrument or level to which the telescope could be attached, and the objects not being sufficiently distinguishable without it, I had no means whereby to determine their absolute elevation in respect of the horizon.

As far as the mere elevation of objects is concerned, the phenomena seem not difficult to be accounted for; but the double horizon, and especially the peculiar circumstances observed on the 6th of January 1795, appear not easy to be explained. They furnish two material questions; first, whether the separation is effected by the refracting matter elevating the upper, or depressing the lower visible horizon? and, secondly, why the apparent vacancy, or gap, described as above, did not cause the tower to disappear, as well as the horizon which intercepted it? My own idea at present is, that the appearance of the lower horizon is effected either by depression, or else by the mass of refracting matter, which causes the elevation, detaching itself from the ground, so as to admit of the natural (unrefracted) horizon being seen below it, at the same time that an elevated one is visible through its body. I also conceived it possible that the lengthened appearance of the tower (then observed) might have arisen from the connexion of two images thereof, viz. the upper and the lower; having noticed something similar in the instance of a tree, partly intercepted by the ridge of a building, and viewed through an irregular spot (which seems to me to be a bubble) in the glass of a window: and probably an attentive observation of objects seen through such irregularities in glass, may help to illustrate all its different phenomena. The tower being a body of an uniform breadth, a deception of the sort alluded to is not perceivable; but perhaps would have been manifest had the object been of the pyramidical form, as many steeples are. And, as the distance of the tower, beyond the intercepting ground at *c*, is only about 3 miles, it seems rather extraordinary that the difference of their absolute elevations should be sufficient to bring so much of the tower into view. At the times of these extraordinary refractions, it was a sharp white frost, with a calm hazy atmosphere.

Modbury, 3d Jan. 1815. JOHN ANDREWS.

See the representations in plate 30, of the appearances, in three different states of the atmosphere, with the explanations of them.

The following curious instance of refraction was given in the 3d vol. of the Trans. of the American Philos. Trans. by Mr. Andrew Ellicott, at Pittsburg, Nov. 5, 1787, from observations at Lake Erie.—On the evening of Sept. 12, there was a fine aurora borealis. The next day was cloudy, but without rain. About noon, the low peninsula, called Presque-isle, which, at its then distance of 25 miles, is commonly invisible, was descried from the borders of the lake, considerably elevated above the horizon; and, viewed through a telescope, the branches of the trees could be plainly discovered. It is very singular that the peninsula was frequently seen double, the images, one above the other, separating and coinciding repeatedly, like those observed in shifting the index of a Godfrey's quadrant. In the evening it began to blow a fresh breeze; which, in the following days, increased into a most violent hurricane. These distinct facts afford some data for the investigation of the curious phenomenon which sailors term Looming. We may offer the following attempt at an explication. It is easy to perceive that, owing to the successive increase of rarity at different heights in the atmosphere, the rays of light, transmitted from a distance, are invariably bent towards the surface of the earth, and therefore bestow on objects an apparent elevation. If this progression of rarity be, from some accidental cause, augmented, the refraction, and its consequent effect, must then become proportionally greater; and this actually takes place in the case under consideration. The lucid complexion of the sky, and the storm which commonly ensues, conspire to indicate that, at no great height, the air is replete with humidity. The double appearance above described may be owing to two fluctuative strata of air, differently charged with moisture, and occasioned probably by opposite currents.

The following is the substance of a letter, on a similar subject, from W. Latham, esq. inserted in the Philos. Trans. of 1798.—On the 26th of July, 1797, about 5 o'clock afternoon, while sitting in his room at Hastings, on the parade, close to the sea shore, nearly fronting the south, Mr. Latham's attention was excited by a number of people running down to the sea side. On inquiring the reason, he was informed that the coast of France was plainly to be distinguished by the naked eye. He immediately went down to the shore, and was surprised to find that, even without the assistance of a telescope, he could plainly see the cliffs on the opposite coast; which, at the very nearest part, are between 40 and 50 miles distant, and are not to be discerned from that low situation by the aid of the best glasses. They appeared to be only a few miles off, and seemed to extend for some leagues along the coast. Mr. L. pursued his walk along the shore, close to the water's edge, conversing with the sailors and fishermen on the subject. At first these could not be persuaded of the reality of the appearance; but soon became so fully convinced, by the cliffs gradually appearing more elevated, and approaching nearer, as it were, that they pointed out, and named to him, the different places they had been accustomed to visit; such as the Bay, the Old Head or Man, the windmill &c, at Boulogne, St. Vallery, and other places on the coast of Picardy; which they afterwards confirmed, when they viewed them through their telescopes. Their remarks were, that the places appeared as near as if they were sailing at a small distance into the harbour.

Having indulged his curiosity on the shore for near an hour, during which time the cliffs appeared to be at some times more bright and near, at others more faint and distant, but never out of sight, Mr. L. went upon the eastern cliff or hill, which is of a considerable height, when a most beautiful scene presented itself to view; for he could at once see Dengeness, Dover cliffs, and the French coast, all along from Calais, Boulogne, &c, to St. Vallery; and as some of the fishermen affirmed, as far to the westward even as Dieppe. By the telescope, the French fishing-boats were plainly to be seen at anchor; and the different colours of the land upon the heights, together with the buildings, were perfectly discernible. This curious phenomenon continued in the highest splendour till past 8 o'clock (though a black cloud totally obscured the face of the sun for some time) when it gradually vanished.

The day was extremely hot, 76° at 5 afternoon, and the three preceding days remarkably fine and clear. Not a breath of wind was stirring the whole of the day; but the small pennons at the mast-heads of the fishing-boats in the harbour were in the morning at all points of the compass.—Mr. L. was, a few days afterwards, at Winchelsea, and at several places along the coast, where he was informed that the above phenomenon had been equally visible.—The cape of land called Dengeness, which extends nearly 2 miles into the sea, and is about 16 miles distant from Hastings, in a straight line, appeared as if quite close to it, as did the fishing-boats, and other vessels which were sailing between the two places.

Similar and still more extraordinary instances of atmospherical refraction have been since described in different volumes of the Philos. Trans. for the years 1795, 1797, 1799, 1800 &c, by Mr. Dalby, Cap. Huddart, Sir Henry Englefield, Mr. Latham, Mr. Vince, and Dr. Wollaston. Mr. Huddart first noticed a distinct image, inverted beneath the object itself; and described several such appearances, accompanied with an optical explanation, remarking that the lowest strata of the air were at the time endued with a weaker refractive power, than others at a small elevation. Mr. Vince has given an instance where erect, as well as inverted images, were visible above, instead of beneath, the objects themselves; and, by tracing the progress of the rays of light, in a manner similar to Mr. Huddart's, concludes that these phenomena arose from unusual variations of increasing density in the lower strata of the atmosphere. In the vol. for 1795, Mr. Dalby mentions having seen the top of a hill appear detached; for the sky was seen under it. In this case, as well as in the preceding, says Dr. W., it is probable that inversion took place, and that the lower half of the portion detached was an inverted image of the upper, as the sky could only be seen beneath it by an inverted course of the rays.

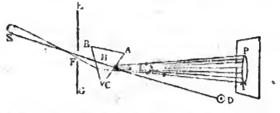
Since the causes of such peculiarities of terrestrial refraction had not received so full an explanation as might be wished, Dr. Wollaston has endeavoured, 1st, To investigate theoretically the successive variations of increasing or decreasing density to which fluids in general are liable, and the laws of the refractions occasioned by them. 2dly. To illustrate and confirm the truth of this theory by experiments with fluids of known density. And lastly, to ascertain, by trial on the air itself, the causes and extent of those variations of its refractive density, on which the inversions of objects, &c, appear to depend. See vol. 90, or my Abridgement, vol. 18, p. 667.

In a late letter from Mr. Dalby he says, he repeatedly observed, when measuring the base on King's Sedgemoor, those extraordinary refractions. The moor is several miles in length, and as level as the sea. When the sun shone out after a shower of rain, he placed a telescope on the top of the front wheel of a carriage, and then the cattle grazing on the moor, at the distance of 4 or 5 miles, appeared through the telescope in their proper shapes and position, without any inversion; but when the telescope was laid on the box near the axle, at about 2 feet below the top of the wheel, or 2 feet from the ground, he saw the inverted images of the cattle complete. Suppose, says he, a looking-glass laid on a table before you; then if you conceive flies, or mice, or any small animals, to be walking on the glass, you will have a perfect idea of the appearance. (See an idea of it represented, plate xxxi, fig. 1). It was curious to see cows and horses with their backs downwards, walking foot to foot against others above. The lower or reflected images were as bright and well defined, as the upper or real objects. In moving the telescope from the top of the wheel, down towards the axle, the first change observed, was the lengthening of the animals' legs; afterwards, before the complete inversion took place, the appearances were so singularly fantastical, that it is impossible to describe them.

The inversion, above mentioned, is evidently the effect of reflection from a stratum of dense vapour; for I never could perceive any thing of the kind but when the sun shone out immediately after a shower of rain, and the evaporation was copious. Such refractions and reflections will account for those strange appearances noticed by some travellers while they were crossing the extensive flats in Arabia and Egypt.

A similar phenomenon Mr. Dalby observed while he was crossing, in a small boat, from Mutton Cove, Plymouth Dock, to the Passage-house below Mount Egdecumbe. He says, "When my eye was brought down to the edge of the boat, about a foot from the surface of the water, the summit of the distant rock called the Mewer-stone, in Plymouth harbour, appeared totally detached, or lifted up, from the lower part. This proves that the vapour rising from the sea must have had a great refractive power near the surface; for no apparent separation took place when the eye was 2 or 3 feet from the water."

REFRANGIBILITY *of Light*, the disposition of the rays to be refracted. And a greater or less refrangibility, is a disposition to be more or less refracted, in passing at equal angles of incidence into the same medium.—That the rays of light are differently refrangible, is the foundation of Newton's whole theory of light and colours; and the truth and circumstances of the principle he evinced from such experiments as the following.



Let EG represent the window-shutter of a dark room, and F a hole in it, through which the light passes, from the luminous object S, to the glass prism ABC within the room, which refracts it towards the opposite side, or a screen, at PT, where it appears of an oblong form; its length being about 5 times the breadth, and exhibiting the various colours of the rainbow; whereas without the interposition of the prism, the ray of light would have proceeded on in its first direction to D. Hence then it follows, 1. That the rays of light are refrangible. This appears by the ray being refracted from its original direction SHD, into another, HP or HT, by passing through a different medium.—2. That the ray SFH is a compound one, which, by means of the prism, is decompounded or separated into its parts, HP, HT, &c, which it hence appears are all endued with different degrees of refrangibility, as they are transmitted to all the intermediate points from T to P, and there painting all the different colours.—From this, and a great variety of other experiments, Newton proved, that the blue rays are more refracted than the red ones, and that there is likewise unequal refraction in the intermediate rays; and upon the whole it appears that the sun's rays have not all the same refrangibility, and consequently are not of the same nature. It is also observed that those rays which are most refrangible, are also most reflexible. See REFLEXIBILITY; also Newton's Optics, pa. 22 &c, 3d edit.

The difference between refrangibility and reflexibility was first discovered by Sir Isaac Newton, in 1671-2, and communicated to the Royal Society, in a letter dated Feb. 6 of that year, which was published in the Philos. Trans. numb. 80, pa. 3075; and from that time it was vindicated by him, from the objections of several persons; particularly Pardies, Mariotte, Linus or Lin, and other gentlemen of the English college at Liege; and at length it was more fully laid down, illustrated, and confirmed, by a great variety of experiments, related in his excellent treatise on Optics.

But further, as not only these colours of light produced by refraction in a prism, but also those reflected from opaque bodies, have their different degrees of refrangibility and reflexibility; and as a white light arises from a mixture of the several coloured rays together, the same great author concluded that all homogeneous light has its proper colour, corresponding to its degree of refrangibility, and not capable of being changed by any reflections, or any refractions; that the sun's light is composed of all the primary colours; and that all compound colours arise from the mixture of the primary ones, &c.

The different degrees of refrangibility, he conjectures to arise from the different magnitude of the particles composing the different rays. Thus, the most refrangible rays, that is the red ones, he supposes may consist of the largest particles; the least refrangible, i. e. the violet rays, of the smallest particles; and the intermediate rays, yellow, green, and blue, of particles of intermediate sizes. See COLOUR.

Dr. Herschel has made many ingenious observations and experiments on the different degrees of refrangibility of the sun's rays; from which it appears, that beside the seven coloured rays of light which formed the basis of Newton's theory, there are other rays that are perfectly colourless; a summary of which experiments is given under the article Sun, in treating of the nature of his rays. See SUN.

For the method of correcting the effect of the different refrangibility of the rays of light in glasses, see ABERRATION and TELESCOPE.

REGEL, or RIGEL, a fixed star of the first magnitude, in the left foot of Orion.

REGIOMONTANUS. See *John* MULLER.

REGION, of the Air or Atmosphere. Authors divide the atmosphere into three stages, called the upper, middle, and lower regions.—The lowest region is that in which we breathe, and is bounded by the reflection of the sun's rays, that is, by the height to which they rebound from the earth.—The middle region is that in which the clouds reside, and where meteors are formed, &c; extending from the extremity of the lowest, to the tops of the highest mountains.—The upper region commences from the tops of the mountains, and reaches to the utmost limits of the atmosphere. In this region there probably reigns a perpetual equable calmness, clearness, and serenity.

Elementary REGION, according to the Aristotelians, is a sphere terminated by the concavity of the moon's orb, comprehending the earth's atmosphere.

Ethereal REGION, is the whole extent of the universe, comprising all the heavens with the orbs of the fixed stars and other celestial bodies.

REGION, in Geography, a country or particular division of the earth, or a tract of land inhabited by people of the same nation.

REGIONS *of the Moon*. Modern astronomers divide the moon into several regions, or provinces, to each of which they give its proper name.

REGIONS *of the Sea*, are the two parts into which the whole depth of the sea is conceived to be divided. The upper of these extends from the surface of the water, down as low as the rays of the sun can pierce, and extend their influence; and the lower region extends from thence to the bottom of the sea.

Subterranean REGIONS. These are three, into which the earth is divided, at different depths below the surface, according to different degrees of cold or warmth; and it is imagined that the 2d or middlemost of these regions is the coldest of the three.

REGIS (PETER SYLVAIN), a French philosopher, and great propagator of Cartesianism, was born in Agenois 1632. He studied the languages and philosophy under the Jesuits at Cahors, and afterwards divinity in the university of that town, being designed for the church. His progress in learning was so uncommon, that at the end of four years he was offered a doctor's degree without the usual charges; but he did not think it became him till he should study also in the Sorbonne at Paris. He accordingly repaired to the capital for that purpose; but he soon became disgusted with theology; and, as the philosophy of Descartes began at that time to become popular through the lectures of Rohault, he conceived a taste for it, and gave himself up entirely to its doctrines. Having, by attending those lectures, and by close study, become an adept in that philosophy, he went to Toulouse in 1665, where he gave lectures in it himself. Having a clear and fluent manner, and a happy way of explaining his subject, he drew many persons to his discourses; the magistrates, the literati, the ecclesiastics, and the very women, who all now affected to renounce the ancient philosophy.

In 1671, he received at Montpellier the same applauses for his lectures as at Toulouse. Finally, in 1680 he returned to Paris; where the concourse about him was such, that the sticklers for Peripateticism began to be alarmed. These applying to the archbishop of Paris, he thought it expedient, in the name of the king, to put a stop to the lectures; which accordingly were discontinued for several months. Afterwards his whole time was spent in propagating the new philosophy, both by lectures, and by publishing books; and in defence of his system, he had disputes with Huet, Du Hamel, Malbranche, and others. His works, though abounding with ingenuity and learning, have been neglected in consequence of the great discoveries and advancement in philosophic knowledge that has been since made.—He was chosen a member of the Academy of Sciences in 1699; and died in 1707, at 75 years of age.

His works, which he published, are,

1. A system of Philosophy; containing Logic, Metaphysics, and Morals: in 1690, 3 vols in 4to. being a compilation of the different ideas of Descartes.—It was reprinted the year after at Amsterdam, with the addition of a Discourse on Ancient and Modern Philosophy.

2. The Use of Reason and of Faith.

3. An Answer to Huet's Censures of the Cartesian Philosophy; and an Answer to Du Hamel's Critical Reflections.

4. Some pieces against Malbranche, to show that the apparent magnitude of an object depends solely on the magnitude of its image, traced on the retina.

5. A small piece on the question, Whether Pleasure makes our present Happiness?

REGRESSION, or RETROGRADATION *of Curves*, &c. See RETROGRADATION.

REGULAR *Figure*, in Geometry, is a figure that is both equilateral and equiangular, or having all its sides and angles equal to one another.—For the dimensions, properties, &c, of regular figures, see POLYGON.

REGULAR *Body*, called also, *Platonic Body*, is a body or solid comprehended by like, equal, and regular plane figures, and whose solid angles are all equal. The plane figures by which the solid is contained, are the faces of the solid. And the sides of the plane figures are the edges, or linear sides of the solid.

There are only five regular solids, viz,

The tetraedron, or regular triangular pyramid, having 4 triangular faces;

The hexaedron, or cube, having 6 square faces;

The octaedron, having 8 triangular faces;

The dodecaedron, having 12 pentagonal faces;

The icosaedron, having 20 triangular faces.

Besides these five, there can be no other regular bodies in nature.

PROB. 1. *To construct or form the Regular Solids.*—See the method of describing these figures under the article BODY.

2. *To find either the Surface or the Solid Content of any of the Regular Bodies.*—Multiply the proper tabular area or surface (taken from the following table) by the square of the linear edge of the solid, for the superficies. And multiply the tabular solidity, in the last column of the table, by the cube of the linear edge, for the solid content.

Surfaces and Solidities of Regular Bodies, the Side being unity or 1.

No. of sides.	Name.	Surface.	Solidity.
4	Tetraedron	1·7320508	0·1178513
6	Hexaedron	6·0000000	1·0000000
8	Octaedron	3·4641016	0·4714045
12	Dodecaedron	20·6457788	7·6631189
20	Icosaedron	8·6602540	2·1816950

3. The diameter of a sphere being given, to find the side of any of the Platonic bodies, that may be either inscribed in the sphere, or circumscribed about the sphere, or that is equal to the sphere.

Multiply the given diameter of the sphere by the proper or corresponding number, in the following table, answering to the thing sought, and the product will be the side of the Platonic body required.

The diam. of a sphere being 1, the side of a	That may be inscribed in the sphere, is	That may be circumscribed about the sphere, is	That is equal to the sphere, is
Tetraedron	0·816497	2·44948	1·64417
Hexaedron	0·577350	1·00000	0·88610
Octaedron	0·707107	1·22474	1·03576
Dodecaedron	0·525731	0·66158	0·62153
Icosaedron	0·356822	0·44903	0·40883

4. The side of any of the five Platonic bodies being given, to find the diameter of a sphere, that may either be inscribed in that body, or circumscribed about it, or that is equal to it.—As the respective number in the table above, under the title, *inscribed*, *circumscribed*, or *equal*, is to 1, so is the side of the given Platonic body, to the diameter of its inscribed, circumscribed, or equal sphere.

5. The side of any one of the five Platonic bodies being given; to find the side of any of the other four bodies, that may be equal in solidity to that of the given body.—As the number under the title *equal* in the last column of the table above, against the given Platonic body, is to the number under the same title, against the body whose side is sought, so is the side of the given Platonic body, to the side of the body sought.

See demonstrations of many other properties of the Platonic bodies, in my Mensuration, part 3 sect. 2 pa. 183, &c, 4th edition.

REGULAR *Curve*. See CURVE.

REGULATOR *of a Watch*, is a small spring belonging to the balance, serving to adjust the going, and to make it go either faster or slower.

REGULUS, in Astronomy, a star of the first magnitude, in the constellation Leo; called also, from its situation, Cor Leonis, or the Lion's Heart; by the Arabs, Albabor; and by the Chaldeans, Kalbeleceid, or Karbeleceid; from an opinion of its influencing the affairs of the heavens; as Theon observes.—The longitude of Regulus, as fixed by Flamsteed, is 25° 31′ 21″, and its latitude 0° 26′ 38″ north. See LEO.

REINFORCE, in Gunnery, is that part of a gun next the breech, which is made stronger to resist the force of the powder. There are usually two reinforces in each piece, called the first and second reinforce. The second is somewhat smaller than the first, because the inflamed powder in that part is less strong.

REINFORCE *Rings* of a cannon, are flat mouldings, like iron hoops, placed at the breech end of the first and second reinforce, projecting beyond the rest of the metal about a quarter of an inch.

REINHOLD (ERASMUS), an eminent astronomer and mathematician, was born at Salfeldt in Thuringia, a province in Upper Saxony, the 11th of October 1511. He studied mathematics under James Milichi at Wittemberg, in which university he afterwards became professor of those sciences, which he taught with great applause; and after writing a number of useful and learned works, he died the 19th of February 1553, at 42 years of age only. His writings are chiefly the following:

1. Theoriæ novæ Planetarum G. Purbachii, augmented and illustrated with diagrams and Scholia; in 8vo, 1542; and again in 1580.—In this work, among other things worthy of notice, he teaches (pa. 75 and 76) that the centre of the lunar epicycle describes an oval figure in each monthly period, and that the orbit of Mercury is also of the same oval figure.

2. Ptolemy's Almagest, the first book, in Greek, with a Latin version, and Scholia, explaining the more obscure passages; in 8vo, 1549.—At the end of pa. 123 he promises an edition of Theon's Commentaries, which are very useful for understanding Ptolemy's meaning; but his immature death prevented Reinhold from giving this and other works which he had projected.

3. Prutenicæ Tabulæ Cœlestium Motuum, in 4to, 1551; again in 1571; and also in 1585.—Reinhold spent seven years labour on this work, in which he was assisted by the munificence of Albert, duke of Prussia, whence the tables had their name: he compared the observations of Copernicus with those of Ptolemy and Hipparchus, whence he constructed these new tables, the uses of which he has fully explained in a great number of precepts and canons, forming a complete introduction to practical astronomy.

4. Primus liber Tabularum Directionum; to which are added, the Canon Fœcundus, or Table of Tangents, to every minute of the quadrant; and New Tables of Climates, Parallels and Shadows, with an Appendix, containing the second Book of the Canon of Directions; in 4to, 1554.—Reinhold here supplies what was omitted by Regiomontanus in his Table of Directions, &c; showing the finding of the sines, and the construction of the tangents, the sines being found to every minute of the quadrant, to the radius 10,000,000; and he produced the Oblique Ascensions from 60 degrees to the end of the quadrant. He teaches also the use of these tables in the solution of spherical problems.

Reinhold prepared likewise an edition of many other works, which are enumerated in the Emperor's Privilege, prefixed to the Prutenic Tables. Namely, Ephemerides for several years to come, computed from the new tables. Tables of the Rising and Setting of several Fixed Stars, for many different climates and times. The illustration and establishment of Chronology, by the eclipses of the luminaries, and the great conjunctions of the planets, and by the appearance of comets, &c. The Ecclesiastical Calendar. The History of Years, or Astronomical Calendar. Isagoge Spherica, or Elements of the Doctrine of the Primum Mobile. Hypotyposes Orbium Cœlestium, or the Theory of Planets. Construction of a New Quadrant. The Doctrine of Plane and Spherical Triangles. Commentaries on the work of Copernicus. Also Commentaries on the 15 books of Euclid, on Ptolemy's Geography, and on the Optics of Alhazen the Arabian. He also made many Astronomical Observations, but with a wooden quadrant, which observations were seen by Tycho Brahé when he passed through Wittemberg in the year 1575, who wondered that so great a cultivator of astronomy was not furnished with better instruments.

Reinhold left a son, named also Erasmus after himself, an eminent mathematician and physician at Salfeldt. He wrote a small work in the German language, on Subterranean Geometry, printed in 4to at Erfurt 1575.—He wrote also concerning the New Star which appeared in Cassiopeia in the year 1572; with an Astrological Prognostication, published in 1574, in the German language.

RELAIS, in Fortification, a French term, the same with berme.

RELATION, in Mathematics, is the habitude or respect of quantities of the same kind to each other, with regard to their magnitude; more usually called Ratio.—And the equality, identity, or sameness of two such relations, is called proportion.

Relation, *Inharmonical*, in Musical Composition, is that whose extremes form a false or unnatural interval, incapable of being sung.—This is otherwise called a false relation, and stands opposed to a just or true one.

RELATIVE *Gravity, Levity, Motion, Necessity, Place, Space, Time, Velocity, &c.* See the several substantives.

RELIEVO, in Architecture, denotes the sally or projecture of any ornament.

REMAINDER, is the difference between two quantities, or that which is left after subtracting one from the other.

RENDERING, in Building. See Pargeting.

REPEATING Circle. See Circular *Instruments.*

REPELLING *Power*, in Physics, is a certain power or faculty, residing in the minute particles of natural bodies, by which, under certain circumstances, they mutually fly from each other: being the reverse or opposite to the attractive power. Newton shows, from observation, that such a force does really exist; and he argues, that as in algebra, where positive quantities cease, there negative ones begin; so in physics, where the attractive force ceases, there a repelling force must begin.

As the repelling power seems to arise from the same principle as the attractive, only exercised under different circumstances, it is governed by the same laws. Now the attractive power we find is stronger in small bodies than in great ones, in proportion to the masses; therefore the repelling is so too: and as the rays of light are the most minute bodies we know of; therefore their repelling force must be the greatest. It is computed by Newton, that the attractive force of the rays of light is above 1000000000000000, or one thousand million of millions of times stronger than the force of gravity on the surface of the earth: hence arises that inconceivable velocity with which light must move to reach from the sun to the earth in little more than 7 minutes of time. For the rays emitted from the body of the sun, by the vibrating motion of its parts, are no sooner got without the sphere of attraction of the sun, than they come within the action of the repelling power.

The elasticity or springiness of bodies, or that property by which, after having their figure altered by an external force, they return to their former shape again, follows from the repelling power. See Repulsion.

REPERCUSSION. See Reflection.

REPETEND, in Arithmetic, denotes that part of an infinite decimal fraction, which is continually repeated ad infinitum. Thus in the numbers 2·13 13 13 &c, the figures 13 are the repetend, and marked thus $\dot{1}\dot{3}$.—These repetends chiefly arise in the reduction of vulgar fractions to decimals. Thus, $\frac{1}{3} = 0{\cdot}333\&c = 0{\cdot}\dot{3}$; and $\frac{1}{6} = 0{\cdot}1666$ $\&c = 1{\cdot}1\dot{6}$; and $\frac{1}{7} = 0{\cdot}142857\ 142857\ \&c = 0{\cdot}\dot{1}4285\dot{7}$. Where it is to be observed, that a point is set over the figure of a single repetend, and over the first and last figure when there are several that repeat.

Repetends are either Single or Compound.

A *Single* Repetend is that in which only one figure repeats; as $0{\cdot}\dot{3}$, or $0{\cdot}\dot{6}$, &c.

A *Compound* Repetend, is that in which two or more figures are repeated; as $\cdot\dot{1}\dot{3}$, or $\cdot\dot{2}1\dot{5}$, or $\cdot\dot{1}4285\dot{7}$.

Similar Repetends are such as begin at the same place, and consist of the same number of figures: as $\cdot\dot{3}$ and $\cdot\dot{6}$, or $1{\cdot}\dot{3}4\dot{1}$ and $2{\cdot}\dot{1}5\dot{6}$.

Dissimilar Repetends begin at different places, and consist of an unequal number of figures.

To find the finite Value of any Repetend, or to reduce it to a vulgar fraction. Take the given repeating figure or figures for the numerator; and for the denominator, take as many 9's as there are recurring figures or places in the given repetend.

So $\cdot\dot{3} = \frac{3}{9} = \frac{1}{3}$; and $\cdot0\dot{5} = \cdot0\frac{5}{9} = \frac{5}{90} = \frac{1}{18}$;

and $\cdot\dot{1}2\dot{3} = \frac{123}{999} = \frac{11}{333}$; and $2{\cdot}\dot{6}\dot{3} = 2\frac{63}{99} = 2\frac{7}{11}$;

and $\cdot0\dot{5}9440\dot{5} = \frac{594405}{9999990} = \frac{17}{280}$; &c.

Hence it follows, that every such infinite repetend has a certain determinate and finite value, or can be expressed by a terminate vulgar fraction. And consequently, that an infinite decimal which does not repeat or circulate, cannot be completely expressed by a finite vulgar fraction.

It may further be observed, that if the numerator of a vulgar fraction be 1, and the denominator any prime number, except 2 and 5, the decimal which shall be equal to that vulgar fraction, will always be a repetend, beginning at the first place of decimals; and this repetend must necessarily be a submultiple, or an aliquot part of a number expressed by as many 9's as the repetend has figures; that is, if the repetend have six figures, it will be a submultiple of 999999; if four figures, a submultiple of 9999; &c. Whence it follows, that if any prime number be called p, the series 9999&c, produced as far as is necessary, will always be divisible by p, and the quotient will be the repetend of the decimal fraction $1 \div p$.

The same is also true of any odd number whatever that is not divisible by 5; and for any repetend as well as 9. That is, any odd number, not divisible by 5, is a divisor of any repetend digit carried to a sufficient number of places, and these will never exceed the number expressed by the divisor.

It is also a curious circumstance, that all fractions whose denominators are the same, are expressed in decimals by repetends which have the same effective figures, though varied in their position. Thus,

$\frac{1}{7} = \cdot142857\ 142857$, &c.
$\frac{2}{7} = \cdot285714\ 285714$, &c.
$\frac{3}{7} = \cdot428571\ 428571$, &c.
$\frac{4}{7} = \cdot571428\ 571428$, &c.
$\frac{5}{7} = \cdot714285\ 714285$, &c.
$\frac{6}{7} = \cdot857142\ 857142$, &c.

RESIDUAL *Figure*, in Geometry, the figure remaining after subtracting a less from a greater.

Residual *Root*, is a root composed of two parts or members, only connected together with the sign − or minus. Thus, $a-b$, or $5-3$, is a residual root; and is so called, because its true value is no more than the residue, or difference between the parts a and b, or 5 and 3, which in this case is 2.

RESIDUUM *of a Charge*, in Electricity, first discovered by Mr. Gralath, in Germany, in 1746, is that part of the charge that lay on the uncoated part of a Leyden phial, which does not part with all its electricity at once; so that it is afterwards gradually diffused to the coating.

RESISTANCE, or Resisting *Force*, in Physics, any power which acts in opposition to another, so as to destroy or diminish its effect.

There are different kinds of resistance, arising from the various natures and properties of the resisting bodies, and governed by various laws; as, the resistance of solids, the resistance of fluids, the resistance of the air, &c. Of each of these in their order, as below.

Resistance *of Solids*, in Mechanics, is the force with which the quiescent parts of solid bodies oppose the motion of others contiguous to them. Of these, there are two kinds. The first, where the resisting and the resisted parts, i. e. the moving and quiescent bodies, are only contiguous, and do not cohere; constituting separate bodies or masses. This resistance is what Leibnitz calls Resistance of the surface, but which is more properly called Friction: for the laws of which, see the article Friction.

The 2d case of resistance, is where the resisting and resisted parts are not only contiguous, but cohere, being parts of the same continued body or mass. This resistance was first considered by Galileo, and may properly be called Renitency.—As to what regards the resistance of bodies when struck by others in motion, see Percussion, and Collision.

Theory of the Resistance of the Fibres of Solid Bodies.—To conceive an idea of this resistance, or renitency of the parts, suppose a cylindrical body suspended vertically by one end. Here all its parts, being heavy, tend downwards, and endeavour to separate the two contiguous planes or surfaces where the body is the weakest; but all the parts of them resist this separation by the force with which they cohere, or are bound together. Here then are two opposite powers; viz, the weight of the cylinder, which tends to break it; and the force of cohesion of the parts, which resists the fracture.

If now the base of the cylinder be increased, without increasing its length; it is evident that both the resistance and the weight will be increased in the same ratio as the base; and hence it appears that all cylinders of the same matter and length, whatever their bases be, have an equal resistance, when vertically suspended.

But if the length of the cylinder be increased, without increasing its base, its weight is increased, while the resistance or strength continues unaltered; consequently the lengthening has the effect of weakening it, or increases its tendency to break.

Hence, to find the greatest length a cylinder of any matter may have, when it just breaks with the addition of another given weight, we need only take any cylinder of the same matter, and fasten to it the least weight that is just sufficient to break it; and then consider how much it must be lengthened, so that the weight of the part added, together with the given weight, may be just equal to that weight, and the thing is done. Thus, let l denote the first length of the cylinder, c its weight, g the given weight the lengthened cylinder is to bear, and w the least weight that breaks the cylinder l, also x the length sought; then as $l : x :: c : \frac{cx}{l}$ = the weight of the longest cylinder sought; and this, together with the given weight g, must be equal to c together with the weight w; hence then $\frac{cx}{l} + g = c + w$; therefore $x = \frac{c + w - g}{c} l$ = the whole length of the cylinder sought. If the cylinder must just break with its own weight, then is $g = 0$, and in that case $x = \frac{c + w}{c} l$ is the whole length that just breaks by its own weight. By this means Galileo found that a copper-wire, and of consequence any other cylinder of copper, might be extended to 4801 braccios or fathoms of 6 feet each.

If the cylinder be fixed by one end into a wall, with the axis horizontally; the force to break it, and its resistance to fracture will here be both different; as both the weight to cause the fracture, and the resistance of the fibres to oppose it, are combined with the effects of the lever; for the weight to cause the fracture, whether of the beam alone, or combined with an additional weight hung to it, is to be supposed collected into the centre of gravity, where it is considered as acting by a lever equal to the distance of that centre beyond the face of the wall where the cylinder or other prism is fixed; and then the product of the said whole weight and distance, will be the momentum or force to break the prism. Again, the resistance of the fibres may be supposed collected into the centre of the transverse section, and all acting there at the end of a lever equal to the vertical semidiameter of the section, the lowest point of that diameter being immoveable, and about which the whole diameter turns when the prism breaks; and hence the product of the adhesive force of the fibres multiplied by the said semidiameter, will be the momentum of resistance, and which must be equal to the former momentum when the prism just breaks.

Hence, to find the length a prism will bear, fixed so horizontally, before it breaks, either by its own weight, or by the addition of any adventitious weight; take any length of such a prism, and load it with weights till it just break. Then, put

l = the length of this prism,
c = its weight,
w = the weight that breaks it,
a = distance of weight w,
g = any given weight to be borne,
d = its distance,
x = the length required to break.

Then $l : x :: c : \frac{cx}{l}$ the weight of the prism x, and $\frac{cx}{l} \times \frac{1}{2}x = \frac{cx^2}{2l}$ = its momentum; also dg = the momentum of the weight g; therefore $\frac{cx^2}{2l} + dg$ is the momentum of the prism x and its added weight. In like manner $\frac{1}{2}cl + aw$ is that of the former or short prism and the weight that brake it; consequently $\frac{cx^2}{2l} + dg = \frac{1}{2}cl + aw$, and $x = \sqrt{\frac{aw + \frac{1}{2}cl - dg}{c} \times 2l}$ is the length sought, that just breaks with the weight g at the distance d. If this weight g be nothing, then $x = \sqrt{\frac{aw + \frac{1}{2}cl}{c} \times 2l}$ is the length of the prism that just breaks with its own weight.

If two prisms of the same matter, having their bases and lengths in the same proportion, be suspended horizontally; it is evident that the greater has more weight than the lesser, both on account of its length, and of its base; but it has less resistance on account of its length, considered as a longer arm of a lever, and has only more resistance on account of its base; therefore it exceeds the lesser in its momentum more than it does in its resistance, and consequently it must break more easily.

Hence appears the reason why, in making small machines and models, people are apt to be mistaken as to the resistance and strength of certain horizontal pieces, when they come to execute their designs in large, by observing the same proportions as in the small.

When the prism, fixed vertically, is just about to break, there is an equilibrium between its positive and relative weight; and consequently those two opposite powers are to each other reciprocally as the arms of the lever to which they are applied, that is, as half the diameter to half the axis of the prism. On the other hand, the resistance of a body is always equal to the greatest weight which it will just sustain in a vertical position, that is, to its absolute weight. Therefore, substituting the absolute weight for the resistance, it appears, that the absolute weight of a body, suspended horizontally, is to its relative weight, as the distance of its centre of gravity from the fixed point or axis of motion, is to the distance of the centre of gravity of its base from the same.

The discovery of this important truth, at least of an equivalent to it, and to which this is reducible, we owe to Galileo; on whose system of resistance, however, Mariotte made an ingenious remark, which gave birth to a new system. Galileo supposes that where the body breaks, all the fibres break at once; so that the body always resists with its whole absolute force, or the whole force that all its fibres have in the place where it breaks. But Mariotte, finding that all bodies, even glass itself, bend before they break, shows that fibres are to be considered as so many little bent springs, which never exert their whole force, till stretched to a certain point, and never break till entirely unbent. Hence those nearest the fulcrum of the lever, or lowest point of the fracture, are stretched less than those farther off, and consequently employ a less part of their force, and break later.

This consideration only takes place in the horizontal situation of the body: for in the vertical, the fibres of the base all break at once; so that the absolute weight of the body must exceed the united resistance of all its fibres; a greater weight is therefore required here than in the horizontal situation, that is, a greater weight is required to overcome their united resistance, than to overcome their several resistances one after another.

Varignon has improved on the system of Mariotte, and shown that to Galileo's system, it adds the consideration of the centre of percussion: for in each system, the section, where the body breaks, moves on the axis of equilibrium, or line at the lower extremity of the same section; but in the second, the fibres of this section are continually stretching more and more, and that in the same ratio, as they are situated farther and farther from the axis of equilibrium, and consequently are still exerting a greater and greater part of their whole force.

These unequal extensions, like all other forces, must have some common centre where they are united, making equal efforts on each side of it: and as they are precisely in the same proportion as the velocities which the several points of a rod moved circularly would have to one another, the centre of extension of the section where the body breaks, must be the same as its centre of percussion. Galileo's hypothesis, where fibres stretch equally, and break all at once, corresponds to the case of a rod moving parallel to itself, where the centre of extension or percussion does not appear, as being confounded with the centre of gravity.

Hence it follows, that the resistance of bodies in Mariotte's system, is to that in Galileo's, as the distance of the centre of percussion, taken on the vertical diameter of the fracture, is to the whole of that diameter: and hence also, the resistance being less than what Galileo imagined, the relative weight must also be less, and in the ratio just mentioned. So that, after conceiving the relative weight of a body, and its resistance equal to its absolute weight, as two contrary powers applied to the two arms of a lever, in the hypothesis of Galileo, there needs nothing to change it into that of Mariotte, but to imagine that the resistance, or the absolute weight, is become less, in the ratio above mentioned, every thing else remaining the same.

One of the most curious, and perhaps the most useful questions in this research, is to find what figure a body must have, that its resistance may be equal or proportional in every part to the force tending to break it. Now to this end, it is necessary, some part of it being conceived as cut off by a plane parallel to the fracture, that the momentum of the part retrenched be to its resistance, in the same ratio as the momentum of the whole is to its resistance; these four powers acting by arms of levers peculiar to themselves, and are proportional in the whole, and in each part, of a solid of equal resistance; and from this proportion, Varignon easily deduces two solids, which shall resist equally in all their parts, or be no more liable to break in one part than in another: Galileo had found one before. That discovered by Varignon is in the form of a trumpet, and is to be fixed into a wall at its greater end; so that its magnitude or weight is always diminished in proportion as its length, or the arm of the lever by which its weight acts, is increased: and it is remarkable that, however different the two systems may be, the solids of equal resistance are the same in both.

For the resistance of a solid supported at each end, as of a beam between two walls, see BEAM.

RESISTANCE *of Fluids*, is the force with which bodies, moving in fluid mediums, are impeded and retarded in their motion. A body moving in a fluid is resisted from two causes. The first of these is the cohesion of the parts of the fluid. For a body, in its motion, separating the parts of a fluid, must overcome the force with which those parts cohere. The second is the inertia, or inactivity of matter, by which a certain force is required to move the particles from their places, in order to let the body pass.

The retardation from the first cause is always the same in the same space, whatever the velocity be, the body remaining the same; that is, the resistance is as the space run through in the same time: but the velocity is also in the same ratio of the space run over in the same time: and therefore the resistance, from this cause, is as the velocity itself.

The resistance from the second cause, when a body moves through the same fluid with different velocities, is as the square of the velocity. For, first the resistance increases according to the number of particles or quantity of the fluid struck in the same time; which number must be as the space run through in that time, that is, as the velocity; but the resistance also increases in proportion to the force with which the body strikes against every part; which force is also as the velocity of the body, being double with a double velocity, and triple with a triple one, &c: therefore, on both these accounts, the resistance is as the velocity multiplied by the velocity, or as the square of the velocity. On the whole therefore, on account of both causes, viz, the tenacity and inertia of the fluid, the body is resisted partly as the velocity and partly as the square of the velocity.

But when the same body moves through different fluids with the same velocity, the resistance from the second cause follows the proportion of the matter to be removed in the same time, which is as the density of the fluid.

Hence therefore, if d denote the density of the fluid,
v the velocity of the body,
and a and b constant coefficients:
then $adv^2 + bv$ will be proportional to the whole resist-

ance to the same body, moving with different velocities, in the same direction, through fluids of different densities, but of the same tenacity.

But, to take in the consideration of different tenacities of fluids; if t denote the tenacity, or the cohesion of the parts of the fluid, then $adv^2 + btv$ will be as the whole resistance.

Indeed the quantity of resistance from the cohesion of the parts of fluids, except in glutinous ones, is very small in respect of the other resistance; and it also increases in a much lower degree, being only as the velocity, while the other increases as the square of the velocity, and rather more. Hence then the term btv is very small in respect of the other term adv^2; and consequently the resistance is nearly as this latter term; or nearly as the square of the velocity. Which rule has been employed by most authors, and is very near the truth in slow motions; but in very rapid ones, it differs considerably from the truth, as we shall perceive below; not indeed from the omission of the small term btv, due to the cohesion, but from the want of the full counter pressure on the hinder part of the body, a vacuum, either perfect or partial, being left behind the body in its motion; and also perhaps to some compression or accumulation of the fluid against the fore part of the body. Hence,

To conceive the resistance of fluids to a body moving in them, we must distinguish between those fluids which, being greatly compressed by some incumbent weight, always close up the space behind the body in motion, without leaving any vacuity there; and those fluids which, not being much compressed, do not quickly fill up the space quitted by the body in motion, but leave a kind of vacuum behind it. These differences, in the resisting fluids, will occasion very remarkable varieties in the laws of their resistance, and are absolutely necessary to be considered in the determination of the action of the air on shot and shells; for the air partakes of both these affections, according to the different velocities of the projected body.

In treating of these resistances too, the fluids may be considered either as continued or discontinued, that is, having their particles contiguous or else as separated and unconnected; and also either as elastic or non-elastic. If a fluid were so constituted, that all the particles composing it were at some distance from each other, and having no action between them, then the resistance of a body moving in it would be easily computed, from the quantity of motion communicated to those particles; for instance, if a cylinder moved in such a fluid in the direction of its axis, it would communicate to the particles it met with, a velocity equal to its own, and in its own direction, when neither the cylinder nor the parts of the fluid are elastic: whence, if the velocity and diameter of the cylinder be known, and also the density of the fluid, there would thence be determined the quantity of motion communicated to the fluid, which (as action and reaction are equal) is the same with the quantity lost by the cylinder, and consequently the resistance would thus be ascertained.

In this kind of discontinued fluid, the particles being detached from each other, every one of them can pursue its own motion in any direction, at least for some time, independent of the neighbouring ones; so that, instead of a cylinder moving in the direction of its axis, if a body with a surface oblique to its direction be supposed to move in such a fluid, the motion which the parts of the fluid will hence acquire, will not be in the direction of the resisted body, but perpendicular to its oblique surface; whence the resistance to such a body will not be estimated from the whole motion communicated to the particles of the fluid, but from that part of it only which is in the direction of the resisted body. In fluids then, where the parts are thus discontinued from each other, the different obliquities of that surface which goes foremost, will occasion considerable changes in the resistance; though the transverse section of the solid should in all cases be the same: And Newton has particularly determined that, in a fluid thus constituted, the resistance of a globe is but half the resistance of a cylinder of the same diameter, moving, in the direction of its axis, with the same velocity.

But though the hypothesis of a fluid thus constituted be of great use in explaining the nature of resistances, yet we know of no such fluid existing in nature; all the fluids with which we are conversant being so constituted, that their particles either lie contiguous to each other, or at least act on each other in the same manner as if they did: consequently, in these fluids, no one particle that is contiguous to the resisted body, can be moved, without moving at the same time a great number of others, some of which will be distant from it; and the motion thus communicated to a mass of the fluid, will not be in any one determined direction, but different in all the particles, according to the different positions in which they lie in contact with those from which they receive their impulse; whence, great numbers of the particles being diverted into oblique directions, the resistance of the moving body, which will depend on the quantity of motion communicated to the fluid in its own direction, will be different in quantity from what it would be in the foregoing supposition, and its estimation becomes much more complicated and operose.

If the fluid be compressed by the incumbent weight of its upper parts (as all fluids are with us, except at their very surface), and if the velocity of the moving body be much less than that with which the parts of the fluid would rush into a void space, in consequence of their compression; it is evident, that in this case the space left by the moving body will be instantaneonsly filled up by the fluid; and the parts of the fluid against which the foremost part of the body presses in its motion, will, instead of being impelled forwards in the direction of the body, in some measure circulate towards the hinder part of it, in order to restore the equilibrium, which the constant influx of the floid behind the body would otherwise destroy; whence the progressive motion of the fluid, and consequently the resistance of the body, which depends upon it, would in this instance be much less, than in the hypothesis where each particle is supposed to acquire, from the stroke of the resisting body, a velocity equal to that with which the body moved, and in the same direction. Newton has determined, that the resistance of a cylinder, moving in the direction of its axis, in such a compressed fluid as we have here treated of, is but one-fourth part of the resistance to the same cylinder, if it moved with the same velocity in a fluid constituted in the manner described in the first hypothesis, each fluid being supposed of the same density.

But again, it is not only in the quantity of their resistance that these fluids differ, but also in the different manner in which they act upon solids of different forms moving in them. In the discontinued fluid, first described, the obliquity of the foremost surface of the moving body would diminish the resistance; but the same thing does not hold true in compressed fluids, at least not in any considerable degree; for the chief resistance in compressed fluids arises from the greater or less facility with which the fluid, impelled by the fore part of the body, can circulate towards its hinder part; and this being little, if at all, affected by the form of the moving body, whether it be cylindrical, conical, or spherical, it follows, that while the transverse section of the body is the same, and consequently the quantity of impelled fluid also, the change of figure in the body will scarcely affect the quantity of its resistance.

And this case, viz, the resistance of a compressed fluid to a solid, moving in it with a velocity much less than what the parts of the fluid would acquire from their compression, has been very fully considered by Newton, who has ascertained the quantity of such a resistance, according to the different magnitudes of the moving body, and the density of the fluid: but he expressly informs us that the rules he has laid down, are not generally true, being only so on a supposition that the compression of the fluid be increased in the greater velocities of the moving body: however, some unskilful writers, who have followed him, overlooking this caution, have applied this determination to bodies moving with all degrees of velocity, without attending to the different compressions of the fluids they are resisted by; and by this means they have accounted the resistance, for instance, of the air to musket and cannon shot, to be but about one-third part of what it is found to be by experience.

It is indeed evident that the resisting power of the medium must be increased, when the resisted body moves so fast that the fluid cannot instantaneously press in behind it, and fill the deserted space; for when this happens, the body will be deprived of the pressure of the fluid behind it; which in some measure balanced its resistance, or at least the fore pressure, and must support on its fore part the whole weight of a column of the fluid, over and above the motion it gives to the parts of the same; and besides, the motion in the particles driven before the body, is less affected in this case by the compression of the fluid, and consequently they are less deflected from the direction in which they are impelled by the resisted surface; whence it happens that this species of resistance approaches more and more to that described in the first hypothesis, where each particle of the fluid, being unconnected with the neighbouring ones, pursued its own motion, in its own direction, without being interrupted or deflected by their contiguity; and therefore, as the resistance of a discontinued fluid to a cylinder, moving in the direction of its axis, is 4 times greater than the resistance of a fluid sufficiently compressed of the same density, it follows that the resistance of a fluid, when a vacuity is left behind the moving body, may be near 4 times greater than that of the same fluid, when no such vacuity is formed; for when a void space is thus left, the resistance approaches in its nature to that of a discontinued fluid.

This then may probably be the case in a cylinder moving in the same compressed fluid, according to the different degrees of its velocity; so that if it set out with a great velocity, and moves in the fluid till that velocity be much diminished, the resisting power of the medium may be near 4 times greater in the beginning of its motion than in the end.

In a globe, the difference will not be so great, because, on account of its oblique surface, its resistance in a discontinued medium is but about twice as much as in one properly compressed; for its oblique surface diminishes its resistance in one case, and not in the other: however, as the compression of the medium, even when a vacuity is left behind the moving body, may yet confine the oblique motion of the parts of the fluid, which are driven before the body, and as in an elastic fluid, such as our air is, there will be some degree of condensation in those parts; it is highly probable that the resistance of a globe, moving in a compressed fluid with a very great velocity, may greatly exceed the proportion of the resistance to slow motions.

And as this increase of the resisting power of the medium will take place, when the velocity of the moving body is so great, that a perfect vacuum is left behind it, so some degree of augmentation will be sensible in velocities much short of this; for even when, by the compression of the fluid, the space left behind the body is instantaneously filled up; yet, if the velocity with which the parts of the fluid rush in behind, is not much greater than that with which the body moves, the same reasons that have been urged above, in the case of an absolute vacuity, will hold in a less degree in this instance; and therefore it is not to be supposed that, in the increased resistance which has been hitherto treated of, it immediately vanishes when the compression of the fluid is just sufficient to prevent a vacuum behind the resisted body; but we must consider it as diminishing only according as the velocity, with which the parts of the fluid follow the body, exceeds that with which the body moves.

Hence then it may be concluded, that if a globe sets out in a resisting medium, with a velocity much exceeding that with which the particles of the medium would rush into a void space, in consequence of their compression, so that a vacuum is necessarily left behind the globe in its motion; the resistance of this medium to the globe will be much greater, in proportion to its velocity, than what we are sure, from sir I. Newton, would take place in a slower motion: and we may further conclude, that the resisting power of the medium will gradually diminish as the velocity of the globe decreases, till at last, when it moves with velocities which bear but a small proportion to that with which the particles of the medium follow it, the resistance becomes the same with what is assigned by Newton in the case of a compressed fluid.

And from this determination may be seen, how false that position is, which asserts the resistance of any medium to be always in the duplicate ratio of the velocity of the resisted body; for it plainly appears, by what has been said, that this can only be considered as nearly true in small variations of velocity, and can never be applied in comparing together the resistances to all velocities whatever, without incurring the most enormous errors. See Robins's Gunnery, chap. 2, prop. 1, and my Tracts and Course of Mathem. vols. 2 and 3. See also the articles Resistance *of the Air*, Projectile, and Gunnery.

Resistance and retardation are used indifferently for each other, as being both in the same proportion, and the same resistance always generating the same retardation. But with regard to different bodies, the same resistance frequently generates different retardations; the resistance being as the quantity of motion, and the retardation as that of the celerity. For the difference and measure of the two, see Retardation.

The retardations from this resistance may be compared together, by comparing the resistance with the gravity or quantity of matter. It is demonstrated that the resistance of a cylinder, which moves in the direction of its axis, is equal to the weight of a column of the fluid, whose base is equal to that of the cylinder, and its altitude equal to the height through which a body must fall in vacuo, by the force of gravity, to acquire the velocity of the moving body. So that, if a denote the area of the face or end of the cylinder, or other prism, v its velocity, and n the specific gravity of the fluid; then, the altitude due to the velocity v being $\frac{v^2}{4g}$, the whole resistance, or motive force m, will be $a \times n \times \frac{v^2}{4g} = \frac{anv^2}{4g}$; the quantity g being $= 16\frac{1}{12}$ feet, or the space a body falls, in vacuo, in the first second of time. And the resistance to a globe of the same diameter would be the half of this.—Let a ball, for instance, of 3 inches diameter, be moved in water with a celerity of 16 feet per second of time: now from experiments on pendulums, and on falling bodies, it has been found, that this is the celerity which a body acquires in falling from the height of 4 feet; therefore the weight of a cylinder of water of 3 inches diameter, and 4 feet high, that is a weight of about 12lb 4oz, is equal to the resistance of the cylinder; and consequently the half of it, or 6lb 2oz is that of the ball. Or, the formula $\frac{anv^2}{4g}$ gives $\frac{.7854 \times 9 \times 1000 \times 16 \times 16}{144 \times 4 \times 16} = 196$oz, or 12lb 4oz, for the resistance of the cylinder, or 6lb. 2oz. for that of the ball, the same as before.

Let now the resistance, so discovered, be divided by the weight of the body, and the quotient will show the ratio of the retardation to the force of gravity. So, if the said ball, of 3 inches diameter, be of cast iron, it will weigh nearly 61 ounces, or 3¾lb; and the resistance being 6lb 2oz, or 98 ounces; therefore, the resistance being to the gravity as 98 to 61, the retardation, or retarding force, will be $\frac{98}{61}$ or $1\frac{3}{5}$, the force of gravity being 1. Or thus; because a, the area of a great circle of the ball, is $= pd^2$, where d is the diameter, and $p = .7854$, therefore the resistance to the ball is $m = \frac{pnd^2v^2}{8g}$; and because its solid content is $w = \frac{2}{3}pd^3$, and its weight $\frac{2}{3}Npd^3$, where N denotes its specific gravity; therefore, dividing the resistance or motive force m by the weight w, gives $\frac{m}{w} = \frac{3nv^2}{16Ndg} = f$ the retardation, or retarding force, that of gravity being 1; which is therefore as the square of the velocity directly, and as the diameter inversely; and this is the reason why a large ball overcomes the resistance better than a small one, of the same density. See my Tracts and Course as above.

Resistance *of Fluid Mediums to the Motion of Falling Bodies.*—A body freely descending in a fluid, is accelerated by the relative gravity of the body, (that is, the difference between its own absolute gravity and that of a like bulk of the fluid,) which continually acts upon it, yet not equably, as in a vacuum; for the resistance of the fluid occasions a retardation, or diminution of acceleration, which diminution increases with the velocity of the body. Hence it happens, that there is a certain velocity, which is the greatest that a body can acquire by falling; for if its velocity be such, that the resistance arising from it becomes equal to the relative weight of the body, its motion can be no longer accelerated; for the motion here continually generated by the relative gravity, will be destroyed by the resistance, or the force of resistance is equal to the relative gravity, and the body must then go on equably; for after the velocity is arrived at such a degree, that the resisting force is equal to the weight that urges it, it can increase no longer, and the globe must afterward continue to descend with that velocity uniformly. And a body continually comes nearer and nearer to this greatest celerity, but can never attain it accurately. Now, N and n being the specific gravities of the globe and fluid, $N-n$ will be the relative gravity of the globe in the fluid, and therefore $w = \frac{2}{3}pd^3(N-n)$ is the weight by which it is urged downward; also $m = \frac{pnd^2v^2}{8g}$ is the resistance, as above; therefore these two must be equal when the velocity can be no further increased, or $m = w$, that is $\frac{pnd^2v^2}{8g} = \frac{2}{3}pd^3(N-n)$, or $nv^2 = \frac{16}{3}dg(N-n)$; and hence $v = \sqrt{(\frac{16}{3}dg \times \frac{N-n}{n})}$ is the said uniform or greatest velocity which the body can attain; which is evidently the greater in the subduplicate proportion of d the diameter of the ball. But v is always $= \sqrt{4gfs}$, the velocity generated by any accelerative force f in describing the space s; which being compared with the former, it gives $s = \frac{4}{3}d$, when f is $= \frac{N-n}{n}$; that is, the greatest velocity is that which is generated by the accelerating force $\frac{N-n}{n}$ in passing over the space $\frac{4}{3}d$ or $\frac{4}{3}$ of the diameter of the ball, or it is equal to the velocity generated by gravity in describing the space $\frac{N-n}{n} \times \frac{4}{3}d$. For ex. if the ball be of lead, which is about $11\frac{1}{3}$ times the density of water; then $N = 11\frac{1}{3}$, $n = 1$, $N-n = \frac{N-n}{n} = 10\frac{1}{3} = \frac{31}{3}$, and $\frac{N-n}{n} \times \frac{4}{3}d = \frac{124}{9}d = 13\frac{7}{9}d$; that is, the uniform or greatest velocity of a ball of lead, descending in water, is equal to that which a heavy body acquired by falling in vacuo through a space equal to $13\frac{7}{9}$ of the diameter of the ball, which velocity is $v = 2\sqrt{(\frac{4}{3}dg \times \frac{N-n}{n})} = 2\sqrt{13\frac{7}{9}dg} = 8\sqrt{13\frac{7}{9}d}$ nearly, or 8 times the root of the same space.

Hence it appears, how soon small bodies come to their greatest or uniform velocity in descending in a fluid, as water, and how very small that velocity is: which explains the reason of the slow precipitation of mud, and small particles, in water, as also why, in precipitations, the larger and gross particles descend soonest, and the lowest.

Further, where $N = n$, or the density of the fluid is equal to that of the body, then $N-n = 0$, consequently the velocity and distance descended are each nothing, and the body will just float in any part of the fluid.

Moreover, when the body is lighter than the fluid, then N is less than n, and $N-n$ becomes a negative quantity, or the force and motion tend the contrary way, that is, the ball will ascend up towards the top of the fluid by a motive force which is as $n-N$. In this case then, the body ascending by the action of the fluid, is moved exactly by the same laws as a heavier body falling in the fluid. And wherever the body is placed, it is sustained by the fluid, and carried up with a force equal to the difference of the weight of a quantity of the fluid of the same bulk as the body, from the weight of the body; there is therefore a force which continually acts equably on the body; by which not only the action of gravity of the body is counteracted, so as that it is not to be considered in this case; but the body is also carried upwards by a motion equably accelerated, in the same manner as a body heavier than a fluid descends by its relative gravity: but the equability of acceleration is destroyed in the same manner by the resistance, in the ascent of a body lighter than the fluid, as it is destroyed in the descent of a body that is heavier.

The resistance to a plane surface of 1 foot square, in passing through water with various degrees of velocity, is as below:

Velocities per hour in miles.	Resistances in avoirdupois pounds.
1	40lbs
1½	90
2	160
2½	250
3	360
3½	490
4	640
&c.	

For the circumstances of the correspondent velocity, space, and time, &c, of a body moving in a fluid in which it is projected with a given velocity, or descending by its own weight, &c, see my Tracts and Course, as before-mentioned.

Resistance *of the Air*, in Pneumatics, is the force with which the motion of bodies, particularly of projectiles, is retarded by the opposition of the air or atmosphere. See Gunnery, Projectiles, &c.

The air being a fluid, the general laws of the resistance of fluids obtain in it; subject only to some variations and irregularities from the different degrees of density in the different stations or regions of the atmosphere.

The resistance of the air is chiefly of use in military projectiles, in order to allow for the differences caused by it in their flight and range. Before the time of Mr. Robins, it was thought that this resistance to the motion of such heavy bodies as iron balls and shells, was too inconsiderable to be regarded, and that the rules and conclusions derived from the common parabolic theory, were sufficiently exact for the common practice of gunnery. But that gentleman showed, in his New Principles of Gunnery, that, so far from being inconsiderable, it is in reality enormously great, and by no means to be rejected without incurring the grossest errors; so much so, that balls or shells which range, at the most, in the air, to the distance of two or three miles, would in a vacuum range to 20 or 30 miles, or more. To determine the quantity of this resistance, in the case of different velocities, Mr. Robins discharged musket-balls, with various degrees of known velocity, against his ballistic pendulums, placed at several different distances, and so discovered by experiment the quantity of velocity lost, when passing through those distances or spaces of air, with the several known degrees of celerity. For having thus known the velocity lost or destroyed, in passing over a certain space, in a certain time, (which time is very nearly equal to the quotient of the space divided by the medium velocity between the greatest and least, or between the velocity at the mouth of the gun and that at the pendulum;) that is, knowing the velocity v, the space s, and time t, the resisting force is thence easily known, being equal to $\frac{vb}{2gt}$ or $\frac{vvb}{2gs}$, where b denotes the weight of the ball, and v the medium velocity above-mentioned. The balls employed on this occasion by Mr. Robins, were leaden ones, of $\frac{1}{11}$ of a pound weight, and $\frac{3}{4}$ of an inch diameter; and to the medium velocity of

1600 feet the resistance was 11lb,
1065 feet - - - - - - it was $2\frac{4}{5}$;

but by the theory of Newton, before laid down, the former of these should be only $4\frac{1}{2}$lb, and the latter 2 lb: so that, in the former case the real resistance is more than double of that given by the theory, being increased as 9 to 22; and in the lesser velocity the increase is from 2 to $2\frac{4}{5}$, or as 5 to 7 only.

Mr. Robins also invented another machine, having a whirling or circular motion, by which he measured the resistances to larger bodies, though with much smaller velocities: it is described, and a figure of it given, near the end of the 1st vol. of his works, and in the 3d vol. of my Tracts.

That this resisting power of the air to swift motions is very sensibly increased beyond what Newton's theory for slow motions makes it, seems hence to be evident. By other experiments it appears that the resistance is very sensibly increased, even in the velocity of 400 feet. However, this increased power of resistance diminishes as the velocity of the resisted body diminishes, till at length, when the motion is sufficiently abated, the actual resistance coincides with that supposed in the theory nearly. For these varying resistances Mr. Robins has given a rule, though not correct, extending to 1670 feet velocity.

Mr. Euler has shown, that the common doctrine of resistance answers pretty well when the motion is not very swift, but in swift motions it gives the resistance less than it ought to be, on two accounts. 1. Because in quick motions, the air does not fill up the space behind the body fast enough to press on the hinder parts, to counterbalance the weight of the atmosphere on the fore part. 2. The density of the air before the ball being increased by the quick motion, will press more strongly on the fore part, and so will resist more than lighter air in its natural state. And he has also shown that Mr. Robins has restrained his rule to velocities not exceeding 1670 feet per second; whereas had he extended it to greater velocities, the result must have been erroneous; and he gives another formula himself, and deduces conclusions differing from those of Mr. Robins. See his Principles of Gunnery investigated, translated by Brown in 1777, pa. 224 &c.

Mr. Robins having proved that, in very great changes of velocity, the resistance does not accurately follow the duplicate ratio of the velocity, lays down two positions, which he thought might be of some service in the practice of artillery, till a more complete and accurate theory of resistance, and the changes of its augmentation, could be obtained. The first of these is, that till the velocity of the projectile surpass 1100 or 1200 feet in a second, the resistance may be esteemed to be in the duplicate ratio of the velocity: and the second is, that when the velocity exceeds 1100 or 1200 feet, then the absolute quantity of the resistance will be near 3 times as great as it would be by a comparison with the smaller velocities. On these principles he proceeds in approximating to the actual ranges of pieces with small angles of elevation, viz, such as do not exceed 8° or 10°, which he sets down in a table, compared with their corresponding potential ranges. See his Mathematical Tracts, vol. 1, pa. 179 &c. But we shall see presently that these positions are both without foundation; that there is no such thing as a sudden or abrupt change in the law of resistance, from the square of the velocity to one that gives a quantity three times as much; but that the change is slow and gradual, from the lowest to the highest velocities; and that the increased real resistance no where rises much higher than double of that which Newton's theory gives it.

Mr. Glenie, in his History of Gunnery, 1776, pa. 49, observes, in consequence of some experiments with a rifled piece, properly fitted for experimental purposes, that the resistance of the air to a velocity somewhat less than that mentioned in the first of the above propositions, is considerably greater than in the duplicate ratio of the velocity; and that, to a celerity somewhat greater than that stated in the second, the resistance is considerably less than that which is treble the resistance in the said ratio. Some of Robins's own experiments seem necessarily to make it so; since, to a velocity no quicker than 400 feet in a second, he found the resistance to be somewhat greater than in that ratio. But the true value of the ratio, and other circumstances of this resistance, will more fully appear from what follows.

The subject of the resistance of the air, as begun by Robins, has been prosecuted by myself, to a very great extent and variety, both with the whirling machine, and with cannon balls of all sizes, from 1lb to 6lb weight, as well as with figures of many other different shapes, both on the fore part and hind part of them, and with planes set at all varieties of angles of inclination to the path or motion of the same; from all which I have obtained the real resistance to bodies for all velocities, from 1 up to 2000 feet per second: together with the law of the resistance to the same body for all different velocities, and for different sizes with the same velocity, and also for all angles of inclination; a full account of which is given in the 2d and 3d vols. of my Tracts. Some of the tables and rules are abstracted as below.

1	2	3	4	5	6	7	8	9

In this table are contained the resistances to several forms of bodies, when moved with various degrees of velocity, from 3 feet per second to 20. The names of the bodies are at the tops of the columns, as also which end went foremost through the air; the different velocities are in the first column, and the resistances on the same line, in their several columns, in avoirdupois ounces and decimal parts. So on the first line are contained the resistances when the bodies move with a velocity of 3 feet in a second, viz, in the 2d column for the small hemisphere, of 4¾ inches diameter, its resistance ·028 oz when the flat side went foremost; in the 3d and 4th columns the resistances to a larger hemisphere, first with the flat side, and next the round side foremost, the diameter of this, as well as all the following figures being 6⅖ inches, and therefore the area of the great circle = 32 sq. inches, or ⅔ of a sq. foot; then in the 5th and 6th columns are the resistances to a cone, first its vertex and then its base foremost, the altitude of the cone being 6⅗ inches, being only ⅕ inch more than the diameter of its base; in the 7th column the resistance to the end of the cylinder, and in the 8th that against the whole globe or sphere. All the numbers show the real weights which are equal to the resistances; and at the bottoms of the columns are placed proportional numbers, which show the mean proportions of the resistances of all the figures to one another, with any velocity. Lastly, in the 9th column are placed the exponents of the power of the velocity which the resistances in the 8th column bear to each other, viz, which that of the 10 feet velocity bears to each of the following ones, the medium of all of them being as the 2·04 power of the velocity, that is, very little above the square or second power of the velocity, so far as the velocities in this table extend.—From this table the following inferences are easily deduced.

1. That the resistance is nearly in the same proportion as the surfaces; a small increase only taking place in the greater surfaces, and for the greater velocities. Thus, by comparing together the numbers in the 2d and 3d columns, for the bases of the two hemispheres, the areas of which bases are in the proportion of 17¾ to 32, or 5 to 9 very nearly, it appears that the numbers in those two columns, expressing the resistances, are nearly as 1 to 2 or 5 to 10, as far as the velocity of 12 feet; but after that, the resistances on the greater surface increase gradually more and more above that proportion.

2. The resistance to the same surface, with different velocities, is, in these slow motions, nearly as the square of the velocity; but gradually increases more and more above that proportion as the velocity increases. This is manifest from all the columns: and the index of the power of the velocity is set down in the 9th column, for the resistances in the 8th, the medium being 2·04; by which it appears that the resistance to the same body is, in these slow motions, as the 2·04 power of the velocity, or nearly as the square of it.

3. The round ends, and sharp ends, of solids, suffer less resistance than the flat or plane ends, of the same diameter; but the sharper end has not always the less resistance. Thus, the cylinder, and the flat ends of the hemisphere and cone, have more resistance, than the round or sharp ends of the same; but the round side of the hemisphere has less resistance than the sharper end of the cone.

4. The resistance on the base of the hemisphere, is to that on the round, or whole sphere, as 2⅓ to 1, instead of

2 to 1, as the theory gives that relation. Also the experimented resistance, on each of these, is nearly $\frac{1}{4}$ more than the quantity assigned by the theory.

5. The resistance on the base of the cone, is to that on the vertex, nearly as $2\frac{7}{10}$ to 1; and almost in the same ratio is radius to the sine of the angle of inclination of the side of the cone to its path or axis. So that, in this instance, the resistance is directly as the sine of the angle of incidence, the transverse section being the same.

6. When the hinder parts of bodies are of different forms, the resistances are different, though the fore-parts be exactly alike and equal; owing probably to the different pressures of the air on the hinder parts. Thus, the resistance to the fore part of the cylinder, is less than on the equal flat surface of the cone, or of the hemisphere; because the hinder part of the cylinder is more pressed or pushed, by the following air than those of the other two figures; also, for the same reason, the base of the hemisphere suffers a less resistance than that of the cone, and the round side of the hemisphere less than the whole sphere.

See other deductions in my Tracts, vol. 3, pa. 193 &c.

TABLE II. *Resistances both by Experiment and Theory, to a Globe of 1·965 Inches Diameter.*

1900	1447	709	2·04	2·104
2000	1569	786	2·00	2·098

In the first column of this table are contained the several velocities, from 0 up to the great velocity of 2000 feet per second, with which the ball or globe moved. In the 2d column are the experimented resistances, in avoirdupois ounces. In the 3d column are the correspondent resistances, as computed by the foregoing theory. In the 4th column are the ratios of these two resistances, or the quotients of the former divided by the latter. And in the 5th or last, the indexes of the power of the velocity which is proportional to the experimented resistance; which are found by comparing the resistance of 20 feet velocity with each of the following ones.

From the 2d, 3d and 4th columns it appears, that at the beginning of the motion, the experimented resistance is nearly equal to that computed by theory; but that, as the velocity increases, the experimented resistance gradually exceeds the other more and more, till at the velocity of 1300 feet the former becomes double the latter; after which, the difference increases a little farther, till at the velocity of 1600 or 1700, where that excess is the greatest, and is rather less than $2\frac{1}{10}$; and after this, the difference decreases gradually as the velocity increases, and at the velocity of 2000, the former resistance again becomes just double the latter.

From the last column it appears that, near the beginning, or in slow motions, the resistances are nearly as the square of the velocities; but that the ratio gradually increases, with some small variation, till at the velocity of 1500 or 1600 feet it becomes as the $2\frac{1}{9}$ power of the velocity nearly, which is its highest ascent; and after that it gradually decreases again, as the velocity goes higher. And similar conclusions have also been derived from experiments with larger balls or globes.

And hence we perceive that Mr. Robins's positions are erroneous on two accounts, viz, both in stating that the resistance changes suddenly, or all at once, from being as the square of the velocity, so as then to become as some higher and constant power; and also when he states the resistance as rising to the height of three times that which is given by the theory: since the ratio of the resistance both increases gradually from the beginning, and yet never ascends higher than $2\frac{9}{100}$ of the theory.

TABLE III. *Resistance to a Plane, set at various Angles of Inclination to its Path.*

85	·839	·839	·838
90	·840	·840	·840

In the second column of this table are contained the actual experimented resistances, in ounces, to a plane of 32 square inches, or $\frac{2}{9}$ of a square foot, moved through the air with a velocity of exactly 12 feet per second, when the plane was set so as to make, with the direction of its path, the corresponding angles in the first column.

And from these has been deduced this formula, or theorem, viz, $\cdot84s^{1\cdot842c}$, which brings out very nearly the same numbers, and is a general theorem for every angle, for the same plane of $\frac{2}{9}$ of a foot, and moved with the same velocity of 12 feet in a second of time; where *s* is the sine, and *c* the cosine of the angles of inclination in the first column.

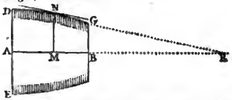
If a theorem be desired for any other velocity *v*, and any other plane whose area is *a*, it will be this: $\frac{1}{55}av^2s^{1\cdot842c}$, or more nearly $\frac{1}{42}av^{2\cdot04}s^{1\cdot842c}$; which denotes the resistance nearly to any plane surface whose area is *a*, moved through the air with the velocity *v*, in a direction making with that plane an angle, whose sine is *s*, and cosine *c*.

If it be water or any other fluid, different from air, this formula will be varied in proportion to the density.

By this theorem were computed the numbers in the 3d column; which it is evident agree very nearly with the experiment resistances in the 2d column, excepting in two or three of the small numbers near the beginning, which are of the least consequence. In all other cases, the theorem gives the true resistance very nearly. In the 4th or last column are entered the sines of the angles of the first column, to the radius ·84, in order to compare them with the resistances in the other columns. Whence it appears, that those resistances are not always proportional to the sines of the angles, nor yet to the squares of the sines, nor to any other power of them whatever. In the beginning of the columns, the sines much exceed the resistances all the way till the angle be between 55 and 60 degrees; after which the sines are less than the resistances all the way to the end, or till the angle become of 90 degrees.

Mr. James Bernoulli gave some theorems for the resistances of different figures, in the Acta Erud. Lips. for June 1693, pa. 252 &c. But as these are deduced from theory only, which we find to be so different from experiment, they cannot be of much use. Messieurs Euler, Dalembert, Gravesande, and Simpson, have also written pretty largely on the theory of resistances, besides what had been done by Newton. Also Mr. Vince, in the Philos. Trans. an. 1795, pa. 24.

Solid of Least RESISTANCE. Sir Isaac Newton, from his general theory of resistance, deduces the figure of a solid which shall have the least resistance, of the same base, height, and content.



The figure is this. Suppose DNG to be a curve of such a nature, that if from any point N the ordinate NM be drawn perpendicular to the axis AB; and from a given point G there be drawn GR parallel to a tangent at N, and meeting the axis produced in R; then if MN be to GR, as GR^3 to $4BR \times BG^2$, a solid described by the revolution of this figure about its axis AB, moving in a medium from A towards B, is less resisted than any other circular solid of the same base, &c.

This theorem, which Newton gave without a demonstration, has been demonstrated by several mathematicians, as Facio, Bernoulli, Hospital, &c. See Maclaurin's Flux. sect. 606 and 607; also Horsley's edit. of Newton, vol. 2, pa. 390. See also Act. Erud. 1699, pa. 514; and Mem. de l'Acad. &c; also Robins's View of Newton's method for comparing the Resistance of Solids, 8vo, 1734; and Simpson's Fluxions, art. 413; or my Principles of Bridges, in my Tracts, prop. 15.

M. Bouguer has resolved this problem in a very general manner; and not in supposing the solid to be formed by the revolutions of any figure whatever. The problem, as enunciated and resolved by M. Bouguer, is this: any base being given, to find what kind of solid must be formed upon it, so that the impulse upon it may be the least possible. Properly however it ought to be the retardive force, or the impulse divided by the weight or mass of matter in the body, that ought to be the minimum.

RESOLUTION, in Physics, the reduction of a body into its original or natural state, by a dissolution or separation of its aggregated parts. Thus, snow and ice are said to be resolved into water; water resolves in vapour by heat; and vapour is again resolved into water by cold; also any compound is resolved into its ingredients, &c.—Some of the modern philosophers, particularly Boyle, Mariotte, Boerhaave, &c, maintain, that the natural state of water is to be congealed, or in ice; inasmuch as a certain degree of heat, which is a foreign and violent agent, is required to make it fluid: so that near the pole, where this foreign agent is wanting, it constantly retains its fixed or icy state.

RESOLUTION, or SOLUTION, in Mathematics, is an orderly enumeration of several things to be done, to obtain what is required in a problem.—Wolfius makes a problem to consist of three parts: the proposition (or what is properly called the problem), the resolution, and the demonstration. As soon as a problem is demonstrated, it is converted into a theorem; of which the resolution is the hypothesis; and the proposition the thesis. For the process of a mathematical resolution, see the following article.

RESOLUTION in *Algebra*, or *Algebraical* RESOLUTION, is of two kinds; the one practised in numerical problems, the other in geometrical ones.

In Resolving a Numerical Problem Algebraically, the method is this. 1st, the given quantities are distinguished from those that are sought; and the former denoted by the initial letters of the alphabet, but the latter by the last letters.—2d, Then as many equations are formed as there are unknown quantities. If that cannot be done from the proposition or data, the problem is indeterminate; and certain arbitrary assumptions must be made, to supply the defect, and which can satisfy the question. When the equations are not contained in the problem itself, they are to be found by particular theorems concerning equations, ratios, proportions, &c.—Since, in an equation, the known and unknown quantities are mixed together, they must be separated in such a manner, that the unknown one remain alone on one side, and the known ones on the other. This reduction, or separation, is made by addition, subtraction, multiplication, division, extraction of roots, and raising of powers; resolving every kind of combination of the quantities, by their counter or reverse ones, and performing the same operation on all the quantities or terms, on both sides of the equation, that the equality may still be preserved.

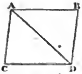
To Resolve a Geometrical Problem Algebraically.—The same kind of operations are to be performed, as in the former article; besides several others, that depend on the nature of the diagram, and geometrical properties. As, 1st, the thing required or proposed, must be supposed done, the diagram being drawn or constructed in all its parts, both known and unknown. 2. We must then examine the geometrical relations which the lines of the figure have among themselves, without regarding whether they are known or unknown, to find what equations arise from those relations, for finding the unknown quantities. 3. It is often necessary to form similar triangles and rectangles, sometimes by producing of lines, or drawing parallels and perpendiculars, and forming equal angles, &c; till equations can be formed, from them, including both the known and unknown quantities.

If we do not thus arrive at proper equations, the thing is to be tried in some other way. And sometimes the thing itself, that is required, is not to be sought directly, but some other thing, bearing certain relations to it, by means of which it may be found.

The final equation being at last arrived at, the geometrical construction is to be deduced from it, which is performed in various ways according to the different kinds of equations. See ANALYSIS.

RESOLUTION *of Forces*, or *of Motion*, is the resolving or dividing of any one force or motion, into several others, in other directions, but which, taken together, shall have the same effect as the single one; and it is the reverse of the composition of forces or motions. See these articles.

Any single direct force AD, may be resolved into two oblique forces, whose quantities and directions are AB, AC, having the same effect, by describing any parallelogram ABDC, whose diagonal is AD. And each of these may, in like manner, be resolved into two others; and so on, as far as we please. And all these new forces, or motions, so found, when acting together, will produce exactly the same effect as the single original one. See also COLLISION, PERCUSSION, MOTION, COMPOSITION, PARALLELOGRAM and POLYGON *of Forces*, &c.



REST, in Physics, the continuance of a body in the same place; or its continual application or contiguity to the same parts of the ambient and contiguous bodies.—See SPACE.

Rest is either Absolute or Relative, as place is.

Some define Rest to be the state of a thing without motion; and hence again rest becomes either absolute or relative, as motion is.

Newton defines true or absolute rest to be the continuance of a body in the same part of absolute and immoveable space; and relative rest to be the continuance of a body in the same part of relative space. Thus, in a ship under sail, relative rest is the continuance of a body in the same part of the ship. But true or absolute rest is its continuance in the same part of universal space in which the ship itself is contained.

Hence, if the earth were really and absolutely at rest, the body relatively at rest in the ship would really and absolutely move, and that with the same velocity as the ship itself. But as the earth also moves, there arises a real and absolute motion of the body at rest; partly from the real motion of the earth in absolute space, and partly from the relative motion of the ship on the sea. Lastly, if the body be likewise relatively moved in the ship, its real motion will arise partly from the real motion of the earth in immoveable space, and partly from the relative motion of the ship on the sea, and of the body in the ship.

It is an axiom in philosophy, that matter is indifferent as to rest or motion. Hence Newton lays it down, as a law of nature, that every body perseveres in its state, either of rest or uniform motion, except so far as it is disturbed by external causes.—The Cartesians assert, that firmness, hardness, or solidity of bodies, consists in this, that their parts are at rest with regard to each other; and this rest they establish as the great nexus, or principle of cohesion, by which the parts are connected together. On the other hand, they make fluidity to consist in a perpetual motion of the parts, &c. But the Newtonian philosophy furnishes us with much better solutions.—Maupertuis asserts, that when bodies are in equilibrio, and any small motion is impressed on them, the quantity of action resulting will be the least possible. This he calls the law of rest; and from this law he deduces the fundamental proposition of statics. See Berlin Mem. tom. 2, pa. 294. And from the same principle too he deduces the laws of percussion.

RESTITUTION, in Physics, the returning of elastic bodies, forcibly bent, to their natural state; by some called the Motion of Restitution.

RETARDATION, in Physics, the act of retarding, that is, of delaying the motion or progress of a body, or of diminishing its velocity.—The retardation of moving bodies arises from two great causes, the resistance of the medium, and the force of gravity.

RETARDATION *from the Resistance* is often confounded with the resistance itself; because, with respect to the same moving body, they are in the same proportion.

But with respect to different bodies, the same resistance often generates different retardations. For if bodies of equal bulk, but different densities, be moved through the same fluid with equal velocity, the fluid will act equally on each; so that they will have equal resistances, but different retardations; and the retardations will be to each other, as the velocities which might be generated by the same forces in the bodies proposed; that is, they are inversely as the quantities of matter in the bodies, or inversely as the densities.

Suppose then bodies of equal density, but of unequal bulk, to move equally fast through the same fluid; then their resistances increase according to their superficies, that is as the squares of their diameters; but the quantities of matter are increased according to their mass or magnitude, that is as the cubes of their diameters: the resistances are the quantities of motion; the retardations are the celerities arising from them; and dividing the quantities of motion by the quantities of matter, we shall have the celerities; therefore the retardations are directly as the squares of the diameters, and inversely as the cubes of the diameters, that is inversely as the diameters themselves.

If the bodies be of equal magnitude and density, and moved through different fluids, with equal celerity, their retardations are as the densities of the fluids. And when equal bodies are carried through the same fluid with different velocities, the retardations are as the squares of the velocities.

So that, if s denote the superficies of a body, w its weight, d its diameter, v the velocity, and n the density of the fluid medium, and N that of the body; then, in similar bodies, the resistance is as nsv^2 or as nd^2v^2, and the retardation, or retarding force, as $\frac{nsv^2}{w}$, or as $\frac{nd^2v^2}{Nd^3} = \frac{nv^2}{Nd}$.

The RETARDATION *from Gravity* is peculiar to bodies projected upwards. For a body thrown upwards is retarded after the same manner as a falling body is accelerated; only in the one case the force of gravity conspires with the motion acquired, and in the other it acts contrary to it.

As the force of gravity is uniform, the retardation from that cause will be equal in equal times. And hence, as it is the same force which generates motion in the falling body, and diminishes it in the rising one, a body rises till it lose all its motion; which it does in the same time in which a body falling would have acquired a velocity equal to that with which the body was thrown up.

Also, a body thrown up will rise to the same height from which, in falling, it would acquire the same velocity with which it was thrown up: therefore the heights which bodies can rise to, when thrown up with different velocities, are to each other as the squares of the velocities.

Hence, the retardations of motions may be compared together. For they are, first, as the squares of the velocities; 2dly, as the densities of the fluids through which the bodies are moved; 3dly, inversely as the diameters of those bodies; 4thly, inversely as the densities of the bodies themselves; as expressed by the theorem above, viz, $\frac{nv^2}{Nd}$.

The Laws of RETARDATION, are the very same as those for acceleration; motion and velocity being destroyed in the one case, in the very same quantity and proportion as they are generated in the other.

RETICULA, or RETICULE, in Astronomy, a contrivance for very accurately measuring the quantity of eclipses, &c. This instrument, introduced some years since by the Paris Acad. of Sciences, is a little frame, consisting of 13 fine silken threads, parallel to, and equidistant from each other; placed in the focus of object-glasses of telescopes; that is, in the place where the image of the luminary is painted in its full extent. Consequently the diameter of the sun or moon is thus seen divided into 12 equal parts or digits: so that, to find the quantity of the eclipse, there is nothing to do but to number the parts that are dark, or that are luminous.—As a square reticule is only proper for the diameter of the luminary, not for the circumference of it, it is sometimes made circular, by drawing 6 concentric equidistant circles; which represents the phases of the eclipse perfectly.—But it is evident that the reticule, whether square or circular, ought to be perfectly equal to the diameter or circumference of the sun or star, such as it appears in the focus of the glass; otherwise the division cannot be just. And this is no easy matter to effect, because the apparent diameter of the sun and moon differs in each eclipse; nay that of the moon differs from itself in the progress of the same eclipse.—Another imperfection in the reticule is, that its magnitude is determined by that of the image in the focus; and of consequence it will only fit one certain magnitude.

But M. Lahire has found a remedy for all these inconveniences, and contrived that the same reticule shall serve for all telescopes, and all magnitudes of the luminary in the same eclipse. The principle on which his invention is founded, is, that two object-glasses applied against each other, having a common focus, and these forming an image of a certain magnitude, this image will increase in proportion as the distance between the two glasses is increased, as far as to a certain limit. If therefore a reticule be taken of such a magnitude, as just to comprehend the greatest diameter the sun or moon can ever have in the common focus of two object-glasses applied to each other, there needs nothing but to remove them from each other, as the body comes to have a less diameter, to have the image still exactly comprehended in the same reticule.

Further, as the silken threads are subject to swerve from the parallelism, &c, by the different temperature of the air, another improvement is, to make the reticule of a thin looking-glass, by drawing lines or circles upon it with the fine point of a diamond. See MICROMETER.

RETIRED FLANK, in Fortification. See FLANK.

RETROCESSION *of Curves, &c.* See RETROGRADATION.

RETROCESSION *of the Equinox.* See PRECESSION.

RETROGRADATION, or RETROGRESSION, in Astronomy, is an apparent motion of the planets, by which they seem to go backwards in the ecliptic, and to move contrary to the order or succession of the signs.

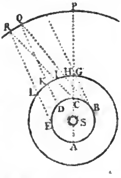
When a planet moves in consequentia, or according to the order of the signs, as from Aries to Taurus, from Taurus to Gemini, &c, which is from west to east, it is said to be Direct.—When it appears for some days in the same place, or point of the heavens, it is said to be Stationary.—And when it goes in antecedentia, or backwards to the foregoing signs, or contrary to the order of the signs, which is from east to west, it is said to be Retrograde. All these different affections or circumstances, may happen in all the planets, except the sun and moon, which are seen to go direct only. But the times of the superior and inferior planets being retrograde are different; the former appearing so about their opposition, and the latter about their conjunction. The intervals of time also between two retrogradations of the several planets, are very unequal.

In Herschel it is	1 year	6 days,
In Saturn - -	1 - - -	13
In Jupiter - -	1 - - -	43
In Mars - - -	2 - - -	50
In Venus - -	1 - -	220
In Mercury -	0 - -	115

Again, Herschel continues retrograde 153 days, Saturn 140, Jupiter 120, Mars 73, Venus 42, and Mercury 22; or nearly so; for the several retrogradations of the same planet are not constantly equal.

These various circumstances however in the motions of the planets are not real, but only apparent; as the inequalities arise from the motion and position of the earth, from which they are viewed; for when they are considered as seen from the sun, their motions appear always uniform and regular. These inequalities are thus explained:

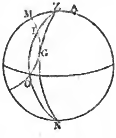
Let S denote the sun; and ABCD&c the path or orbit of the earth, moving from west to east, and in that order; also GK &c the orbit of a superior planet, as Saturn for instance, moving the same way, or in the direction GKLG, but with a much less celerity than the earth's motion. Now when the earth is at the point A of its orbit, let Saturn be at G, in conjunction with the sun, when it will be seen at P in the zodiac, or among the stars; and when the earth has moved from A to B, let Saturn have moved from G to H in its orbit, when it will be seen in the line BHQ, and will appear to have moved from P to Q in the zodiac; also when the earth has got to C, let Saturn be arrived at I, but found at R in the zodiac, where being seen in the line CIR, it appears stationary, or without motion in the zodiac at R. But after this, Saturn will appear for some time in retrogradation, viz, moving backwards, or the contrary way: for when the earth has moved to D, this planet will have got to K, and, being seen in the line DKQ, will appear to have moved retrograde in the zodiac from R to Q; about which place the planet, ceasing to recede any farther, again becomes stationary, and afterwards proceeds forward again; for while the earth moves from D to E, and Saturn from K to L, the latter, being now seen in the line ELR, appears to have moved forward in the zodiac from Q to R: and so on; the superior planets always becoming retrograde a little before they are in opposition to the sun, and continuing so till some time after the opposition: the retrograde motion being swiftest when the planet is in the very opposition itself; and the direct motion swiftest when in the conjunction. The arch RQ, which the planet describes while thus retrograde, is called the arch of retrogradation. These arches are unequal in all the planets, being greatest in the most distant, and gradually less in the nearer ones.



In like manner may be shown the circumstances of the retrogradations of the inferior planets; by which it will appear, that they become stationary a little before their inferior conjunction, and go retrograde till a little time after it; moving the quickest retrograde just at that conjunction, and the quickest direct just at the superior or further conjunction.

RETROGRADATION *of the Nodes of the Moon*, is a motion of the line of the nodes of her orbit, by which it continually shifts its situation from east to west, contrary to the order of the signs, completing its retrograde circulation in the period of about 19 years: after which time, either of the nodes, having receded from any point of the ecliptic, returns to the same again.—Newton has demonstrated, in his Principia, that the Retrogradation of the moon's nodes is caused by the action of the sun, which continually drawing this planet from her orbit, deflects this orbit from a plane, and causes its intersection with the ecliptic continually to vary; and his determinations on this point have been confirmed by observation.

RETROGRADATION *of the Sun*, a motion by which in some situations, in the torrid zone, he seems to move retrograde or backwards. When the sun is in the torrid zone, and has his declination AM greater than the latitude of the place AZ, but either northern or southern as that is, the sun will appear to go retrograde, or backwards, both before and after noon. For draw the vertical circle ZGN to be a tangent to the sun's diurnal circle MGO in G, and another ZON through the sun's rising, at O: thus it is evident, that all the intermediate vertical circles cut the sun's diurnal circle twice; first in the arc GO, and the second time in the arc GI. So that, as the sun ascends through the arc GO, he continually arrives at farther and farther verticals. But as he continues his ascent through the arc GI, he returns to his former verticals; and therefore is seen retrograde for some time before noon. And in like manner it may be shown that he does the same thing for some time after noon. Hence, as the shadow always tends opposite to the sun, it will be retrograde twice every day in all places of the torrid zone, where the sun's declination exceeds the latitude.



RETROGRADATION, or RETROGRESSION, in the Higher Geometry, is the same with what is otherwise called Contrary Flexion or Flexure. See FLEXURE, and INFLEXION.

RETROGRADE, denotes backward, or contrary to the forward or natural direction. See RETROGRADATION.

RETROGRESSION, or RETROCESSION. The same with RETROGRADATION.

RETURNING *Stroke*, in Electricity, is an expression used by lord Mahon (now Earl Stanhope) to denote the effect produced by the return of the electric fire into a body from which, in certain circumstances, it has been expelled.

To understand properly the meaning of these terms, it must be premised that, according to the noble author's experiments, an insulated smooth body, immerged within the electrical atmosphere, but beyond the striking distance of another body, charged positively, is at the same time in a state of threefold electricity. The end next to the charged body acquires negative electricity; the farther end is positively electrified; while a certain part of the body, somewhere between its two extremes, is in a natural, unelectrified, or neutral state; so that the two contrary electricities balance each other. It may further be added, that if the body be not insulated, but have a communication with the earth, the whole of it will be in a negative state. Suppose then a brass ball, which may be called A, to be constantly placed at the striking distance of a prime conductor; so that the conductor, the instant when it becomes fully charged, explodes into it. Let another large or second conductor be suspended, in a perfectly insulated state, farther from the prime conductor than the striking distance, but within its electrical atmosphere: let a person standing on an insulated stool touch this second conductor very lightly with a finger of his right hand; while with a finger of his left hand, he communicates with the earth, by touching very lightly a second brass ball fixed at the top of a metallic stand, on the floor, which may be called B. Now while the prime conductor is receiving its electricity, sparks pass (at least if the distance between the two conductors is not too great) from the second conductor to the right hand of the insulated person; while similar and simultaneous sparks pass out from the finger of his left hand into the second metallic ball B, communicating with the earth. At length however the prime conductor, having acquired its full charge, suddenly strikes into the ball A, of the first metallic stand, placed for that purpose at the striking distance. The explosion being made, and the prime conductor suddenly deprived of its elastic atmosphere, its pressure or action on the second conductor, and on the insulated person, as suddenly ceases; and the latter instantly feels a smart returning stroke, though he has no direct or visible communication (except by the floor) with either of the two bodies, and is placed at the distance of 5 or 6 feet from both of them. This returning stroke is evidently occasioned by the sudden re-entrance of the electric fire naturally belonging to his body and to the second conductor, which had before been expelled by the action of the charged prime conductor upon them; and which returns to its former place in the instant when that action or elastic pressure ceases. When the second conductor and the insulated person are placed in the densest part of the electrical atmosphere of the prime conductor, or just beyond the striking distance, the effects are still more considerable; the returning stroke being in that case extremely severe and pungent, and appearing considerably sharper than even the main stroke itself, received directly from the prime conductor. Lord Mahon observes, that persons and animals may be destroyed, and particular parts of buildings may be much damaged, by an electrical returning stroke, occasioned even by some very distant explosion from a thunder-cloud; possibly at the distance of a mile or more. It is certainly not difficult to conceive that a highly charged thunder-cloud must be productive of effects similar to those produced by the prime conductor; but perhaps the effects are not so great, nor the danger so terrible, as it seems have been apprehended. If the quantity of electric fluid naturally contained, for example, in the body of a man, were immense or indefinite, then the estimate between the effects producible by a cloud, and those caused by a prime conductor, might be admitted; but surely no electrical cloud can expel from a body more than the natural quantity of electricity which it contains. On the sudden removal therefore of the pressure by which this natural quantity had been expelled, in consequence of the explosion of the cloud into the earth, no more (at the utmost) than the whole natural stock of electricity can re-enter his body, provided it be so situated, that the returning fire of other bodies must necessarily pass through his body. But perhaps we have no reason to suppose that this quantity is so great, as that its sudden re-entrance into his body should destroy or injure him.

Allowing therefore the existence of the returning stroke, as sufficiently ascertained, and well illustrated, in a variety of circumstances, by the author's experiments, the magnitude and danger of it do not seem to be so alarming as he apprehends. See Lord Mahon's Principles of Electricity, &c. 4to. 1779, pa. 76, 113, and 131. Also Monthly Review, vol. 62, pa. 436.

REVERSION in *Annuities*, or *Reversionary Payments*, are payments that are not to be made till after some stated period; being thus distinguished from payments that are to be made immediately.

Reversions are either certain, or contingent: of the former kind, are all sums payable after a certain number of years, or any other fixed and determinate period of time, as also on the extinction of any lives. And of the latter sort, are all such reversions as depend on any contingency; and particularly the survivorship of any lives beyond, or after, others. See the articles ASSURANCE, ANNUITIES, LIFE ANNUITIES, and SURVIVORSHIP.

REVERSION *of Series*, in Algebra, is the finding the value of the root, or unknown quantity, whose powers enter the terms of an infinite series, by means of another infinite series in which it is not contained. As, in the infinite series $z = ax + bx^2 + cx^3 + dx^4$ &c; then if there be found $x = Az + Bz^2 + Cz^3$ &c, that series is reverted, or its root x is found in an infinite series of other terms.

This was one of Newton's improvements in analysis, the first specimen of which was given in his Analysis per Æquationes Numero Terminorum Infinitas; and it is of great use in resolving many problems in various parts of the mathematics.

The most usual and general way of reversion, is to assume a series, of a proper form, for the value of the required unknown quantity; then substitute the powers of this value, instead of those of that quantity into the given series; lastly compare the resulting terms with the said given series, and the values of the assumed coefficients will thus be obtained. So, to revert the series $z = ax + bx^2 + cx^3$ &c, or to find the value of x in terms of z; assume it thus, $x = Az + Bz^2 + Cz^3$ &c; then by involving this series, for the several powers of x, and multiplying the corresponding powers by $a, b, c,$ &c, there results

$$\begin{aligned} z = aAz &+ aBz^2 + aCz^3 + aDz^4, \text{ \&c.} \\ &+ bA^2z^2 + 2bABz^3 + 2bACz^4 \\ &\qquad\qquad\qquad\quad + bB^2z^4 \\ &\qquad\quad + cA^3z^3 + 3cA^2Bz^4 \\ &\qquad\qquad\qquad\quad + dA^4z^4 \end{aligned}$$

Then by comparing the corresponding terms of this last series, or making their coefficients equal, there are obtained these equations, viz,

$aA = 1$, and $aB + bA^2 = 0$, and $aC + 2bAB + cA^3 = 0$, &c, which give these values of the assumed coefficients,

$$A = \frac{1}{a};\ B = -\frac{bA^2}{a} = -\frac{b}{a^3};$$

$$C = -\frac{2bAB + cA^3}{a} = \frac{2bb - ac}{a^5};$$

$$D = -\frac{2bAC + bB^2 + 3cA^2B + dA^4}{a}$$

$$= -\frac{5abc - 5b^3 - a^2d}{a^7};\ \text{\&c. consequently}$$

$$x = \frac{1}{a}z - \frac{b}{a^3}z^2 + \frac{2bb - ac}{a^5}z^3 - \frac{5abc - 5b^3 - a^2d}{a^7}z^4, \text{ \&c.}$$

which is therefore a general formula or theorem for every series of the same kind, as to the powers of the quantity x. Thus, for

Ex. Suppose it were required to revert the series $z = x - x^2 + x^3 - x^4$, &c.

Here $a = 1$, $b = -1$, $c = 1$, $d = -1$, &c; which values of these letters being substituted in the theorem, there results $x = z + z^2 + z^3 + z^4$, &c, which is that series reverted, or the value of x in it.

In the same way it will be found that the theorem for reverting the series

$z = ax + bx^3 + cx^5 + dx^7$ &c, is

$$x = \frac{1}{a}z - \frac{b}{a^4}z^3 + \frac{3bb - ac}{a^7}z^5 - \frac{a^2d + 12b^3 - 8abc}{a^{10}}, \text{ \&c.}$$

Various methods of reversion may be seen as given by De Moivre in the Philos. Trans. No. 240; or Maclaurin's Algebra pa. 263; or Stuart's explanation of Newton's Analysis, &c. pa. 455; or Colson's Comment on Newton's Flux. pa. 219; or Horsley's ed. of Newton's works vol. 1, pa. 291; or Simpson's Flux. vol. 2, pa. 302: or most authors on algebra.

REVETEMENT, in Fortification, a strong wall built on the outside of the rampart and parapet, to support the earth, and prevent its rolling into the ditch.

REVOLUTION, in Geometry, the motion of rotation of a line about a fixed point or centre, or of any figure about a fixed axis, or upon any line of surface. Thus, the revolution of a given line about a fixed centre, generates a circle; and that of a right-angled triangle about one side, as an axis, generates a cone; and that of a semicircle about its diameter, generates a sphere or globe, &c.

REVOLUTION, in Astronomy, is the period of a star, planet, or comet, &c; or its course from any point of its orbit, till it return to the same again.

The planets have a twofold revolution. The one about their own axes, usually called their diurnal rotation, which constitutes their day. The other about the sun, called their annual revolution, or period, constituting their year.

REYNEAU (CHARLES-RENE), commonly called father Reyneau, a noted French mathematician, was born at Brissac in the province of Anjou, in the year 1656. At 20 years of age he entered himself among the Oratorians, a kind of religious order, in which the members lived in community without making any vows, and applied themselves chiefly to the education of youth. He was soon after sent, by his superiors, to teach philosophy at Pezenas, and then at Toulon. This requiring some acquaintance with geometry, he contracted a great affection for that science, which he cultivated and improved to a great extent; in consequence he was called to Angers in 1683, to fill the mathematical chair; and the Academy of Angers elected him a member in 1694.

In this occupation father Reyneau, not content with making himself master of every thing worth knowing, which the modern analysis, so fruitful in sublime speculations and ingenious discoveries, had already produced, undertook to reduce into one body, for the use of his scholars, the principal theories scattered about in Newton, Descartes, Leibnitz, Bernoulli, the Leipsic Acts, the Memoirs of the Paris Academy, and in other works; treasures which by being so widely dispersed, proved much less useful than they otherwise might have been. The fruit of this undertaking, was his Analyse Demontrée, or Analysis Demonstrated, which he published in 2 volumes 4to, 1708.

Reyneau, after thus giving lessons to those who understood something of geometry, thought proper to compose a work also for such as were utterly unacquainted with that science. This was in some measure a condescension in him, but his passion to be useful made it easy and agreeable. Accordingly, in 1714 he published a useful volume in 4to on calculation, under the title of Science du Calcul des Grandeurs.

As soon as the Royal Academy of Sciences at Paris, in consequence of a regulation made in the year 1716, opened its doors to other learned men, under the title of Free Associates, father Reyneau was admitted of the number. The works however which we have already mentioned, besides a small piece upon logic, are the only ones he ever published, or probably ever composed, except most of the materials for a second volume of his Science du Calcul, which he left behind him in manuscript. The last years of his life were attended with too much sickness to admit of any extraordinary application. He died in 1728, at 72 years of age, not more regretted on account of his great learning, than of his many virtues, which all conspired in an eminent degree to make that learning agreeable to those about him, and useful to the world. The first men in France deemed it an honour and a happiness to count him among their friends. Of this number were the chancellor of that kingdom, and father Mallebranche, of whom Reyneau was a zealous and faithful disciple.

RHABDOLOGY, or RABDOLOGY, in Arithmetic, a name given by Napier to a method of performing some of the more difficult operations of numbers by means of certain square little rods. Upon these are inscribed the simple numbers; then by shifting them according to certain rules, those operations are performed by simply adding or subtracting the numbers as they stand upon the rods. See Napier's Rabdologia, printed in 1617. See also the article NAPIER'S *Bones*.

RHEO-STATICS, is used by some for the statics, or the science of the equilibrium of fluids.

RHETICUS (GEORGE JOACHIM), a noted German astronomer and mathematician, who was the colleague of Reinhold in the university of Wittemberg, being joint professors of mathematics there together. He was born at Feldkirk in Tyrol the 15th of February 1514. After studying the elements of the mathematics at Zurich with Oswald Mycone, he went to Wittemberg, where he diligently cultivated that science. Here he was made master of philosophy in 1535, and professor in 1537. He quitted this situation however two years after, and went to Fruenburg to put himself under the assistance of the celebrated Copernicus, being induced to this step by his zeal for astronomical pursuits, and the great fame which Copernicus had then acquired. Rheticus assisted this astronomer for some years, and constantly exhorted him to perfect his work, De Revolutionibus, which he published after the death of Copernicus, viz, in 1543, folio, at Norimberg, together with an illustration of the same in a narration, dedicated to Schoner. Here too, to render astronomical calculations more accurate, he began his very elaborate canon of sines, tangents, and secants, to 15 places of figures, and to every 10 seconds of the quadrant, a design which he did not live quite long enough to complete. The canon of sines however to that radius, for every 10 seconds, and for every single second in the first and last degree of the quadrant, computed by him, was published in folio at Francfort 1613 by Pitiscus, who himself added a few of the first sines computed to 22 places of figures. But the larger work, or canon of sines, tangents, and secants, to every 10 seconds, was finished and published after his death, viz, in 1596, by his disciple Valentine Otho, mathematician to the electoral prince Palatine; a particular account and analysis of which work may be seen in the Historical Introduction to my Logarithms.

After the death of Copernicus, Rheticus returned to Wittemberg, viz, in 1541 or 1542, and was again admitted to his office of professor of mathematics. The same year, by the recommendation of Melancthon, he went to Norimberg, where he found certain manuscripts of Werner and Regiomontanus. He afterwards taught mathematics at Leipsic. From Saxony he departed a second time, for what reason is not known, and went to Poland; and from thence to Cassovia in Hungary, where he died December the 4th, 1576, at nearly 63 years of age.

His Narratio de Libris Revolutionum Copernici, was first published at Gedanum in 4to, 1540; and afterwards added to the editions of Copernicus's work. He also composed and published Ephemerides, according to the doctrine of Copernicus, till the year 1551.

Rheticus also projected other works, of various kinds, astronomical, astrological, geographical, chemical, &c, and partly executed them, though they were never published, which are more particularly mentioned in his letter to Peter Ramus in the year 1568, which Adrian Romanus inserted in the preface to the first part of his Idea of Mathematics.

RHOMB-SOLID, consists of two equal and right cones joined together at their bases.

RHOMBOID, or RHOMBOIDES, in Geometry, a quadrilateral figure, whose opposite sides and angles are equal; but which is neither equilateral nor equiangular.

RHOMBUS, is an oblique equilateral parallelogram; or a quadrilateral figure, whose sides are equal and parallel, but the four angles not all equal, two of the opposite ones being obtuse, and the other two opposite ones acute. The two diagonals of a rhombus intersect at right angles. As to the area of the rhombus or rhomboides, it is found, like that of all other parallelograms, by multiplying the length or base by the perpendicular breadth.

RHOMBUS-*Solid*. See RHOMB-*Solid*.

RHUMB, or RUMB, in Navigation, a vertical circle of any given place; or the intersection of a part of such a circle with the horizon. Rhumbs therefore coincide with the points of the horizon. And hence mariners distinguish the rhumbs by the same names as the points and winds. But we may observe, that the rhumbs are denominated from the points of the compass in a different manner from the winds: thus, at sea, the north-east wind is that which blows from the north-east point of the horizon towards the ship in which we are; but we are said to sail upon the north-east rhumb, when we go towards the north-east.—They usually reckon 32 rhumbs, which are represented by the 32 lines in the rose or card of the compass.

Aubin defines a rhumb to be a line on the terrestrial globe, or sea-compass, or sea-chart, representing one of the 32 winds which serve to conduct a vessel. So that the rhumb a vessel pursues is conceived as its route, or course.

Rhumbs are divided and subdivided like points of the compass. Thus, the whole rhumb answers to the cardinal point. The half rhumb to a collateral point, or makes an angle of 45 degrees with the former. And the quarter rhumb makes an angle of 22° 30′ with it. Also the half-quarter rhumb makes an angle of 11° 15′ with the same.

For a table of the rhumbs, or points, and their distances from the meridian, see WIND.

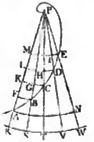
RHUMB-LINE, *Loxodromia*, in Navigation, is a line prolonged from any point of the compass in a nautical chart, except the four cardinal points: or it is the line which a ship, keeping in the same collateral point, or rhumb, describes throughout its whole course; being derived from a Portuguese word.

The chief property of the rhumb-line, or loxodromia, and that from which some authors define it, is, that it cuts all the meridians in the same angle. This angle is called the Angle of the Rhumb, or the Loxodromic angle. And the angle which the rhumb-line makes with any parallel to the equator, is called the Complement of the Rhumb.

An idea of the origin and properties of the rhumb-line, the great foundation of navigation, may be conceived thus: A vessel beginning its course, the wind by which it is driven makes a certain angle with the meridian of the place; and as we shall suppose that the vessel runs exactly in the direction of the wind, it makes the same angle with the meridian which the wind makes. Supposing then the wind to continue the same, as each point or instant of the progress may be esteemed the beginning, the vessel always makes the same angle with the meridian of the place where it is each moment, or in each point of its course which the wind makes.—Now a wind, for example, that is north-east, and which consequently makes an angle of 45 degrees with the meridian, is equally north-east wherever it blows, and makes the same angle of 45 degrees with all the meridians it meets. And therefore a vessel, driven by the same wind, always makes the same angle with all the meridians it meets with on the surface of the earth. If the vessel sail north or south, it describes the great circle of a meridian. If it runs east or west, it cuts all the meridians at right angles, and describes either the circle of the equator, or else a circle parallel to it. But if the vessel sails between the two, it does not then describe a circle; since a circle, drawn obliquely to a meridian, would cut all the meridians at unequal angles, which the vessel cannot do. It describes therefore a particular curve, the essential property of which is, that it cuts all the meridians in the same angle, and it is called the Loxodromy, or Loxodromic Curve, or Rhumb-line.

This curve, on the globe, is a kind of spiral, tending continually nearer and nearer to the pole, and making an infinite number of circumvolutions about it, without ever arriving exactly at it. But the spiral rhumbs on the globe become proportional spirals in the stereographic projection on the plane of the equator. The length of a part of this rhumb-line, or spiral, then, is the distance run by the ship while she keeps in the same course. But as such a spiral line would prove very perplexing in the calculation, it was necessary to have the ship's way in a right line; which right line however must have the essential properties of the curve, viz, to cut all the meridians at right angles. The method of effecting which, see under the article CHART.

The arc of the rhumb-line is not the shortest distance between any two places through which it passes; for the shortest distance, on the surface of the globe, is an arc of the great circle passing through those places; so that it would be a shorter course to sail on the arc of this great circle: but the ship cannot be kept in a great circle, because the angle it makes with the meridians is continually varying, more or less.



Let P be the pole, RW the equator, ABCDEP a spiral rhumb, divided into an indefinite number of equal parts at the points B, C, D, &c; through which are drawn the meridians, PS, PT, PV, &c; and the parallels FB, KC, LD, &c, also draw the parallel AN. Then, as a ship sails along the rhumb-line towards the pole, or in the direction ABCD &c, from A to E, the distance sailed AE is made up of all the small equal parts of the rhumb AB + BC + CD + DE; and the sum of all the small differences of latitude AF + BG + CH + DI make up the whole difference of latitude AM or EN; and the sum of all the small parallels FB + GC + HD + IE is what is called the departure in plane sailing; and ME is the meridional distance, or distance between the first and last meridians, measured on the last parallel; also RW is the difference of longitude, measured on the equator. So that these last three are all different, viz, the departure, the meridional distance, and the difference of longitude.

If the ship sail towards the equator, from E to A: the departure, difference of latitude, and difference of longitude, will be all three the same as before; but the meridional distance will then be AN, instead of ME; the one of which AN being greater than the departure FB + GC + HD + IE, and the other ME less than the same; and indeed that departure is nearly a mean proportional between the two meridional distances ME, AN. Other properties are as below.

1. All the small elementary triangles ABF, BCG, CDH, &c, are mutually similar and equal in all their parts. For all the angles at A, B, C, D, &c are equal, being the angles which the rhumb makes with the meridians, or the angles of the course; also all the angles F, G, H, I, are equal, being right angles; therefore the third angles are equal, and the triangles all similar. Also the hypothenuses AB, BC, CD, &c, are all equal by the hypothesis; and consequently the triangles are both similar and equal.

2. As radius : distance run AE

: : sine of course ∠ A : departure FB + GC &c,

: : cosin. of course ∠ A : dif. of lat. AM.

For in any one ABF of the equal elementary triangles, which may be considered as small right-angled plane triangles, it is, as rad. or sin. ∠ F : sin. course A : : AB : FB : : (by composition) the sum of all the distances AB + BC + CD &c : the sum of all the departures FB + GC + HD &c.

And, in like manner, as radius : cos. course A : : AB : AF : : AB + BC &c : AF + BG &c.

Hence, of these four things, the course, the difference of latitude, the departure, and the distance run, having any two given, the other two are found by the proportions above in this article.

By means of the departure, the length of the rhumb, or distance run, may be connected with the longitude and latitude, by the following two theorems.

3. As radius : half the sum of the cosines of both the latitudes, of A and E : : dif. of long. RW : departure.

Because RS : FB : : radius : sine of PA or cos. RA,

and VW : IE : : radius : sine of PE or cos. EW.

4. As radius : cos. middle latitude : : dif. of longitude : departure.—For the cosine of middle latitude is nearly equal to half the sum of the cosines of the two extreme latitudes.

RICCI (Michael-Angelo), a learned Italian divine, born at Rome in 1619. He was well skilled in the pure mathematical sciences; and he was created a cardinal in 1681; but did not long enjoy that dignity, as he died in 1683, at 64 years of age. He published at Rome, in 4to, Exercitatio Geometrica, a small tract, which was reprinted at London, and annexed to N. Mercator's Logarithmotechnia; having been thought fit to be so reprinted, partly by reason of its scarceness, but chiefly on account of the excellency of the argument, which is, de maximis et minimis, or the doctrine of limits; where the author shows a deep judgment in exhibiting the means of reducing that lately discovered doctrine to pure geometry. In this tract is demonstrated the doctrine of Caravagio de applicationibus, who affirms, that he who is ignorant of it may mispend his time about equations, in searching for that which cannot be found. He delivers also a method of drawing tangents to all the conic sections, and to several other curves.

RICCIOLI (Joannes-Baptista), a learned Italian astronomer, philosopher, and mathematician, was born in 1598, at Ferrara, a city in Italy, in the dominions of the Pope. At 16 years of age he was admitted into the society of the Jesuits. He was endowed with uncommon talents, which he cultivated with extraordinary application; so that the progress he made in every branch of literature and science was surprising. He was first appointed to teach rhetoric, poetry, philosophy, and scholastic divinity, in the Jesuits' colleges at Parma and Bologna; yet he applied himself in the mean time to making observations in geography, chronology, and astronomy. This was his natural bent, and at length he obtained leave from his superiors to quit all other employment, that he might devote himself entirely to those sciences.

He projected a large work, to be divided into three parts, and to contain as it were a complete system of philosophical, mathematical, and astronomical knowledge. The first of these parts, which regards astronomy, was published at Bologna in 1651, 2 vols. folio, with this title, J. B. Riccioli Almagestum Novum, Astronomiam veterem novamque complectens, observationibus aliorum et propriis, novisque theorematibus, problematibus, ac tabulis promotam. Riccioli imitated Ptolemy in this work, by collecting and digesting into proper order, with observations, every thing ancient and modern, which related to his subject; so that Gassendus very justly called his work, "Promptuarium et thesaurum ingentem Astronomiæ."

In the first volume of this work, he treats of the sphere of the world, of the sun and moon, with their eclipses; of the fixed stars, of the planets, of the comets and new stars, of the several mundane systems, and six sections of general problems serving to astronomy, &c.—In the second volume, he treats of trigonometry, or the doctrine of plane and spherical triangles; proposes to give a treatise of astronomical instruments, and the optical part of astronomy (which part was never published); it also treats of geography, hydrography, with an epitome of chronology. —The third, comprehends observations of the sun, moon, eclipses, fixed stars and planets, with precepts and tables of the primary and secondary motions, and other astronomical tables. Riccioli printed also, two other works, in folio, at Bologna, viz,

2. Astronomia Reformata, 1665: the design of which was, that of considering the various hypotheses of several astronomers, and the difficulty thence arising of concluding any thing certain, by comparing together all the best observations, and examining what is most certain in them, thence to reform the principles of astronomy.

3. Chronologia Reformata, 1669.

Riccioli died in 1671, at 73 years of age.

RICOCHET *Firing*, in the Military Art, is a method of firing with small charges, from pieces of ordnance elevated at small angles, as from 3 to 6 degrees. The word signifies duck-and-drake, or rebounding, because the ball or shot, thus discharged, goes bounding and rolling along, killing or destroying every thing in its way, like the bounding of a flat stone along the surface of water when thrown almost horizontally.

RIDEAU, in Fortification, a small elevation of earth, extending itself lengthways on a plain; serving to cover a camp, or give an advantage to a post.

Rideau is sometimes also used for a trench, the earth of which is thrown up on its side, to serve as a parapet for covering the men.

RIFLE Guns, in the Military Art, are those whose barrels, instead of being straight on the inside, are formed with spiral channels, making each about a turn and a half in the length of the barrel. These carry their balls farther and with more certainty than the common pieces. For the nature and qualities of them, see Robins's Tracts, vol. 1, pa. 328 &c.

RIGEL, in Astronomy. See REGEL.

RIGHT, in Geometry, something that lies evenly or equally, without inclining or bending one way or another. Thus, a right-line is that whose parts all tend the same way. In this sense, right means the same as straight, as opposed to curved or crooked.

RIGHT-*Angle*, is that which one line makes with another upon which it stands, so as to incline neither to one side nor the other. And in this sense the word right stands opposed to oblique.

RIGHT-*angled*, is said of a figure when its sides are at right angles or perpendicular to each other.—This sometimes holds in all the angles of the figure, as in squares and rectangles; sometimes only in part, as in right-angled triangles.

RIGHT-*angled Triangle in Numbers.* It was a favourite speculation with the ancient geometers, to express numerically, or in integer numbers, the sides of a right-angled triangle. The rules which they used for that purpose, are equally simple and ingenious. In symbols they are briefly expressed thus; viz, if n denote any odd number, above 1, then

according to Pythagoras, n, and $\frac{n^2-1}{2}$, and $\frac{n^2+1}{2}$, or

according to Plato, $2n$, and n^2-1, and n^2+1,

will represent the three sides of a right-angled triangle, the last term being the hypothenuse. In the second of these forms, which is only the double of the former, n may be any number, above 1, either odd or even; in the former n must be an odd number, to give integral results. In any case, the results are rational at least; and the proposition is manifest, viz, that the sum of the squares of the first two terms, is equal to the square of the third.

But a more general form of the same property is exhibited in the following terms, $2mn$, m^2-n^2, and m^2+n^2, where m and n may be any two numbers taken at pleasure, so as that m be greater than n. And by taking any particular numbers for m and n, an endless series of right-angled triangles, in rational, or even in whole numbers, will be the result.

Vieta employed another form of the like properties, in his curious work, Canon Mathematicus, seu ad Triangula, in which the three sides are either of the three following forms:

$\frac{mn}{\frac{1}{4}m^2+1}$, $\frac{\frac{1}{4}m^2-1}{\frac{1}{4}m^2+1}n$, n | n, $\frac{mn}{\frac{1}{4}m^2-1}$, $\frac{\frac{1}{4}m^2+1}{\frac{1}{4}m^2-1}n$, | n, $\frac{\frac{1}{4}m^2-1}{m}n$, $\frac{\frac{1}{4}m^2+1}{m}n$; where the 3d or last term, in each of the three sets, denotes the hypothenuse of a triangle, and the two leading terms, the base and perpendicular, as it is evident that, in them all, the square of the 3d term is equal to the sum of the squares of the 1st and 2d. And by these forms, Vieta computed the sides of 4300 right-angled triangles, in rational numbers, and arranged them in tables. See an account of them in the introduction to my Mathematical Tables, pa. 5 and 6; or in my Tracts, vol. 1, pa. 285.

If in the second set, $(2n, n^2-1, n^2+1)$, above mentioned, we express fractionwise the second term divided by the first, thus, $\frac{n^2-1}{2n}$, and expound the value of n successively by the numbers 2, 3, 4, 5, &c, we shall obtain a series of fractions, of which the numerators and denominators will be the two less sides of a series of right-angled triangles, in whole numbers.

Or, if for n we substitute $2m+1$, the aforesaid fraction $\frac{n^2-1}{2n}$ becomes $\frac{2m^2+2m}{2m+1} = m + \frac{m}{2m+1}$, in the form of a mixt number, in which the value of m may be any number whatever, the denominator $2m+1$ denoting the least side, the numerator $2m^2+2m$ the other side, and the same increased by 1, viz, $2m^2+2m+1$ the hypothenuse. So, if m be expounded successively by the numbers 1, 2, 3, 4, &c; the series of fractions will be $\frac{4}{3}$, $\frac{12}{5}$, $\frac{24}{7}$, $\frac{40}{9}$, &c, the denominators being the least sides, the numerators the greater, and these increased by 1, the hypothenuses, of the series of triangles. Or if we employ the form $m + \frac{m}{2m+1}$, the same numbers 1, 2, 3, &c, will give the mixed numbers $1\frac{1}{3}$, $2\frac{2}{5}$, $3\frac{3}{7}$, $4\frac{4}{9}$, $5\frac{5}{11}$, $6\frac{6}{13}$, &c, in which the law of continuation is manifest; the denominator of each being the least side, the integer multiplied by the denominator and the numerator added is the greater side, and 1 more is the hypothenuse.

Again, if instead of n, in the first fraction $\frac{n^2-1}{n}$, be substituted $2m+2$, that fraction then becomes $\frac{4m^2+8m+3}{4m+4} = m + \frac{4m+3}{4m+4}$. Then, taking for m successively the numbers 1, 2, 3, 4, &c, this other series of mixed numbers results, viz, $1\frac{7}{8}$, $2\frac{11}{12}$, $3\frac{15}{16}$, $4\frac{19}{20}$, $5\frac{23}{24}$, $6\frac{27}{28}$, &c, expressing another series of the triangles, in the same way as the former one.—And in like manner for any other series.

RIGHT *Cone, Cylinder, Prism,* or *Pyramid,* one whose axis is at right-angles to the base.

RIGHT-*lined Angle*, one formed by right lines.

RIGHT *Sine*, one that stands at right-angles to the diameter; as opposed to versed sine.

RIGHT *Sphere*, is that where the equator cuts the horizon at right-angles; or that which has the poles in the horizon, and the equinoctial in the zenith. Such is the position of the sphere with regard to those who live at the equator, or under the equinoctial. The consequences of which are; that they have no latitude, nor elevation of the pole; they see both poles of the world, and all the stars rise, culminate and set; also the sun always rises and descends at right-angles, and make their days and nights equal. In a right sphere, the horizon is a meridian; and if the sphere be supposed to revolve, all the meridians successively become horizons, one after another.

RIGHT *Ascension, Descension, Parallax,* &c. See the respective articles.

RIGHT *Circle*, in the Stereographic Projection of the Sphere, is a circle at right-angles to the plane of projection, or that which is projected into a right line.

RIGHT *Sailing*, is that in which a voyage is performed on some one of the four cardinal points, east, west, north, or south.—If the ship sail on a meridian, that is, north or south, she does not alter her longitude, but only changes the latitude, and that just as much as the number of degrees she has run.—But if she sail on the equator, directly east or west, she varies not her latitude, but only changes the longitude, and that just as much as the number of degrees she has run.—And if she sail directly east or west upon any parallel, she again does not change her latitude, but only the longitude; yet not the same as the number of degrees of a great circle she has sailed, as on the equator, but more, according as the parallel is remoter from the equinoctial towards the pole. For the less any parallel is, the greater is the difference of longitude answering to the distance run.

RIGIDITY, a brittle hardness; or that kind of hardness which is supposed to arise from the mutual indentation of the component particles within one another. Rigidity is opposed to ductility, malleability, &c.

RING, in Geometry, is a figure returning into itself, the axis being bent round into a circular form.—This is either plane or solid. In the former case, it is the space or figure contained between the circumferences of two concentric circles. In the latter, or solid ring, it resembles a cylinder, or other prism, bent round into a circular form. And, in either of them, the transverse section, perpendicular to the axis, is the same quantity; in the plane ring, it is the same line, or difference of the two radii; in the solid ring, it is the same plane figure.

For the measures of the surface and solidity of rings, multiply the axis by the transverse section perpendicular to it. See my Mensuration, pa. 110 and 194, edit. 4.

RING, in Astronomy and Navigation, an instrument used for taking the sun's altitude &c. It is usually of brass, about 9 inches diameter, suspended by a little swivel, at the distance of 45° from the point of which is a perforation, which is the centre of a quadrant of 90° divided in the inner concave surface.

To use it, let it be held up by the swivel, and turned round to the sun, till his rays, falling through the hole, make a spot among the degrees, which marks the altitude required. This instrument is preferred to the astrolabe, because the divisions are here larger than on that instrument.

RING, of Saturn, is a thin, broad, opaque circular arch, encompassing the body of that planet, like the wooden horizon of an artificial globe, without touching it, and appearing double, when seen through a good telescope.

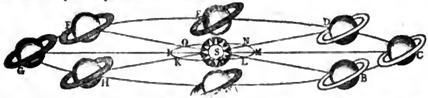
This ring was first discovered by Huygens, who, after frequent observation of the planet, perceived two lucid points, like ansæ or handles, arising out from the body in a right line. Hence, as in subsequent observations he always found the same appearance, he concluded that Saturn was encompassed with a permanent ring; and accordingly produced his New System of Saturn, in 1659. It was however, Galileo who first discovered that the figure of Saturn was not round.

Huygens estimates the space between the globe of Saturn and the ring as equal to the breadth of the ring, or rather more, being about 22000 miles broad; and the greatest diameter of the ring, in proportion to that of the globe, as 9 to 4. But Mr. Pound, by an excellent micrometer applied to the Huygenian glass of 123 feet, determined this proportion, more exactly, to be as 7 to 3.

Observations have also determined, that the plane of the ring is inclined to the plane of the ecliptic in an angle of 30 degrees; that the ring probably turns, in the direction of its plane, round its axis, because when it is almost edgewise to us, it appears rather thicker on one side of the planet than on the other; and the thickest edge has been seen on different sides at different times: the sun shines almost 15 of our years together on one side of Saturn's ring without setting, and as long on the other in its turn; so that the ring is visible to the inhabitants of that planet for almost 15 of our years, and as long invisible, by turns, if its axis has no inclination to its ring; but if the axis of the planet be inclined to the ring, ex. gr. about 30 degrees, the ring will appear and disappear once every natural day to all the inhabitants within 30 degrees of the equator, on both sides, frequently eclipsing the sun in a Saturnian day. Moreover, if Saturn's axis be so inclined to his ring, it is perpendicular to his orbit; by which the inconvenience of different seasons to that planet is avoided.

This ring, seen from Saturn, appears like a large luminous arch in the heavens, as if it did not belong to the planet.

When we see the ring most open, its shadow upon the planet is broadest; and from that time the shadow grows narrower, as the ring appears to do to us; until, by Saturn's annual motion, the sun comes to the plane of the ring, or even with its edge; which, being then directed towards us, becomes invisible, on account of its thinness.



The phenomena of Saturn's ring are illustrated by a view of this figure. Let S be the sun, ABCDEFGH Saturn's orbit, and IKLMNO the earth's orbit. Both Saturn and the earth move according to the order of the letters; and when Saturn is at A, his ring is turned edgewise to the sun S, and he is then seen from the earth as if he had lost his ring, let the earth be in any part of its orbit whatever, except between N and O; for while it describes that space, Saturn is apparently so near the sun as to be hid in his beams. As Saturn goes from A to C, his ring appears more and more open to the earth; at C the ring appears most open; but seems to become more and more narrower as Saturn goes from C to E; and when arrived at this point the ring is again turned edgewise both to the sun and earth; and as neither of its sides is illuminated, it is invisible to us, because its edge is too thin to be perceptible; and Saturn appears again as if he had lost his ring. But as he goes from E to G, his ring opens more and more to our view on the under side; and seems just as open at G as it was at C, and may be seen in the night-time from the earth in any part of its orbit, except about M, when the sun hides the planet from our view.

As Saturn goes from G to A, his ring turns more and more edgewise to us, and therefore, it seems to be narrower; till at A it quite disappears as before. Hence, while Saturn goes from A to E, the sun shines on the upper side of his ring, and the under side is dark; and while he goes from E to A, the sun shines on the under side of his ring, and the upper side is dark. The ring disappears twice in every annual revolution of Saturn, viz, when he is in the 19th degree of Pisces and of Virgo, and when Saturn is in the middle between these points, or in the 19th degree either of Gemini or of Sagittarius, his ring appears most open to us; and then its longest diameter is to its shortest, as 9 to 4. Ferguson's Astr. sect. 204.

There are various hypotheses concerning this ring. Kepler, in his Epitom. Astron. Copern., and after him Dr. Halley, in his Enquiry into the Causes of the Variation of the Needle, Phil. Trans. No. 195, supposes our earth may be composed of several crusts or shells, one within another, and concentric to each other. If this be the case, it is possible the ring of Saturn may be the fragment or remaining ruin of his formerly exterior shell, the rest of which is broken or fallen down upon the body of the planet. And some have supposed that the ring may be a congeries or series of moons revolving about the planet.

Later observations have thrown much more light on this curious phenomenon, especially respecting its dimensions, and rotation, and division into two or more parts. Lalande and Laplace say, that Cassini saw the breadth of the ring divided into two separate parts that are equal, or nearly so. Mr. Short assured M. Lalande, that he had seen many divisions on the ring, with his 12 feet telescope. And Mr. Hadley, with an excellent 5½ feet reflector, saw the ring divided into two parts. Several excellent theories have been given in the French Memoirs, particularly by Laplace, contending for the division of the ring into many parts. But finally, the observations of Dr. Herschel, in several volumes of the Philos. Trans., seem to confirm the division into two concentric parts only. The dimensions of these two rings, and the space between them, he states in the following proportions to each other.

Inner diam. of smaller ring	146345 miles.
Outside diam. of ditto	184393
Inner diam. of larger ring	190248
Outside diam. of ditto	204883
Breadth of the inner ring	20000
Breadth of the outer ring	7200
Breadth of the vacant space	2839

Ring revolves in its own plane, in $10^h\ 32'\ 15''\cdot4$.

So that the outside diameter of the larger ring is almost 26 times the diameter of the earth.

Dr. Herschel adds, "Some theories and observations, of other persons, lead us to consider the question, whether the construction of this ring is of a nature so as permanently to remain in its present state? or whether it be liable to continual and frequent changes, in such a manner as in the course of not many years, to be seen subdivided into narrow slips, and then again as united into one or two circular planes only. Now, without entering into a discussion, the mind seems to revolt, even at first sight, against an idea of the chaotic state in which so large a mass as the ring of Saturn must needs be, if phenomena like these can be admitted. Nor ought we to indulge a suspicion of this being a reality, unless repeated and well-confirmed observations had proved, beyond a doubt, that this ring was actually in so fluctuating a condition." But from his own observations he concludes, "It does not appear to me, that there is a sufficient gound for admitting the ring of Saturn to be of a very changeable nature; and I guess that its phenomena will hereafter be so fully explained, as to reconcile all observations. In the mean-while, we must withhold a final judgment of its construction, till we can have more observations. Its division however into two very unequal parts, can admit of no doubt." See Philos. Trans. vol. 80, pa. 4, 481 &c, and the vol. for 1792, pa. 1 &c, also Hist. de l'Acad. des Scienc. de Paris, 1787, pa. 249 &c.

Rings *of Colours*, in Optics, a phenomenon first observed in thin plates of various substances, by Boyle, and Hooke, but afterwards more fully explained by Newton.

Mr. Boyle having exhibited a variety of colours in colourless liquors, by shaking them till they rose in bubbles, as well as in bubbles of soap and water, and also in turpentine, procured glass blown so thin as to exhibit similar colours; and he observes, that a feather of a proper shape and size, and also a black ribband, held at a proper distance between his eye and the sun, showed a variety of little rainbows, as he calls them, with very vivid colours. Boyle's Works by Shaw, vol. 2, pa. 70. Dr. Hooke, about nine years after the publication of Mr. Boyle's Treatise on Colours, exhibited the coloured bubbles of soap and water, and observed, that though at first it appeared white and clear, yet as the film of water became thinner, there appeared upon it all the colours of the rainbow. He also described the beautiful colours that are seen in thin plates of Muscovy glass; which appeared, through the microscope, to be ranged in rings surrounding the white specks or flaws in them, and with the same order of colours as those of the rainbow, and which were often repeated ten times. He also took two thin pieces of glass, ground plane and polished, and putting them one upon another, pressed them till there began to appear a red coloured spot in the middle; and pressing them closer, he observed several rings of colours encompassing the first place, till, at last, all the colours disappeared out of the middle of the circles, and the central spot appeared white. The first colour that appeared was red, then yellow, then green, then blue, then purple; then again red, yellow, green, blue, and purple; and again in the same order; so that he sometimes counted nine or ten of these circles, the red immediately next to the purple; and the last colour that appeared before the white was blue; so that it began with red, and ended with purple. These rings, he says, would change their places, by changing the position of the eye, so that, the glasses remaining the same, that part which was red in one position of the eye, was blue in a second, green in the third, &c. Birch's Hist. of the Royal Society, vol. 3, pa. 54.

Newton, having demonstrated that every different colour consists of rays which have a different and specific degree of refrangibility, and that natural bodies appear of this or that colour, according to their disposition to reflect this or that species of rays (see Colour), pursued the hint suggested by the experiments of Dr. Hooke, already recited, and casually noticed by himself, with regard to thin transparent substances. On compressing two prisms hard together, in order to make their sides touch one another, he observed, that in the place of contact they were perfectly transparent, which appeared like a dark spot, and when it was looked through, it seemed like a hole in that air, which was formed into a thin plate, by being impressed between the glasses. When this plate of air, by turning the prisms about their common axis, became so little inclined to the incident rays, that some of them began to be transmitted, there arose in it many slender arcs of colours, which increased, as the motion of the prisms was continued, and bended more and more about the transparent spot, till they were completed into circles, or rings, surrounding it; and afterwards they became continually more and more contracted.

By another experiment, with two object-glasses, he was enabled to observe distinctly the order and quality of the colours from the central spot, to a very considerable distance. Next to the pellucid central spot, made by the contact of the glasses, succeeded blue, white, yellow, and red. The next circuit immediately surrounding these, consisted of violet, blue, green, yellow, and red. The third circle of colours was purple, blue, green, yellow, and red. The fourth circle consisted of green and red. All the succeeding colours became more and more imperfect, till, after three or four revolutions, they ended in perfect whiteness.

When these rings were examined in a darkened room, by the coloured light of a prism cast on a sheet of white paper, they became more distinct, and visible to a far greater number than in the open air. He sometimes saw more than twenty of them, whereas in the open air he could not discern above eight or nine.

From other curious observations on these rings, made by different kinds of light thrown upon them, he inferred, that the thicknesses of the air between the glasses, where the rings are successively made, by the limits of the seven colours, red, orange, yellow, green, blue, indigo, and violet, in order, are one to another as the cube roots of the squares of the eight lengths of a chord, which sound the notes in an octave, sol, la, fa, sol, la, mi, fa, sol; that is, as the cube roots of the squares of the numbers 1, $\frac{8}{9}$, $\frac{5}{6}$, $\frac{3}{4}$, $\frac{2}{3}$, $\frac{3}{5}$, $\frac{9}{16}$, $\frac{1}{2}$. These rings appeared of that prismatic colour, with which they were illuminated, and by projecting the prismatic colours immediately upon the glasses, he found that the light, which fell on the dark spaces between the coloured rings, was transmitted through the glasses without any change of colour. From this circumstance he thought that the origin of these rings is manifest; because the air between the glasses is disposed according to its various thickness, in some places to reflect, and in others to transmit the light of any particular colour, and in the same place to reflect that of one colour, where it transmits that of another.

In examining the phenomena of colours made by a denser medium surrounded by a rarer, such as those which appear in plates of Muscovy glass, bubbles of soap and water, &c, the colours were found to be much more vivid than the others, which were made with a rarer medium surrounded by a denser.

From the preceding phenomena it is an obvious deduction, that the transparent parts of bodies, according to their several series, reflect rays of one colour and transmit those of another; on the same account that thin plates, or bubbles, reflect or transmit those rays; and this Newton supposed to be the reason of all their colours. Hence also he has inferred, that the size of those component parts of natural bodies that affect the light, may be conjectured by their colours. See Colour, and Reflection.

Newton, pursuing his discoveries concerning the colours of thin substances, found that the same were also produced by plates of a considerable thickness, divisible into lesser thicknesses. The rings formed in both cases have the same origin, with this difference, that those of the thin plates are made by the alternate reflections and transmissions of the rays at the second surface of the plate, after one passage through it; but that, in the case of a glass speculum, concave on one side, and convex on the other, and quicksilvered over on the convex side, the rays go through the plate and return before they are alternately reflected and transmitted. Newton's Optics, pa. 169, &c. or Newtoni Opera, Horsley's edit. vol 4, pa. 121, &c. p. 184, &c.

The abbé Mazeas, in his experiments on the rings of colours that appear in thin plates, has discovered several important circumstances attending them, which were overlooked by the sagacious Newton, and which tend to invalidate his theory for explaining them. In rubbing the flat side of an object-glass against another piece of flat and smooth glass, he found that they adhered very firmly together after this friction, and that the same colours were exhibited between these plane glasses, which Newton had observed between the convex object-glass of a telescope, and another that was plane; and that the colours were in proportion to their adhesion. When the surfaces of pieces of glass, that are transparent and well polished, are equally pressed, a resistance will be perceived; and wherever this is felt, two or three very fine curve lines will be discovered, some of a pale red, and others of a faint green. If the friction be continued, the red and green lines increase in number at the place of contact; the colours being sometimes mixed without any order, and sometimes disposed in a regular manner; in which case the coloured lines are generally concentric circles, or ovals, more or less elongated, as the surfaces are more or less united.

When the colours are formed, the glasses adhere with considerable force; but if the glasses be separated suddenly, the colours will appear immediately upon their being put together, without the least friction. Beginning with the slightest touch, and increasing the pressure by insensible degrees, there first appears an oval plate of a faint red, and in the centre of it a spot of light green, which enlarges by the pressure, and becomes a green oval, with a red spot in the centre; and this enlarging in its turn, discovers a green spot in its centre. Thus the red and green succeed one another in turns, assuming different shades, and having other colours mixed with them. The greatest difference between these colours exhibited between plane surfaces, and those by curve ones, is, that, in the former, pressure alone will not produce them, except in the case above-mentioned.

In rubbing together two prisms, with very small refracting angles, which were joined so as to form a parallelopiped, the colours appeared with a surprizing lustre at the places of contact, and differently coloured ovals appeared. In the centre there was a black spot, bordered by a deep purple; next to this appeared violet, blue, orange, red tinged with purple, light green, and faint purple.

The other rings appeared to the naked eye to consist of nothing but faint reds and greens. When these coloured glasses were suspended over the flame of a candle, the colours disappeared suddenly, though they still adhered; but being suffered to cool, the colours returned to their former places, in the same order as before. At first the abbé Mazeas had no doubt but that these colours were owing to a thin plate of air between the glasses, to which Newton has ascribed them; but the remarkable difference in the circumstances attending those produced by the flat plates and those produced by the object-glasses of Newton, convinced him that the air was not the cause of this appearance. The colours of the flat plates vanished at the approach of flame, but those of the object-glasses did not. Nor was this difference owing to the plane glasses being less compressed than the convex ones; for though the former were compressed ever so much by a pair of forceps, it did not in the least hinder the effect of the flame. He then put both the plane glasses and the convex ones into the receiver of an air-pump, suspending the former by a thread, and keeping the latter compressed by two strings; but he observed no change in the colours of either of them, in the most perfect vacuum that he could make. Suspecting still that the air adhered to the surface of the glasses, so as not to be separated from them by the force of the pump, he had recourse to other experiments, which rendered it still more improbable that the air should be the cause of these colours. Having laid the coloured plates, after warming them gradually, on burning coals; and thus, when they were nearly red, rubbing them together, he observed the same coloured circles and ovals as before. When he ceased to press upon them, the colours seemed to vanish; but they returned, as he renewed the friction. In order to determine whether the colours were owing to the thickness of some matter interposed between the glasses, he rubbed them together with suet and other soft substances between them; yet his endeavour to produce the colours had no effect. However by continuing the friction with some degree of violence, he observed, that a candle appeared through them encompassed with two or three concentric greens, and with a lively red inclining to yellow, and a green like that of an emerald, and at length the rings assumed the colours of blue, yellow, and violet. The abbé was thus confirmed in his opinion that there must be some error in Newton's hypothesis, by considering that, according to his measures, the colours of the plates varied with the difference of a millionth part of an inch; whereas he was satisfied that there must have been much greater differences in the distance between his glasses, when the colours remained unchanged. From other experiments he concluded, that the plate of water introduced between the glasses was not the cause of their colours, as Newton apprehended; and that the coloured rings could not be owing to the compression of the glasses. After all, he adds, that the theory of light, thus reflected from thin plates, is too delicate a subject to be completely ascertained by a small number of observations. Berlin Mem. for 1752, or Memoires Presentes, vol. 2, pa. 28—43. M. du Tour repeated the experiments of the abbé Mazeas, and added some observations of his own. See Mem. Pres. vol. 4, pa. 288.

Musschenbroeck is also of opinion, that the colours of thin plates do not depend upon the air; but as to the cause of them, he acknowledges that he could not satisfy himself about it. Introd. ad Phil. Nat. vol. 2, pa. 738. See on this subject Priestley's Hist. of Light, &c, per. 6, sect. 5, pa. 498, &c.

For an account of the rings of colours produced by electrical explosions, see Colours *of Natural Bodies*, Circular *Spots*, and Fairy *Circles*.

RISING, in Astronomy, the appearence of the sun, or a star, or other luminary, above the horizon, which before was hid beneath it. By reason of the refraction of the atmosphere, the heavenly bodies always appear to rise before their time; that is, they are seen above the horizon, while they are really below it, by about 33′ of a degree.

There are three poetical kinds of rising of the stars. See Acronical, Cosmical, and Heliacal.

RITTENHOUSE (Dr. David), President of the American Philosophical Society, died July 10, 1796, in the 64th year of his age. He was a native of Pennsylvania; and, in the early part of life, mixed the pursuits of science with the active employments of farming and watch-making. In 1769, he was invited by the American Philosophical Society, in association with other gentlemen, for making astronomical observations, particularly of the transit of Venus, that year; when he greatly distinguished himself by the accuracy of his observations and calculations. He afterwards constructed an observatory, which he superintended in person, and which became the source of many important discoveries, as well as greatly tended to the general diffusion of science in the western world. During the American war he was an active asserter of the cause of independence. After the conclusion of the peace, he successively filled the offices of treasurer of the state of Pennsylvania, and director of the national mint. He succeeded the illustrious Franklin in the office of President of the Philosophical Society; a situation which the bent of his mind, and the course of his studies. had rendered him eminently adequate to fill. Towards the close of his life he had retired from active occupations. He was the author of several excellent papers, chiefly on astronomical subjects, inserted in the Transactions of the American Philosophical Society.

RIVER, in Geography, a stream or current of fresh water, flowing in a bed or channel, from a source or spring, into the sea.—When the stream is not large enough to bear boats, or small loaden vessels, it is properly called by the diminutive, Rivulet or Brook; but when it is considerable enough to carry larger vessels, it is called by the general name River.—Rivulets have their rise sometimes from great rains, or great quantities of thawed snow, especially in mountainous places; but they more usually arise from springs.—Rivers themselves all arise either from the confluence of several rivulets, or from lakes.

River, in Physics, denotes a stream of water running by its own gravity, from the more elevated parts of the earth towards the lower parts, in a natural bed or channel open above.—When the channel is artificial, or cut by art, it is called a canal; of which there are two kinds, viz, that whose channel is every where open, without sluices, called an artificial river, and that whose water is kept up and let off by means of sluices, which is properly a canal.

Modern philosophers endeavour to reduce the motion and flux of rivers to precise laws; and with this view they have applied geometry and mechanics to this subject; so that the doctrine of rivers is become a part of the new philosophy. The authors who have most distinguished themselves in this branch, are the Italians, the French, and the Dutch, but especially the first, and among them more particularly Gulielmini, and Ximenes.

Rivers, says Gulielmini, usually have their sources in mountains or elevated grounds; in the descent from which it is, that they mostly acquire the velocity, or acceleration, which maintains their future current. In proportion as they advance farther, this velocity diminishes, on account of the continual friction of the water against the bottom and sides of the channel; as also from the various obstacles they meet with in their progress, and from their arriving at length in plains where the descent is less. Thus the Reno, a river in Italy, which he says gave occasion, in some measure, to his speculations, is found to have near its mouth a declivity of scarce 52 seconds, being only 1 foot in 4000.

When the acquired velocity is quite spent, by means of the many obstacles that the water meets with, so that the current becomes horizontal, there will then remain nothing to propagate the motion, and continue the stream, but the depth, or the perpendicular pressure of the water, which is always proportional to the depth. And, happily for us, this resource increases, as the occasion for it increases; for in proportion as the water loses of the velocity acquired by the descent, it rises and increases in its depth.—It appears from the laws of motion pertaining to bodies moving on inclined planes, that when water flows freely upon an inclined bed, it acquires a velocity, which is always as the square root of the quantity of descent of the bed. But in an horizontal bed, opened by sluices or otherwise, at one or both ends, the water flows out by its gravity alone.

The upper parts of the water of a river, and those at a distance from the banks, may continue to flow, from the simple cause or principle of declivity, how small soever it be; for not being detained by any obstacle, the minutest difference of level will have its effect; but the lower parts, which roll along the bottom, will scarcely be sensible of so small a declivity; and will only have what motion they receive from the pressure of the superincumbent waters.—The greatest velocity of a river is about the middle of its depth and breadth, or that point which is the farthest possible from the surface of the water, and from the bottom and sides of the bed or channel. Whereas, on the contrary, the least velocity of the water is at the bottom and sides of the bed, because there the resistance arising from friction is the greatest, which is communicated to the other parts of the section of the river inversely as the distances from the bottom and sides.—To find whether the water of a river, almost horizontal, flows by means of the velocity acquired in its descent, or by the pressure of its depth; set up an obstacle perpendicular to it; then if the water rise and swell immediately against the obstacle, it runs by virtue of its fall; but if it first stop a little while, in virtue of its pressure.

Rivers, according to this author, almost always make their own beds. If the bottom have originally been a large declivity, the water, hence falling with a great force, will have swept away the most elevated parts of the soil, and carrying them lower down, will gradually render the bottom more nearly horizontal.—The water having made its bed horizontal, becomes so itself, and consequently rakes with the less force against the bottom, till at length that force becomes only equal to the resistance of the bottom, which is now arrived at a state of permanency, at least for a considerable time; and the longer according to the quality of the soil, clay and chalk resisting longer than sand or mud.

On the other hand, the water is continually wearing away the brims of its channel, and this with the more force, as, by the direction of its stream, it impinges more directly against them. By this means it has a continual tendency to render them parallel to its own course. At the same time that it has thus rectified its edges, it has widened its own bed, and thence becoming less deep, it loses part of its force and pressure: this it continues to do till there is an equilibrium between the force of the water and the resistance of its banks, and then they will remain without farther change. And it appears by experience that these equilibriums are all real, as we find that rivers only deepen and widen to a certain pitch.

The very reverse of all these things does also on some occasions happen. Rivers, whose waters are thick and muddy, raise their bed, by depositing part of the heterogeneous matters contained in them: they also contract their banks, by a continual opposition of the same matter, in brushing over them. This matter, being thrown aside far from the stream of water, might even serve, by reason of the dullness of the motion, to form new banks. If these various causes of resistance to the motion of flowing waters did not exist, viz, the attraction and continual friction of the bottom and sides, the inequalities in both, the windings and angles that occur in their course, and the diminution of their declivity the farther they recede from their springs, the velocity of their currents would be accelerated to 10, 15, or even 20 times more than it is at present in the same rivers, by which they would become absolutely unnavigable.

The union of two rivers into one, makes the whole flow the swifter, because, instead of the friction of four shores, they have only two to overcome, and one bottom instead of two; also the stream, being farther distant from the banks, goes on with the less interruption, besides, that a greater quantity of water, moving with a greater velocity, digs deeper in the bed, and of course retrenches its former width. Hence also it is, that rivers, by being united, take up less space on the surface of the earth, and are more advantageous to low grounds, which drain their superfluous moisture into them, and have also less occasion for dykes to prevent their overflowing.

A very good and simple method of measuring the velocity of the current of a river, or canal, is the following. Take a cylindrical piece of dry, light wood, and of a length something less than the depth of the water in the river; about one end of it let there be suspended as many small weights, as may keep the cylinder in a vertical or upright position, with its head just above water. To the centre of this end fix a small straight rod, precisely in the direction of the cylinder's axis; in order that, when the instrument is suspended in the water, the deviations of the rod from a perpendicularity to the surface of it, may indicate which end of the cylinder goes foremost, and by which may be discovered the different velocities of the water at different depths; for when the rod inclines forward, according to the direction of the current, it is a proof that the surface of the water has the greatest velocity; but when it reclines backward, it shows that the swiftest current is at the bottom; and when it remains perpendicular, it is a sign that the velocities at the top and bottom are equal.

This instrument, being placed in the current of a river or canal, receives all the percussions of the water throughout the whole depth, and will have an equal velocity with that of the whole current from the surface to the bottom at the place where it is put in, and by that means may be found, both with exactness and ease, the mean velocity of that part of the river for any determinate distance and time.

But to obtain the mean velocity of the whole section of the river, the instrument must be put successively both in the middle and towards the sides, because the velocities at those places are often very different from each other. Having by this means found the several velocities, from the spaces run over in certain times, the arithmetical mean proportional of all these trials, which is found by dividing the common sum of them all by the number of the trials, will be the mean velocity of the river or canal. And if this medium velocity be multiplied by the area of the transverse section of the waters at any place, the product will be the quantity running through that place in a second of time.

If it be required to find the velocity of the current only at the surface, or at the middle, or at the bottom, a sphere of wood loaded, or a common bottle corked with a little water in it, of such a weight as will remain suspended in equilibrium with the water at the surface or depth which we want to measure, will be better for the purpose than the cylinder, because it is only affected by the water of that sole part of the current where it remains suspended.

It follows from what has been said in the former part of this article, that the deeper the waters are in their bed in proportion to its breadth, the more their motion is accelerated; so that their velocity increases in the inverse ratio of the breadth of the bed, and also of the magnitude of the section; whence, in order to augment the velocity of water in a river or canal, without increasing the declivity of the bed, we must increase the depth of the channel, and diminish its breadth. And these principles are agreeable to observation; as it is well known, that the velocity of flowing waters depends much more on the quantity and depth of the water, and on the compression of the upper parts on the lower, than on the declivity of the bed; and therefore the declivity of a river must be made much greater in the beginning than toward the end of its course; where it should be almost insensible. If the depth or volume of water in a river or canal be considerable, it will suffice, in the part next the mouth, to allow one foot of declivity through 6000, or 8000, or even (according to Dechales, De Fontibus et Fluviis, prop. 49) 10,000 feet in horizontal extent; at most it need not be above 1 in 6 or 7 thousand. From hence the quantity of declivity in equal spaces must slowly and gradually increase as far as the current is to be made fit for navigation; but in such a manner, that at this upper end there may not be above one foot of perpendicular declivity in 4000 feet of horizontal extent.

To conclude this article, M. de Buffon observes, that people accustomed to rivers can easily foretell when there is going to be a sudden increase of water in the bed from floods, produced by sudden falls of rain in the higher countries through which the rivers pass. This they perceive by a particular motion in the water, which they express by saying, that the river's bottom moves, that is, the water at the bottom of the channel runs off faster than usual; and this increase of motion at the bottom of a river always announces a sudden increase of water coming down the stream. Nor, says he, is their opinion ill grounded; because the motion and weight of the waters coming down, though not yet arrived, must act upon the waters in the lower parts of the river, and communicate by impulsion part of their motion to them, within a certain distance.

On the subject of this article, see an elaborate treatise on rivers and canals, in the Philos. Trans. vol. 69, pa. 555 &c, by Mr. Mann, who has availed himself of the observations of Gulielmini, and most other writers.

ROBERTSON (John), F. R. S. was born in the year 1712; and though he was at first placed out in a trade, yet he must soon have quitted it, as in the title of his first book, a Complete Treatise on Mensuration, in 1739, he is styled Teacher of the mathematics. In this line, as a private teacher, he continued several years, till in 1754 he was appointed Master of the Royal Mathematical School in Christ's Hospital; in which year also he published the first edition of his Elements of Navigation. The year following, however, he left Christ's Hospital, in consequence of an Admiralty appointment to be first master of the Royal Naval Academy at Portsmouth; soon after which he published his Treatise on Mathematical Instruments. In 1766, through the petty cabals of the second master, they were both dismissed from that service by the first lord of the Admiralty; on which Mr. R. returned to London, where he was soon appointed clerk and librarian to the Royal Society; an office which he respectably held to the time of his death, in December 1776, at 64 years of age.

Besides the three works above-mentioned, which were all excellent of their kind, particularly the Navigation, he had many ingenious papers inserted in the Philos. Trans. from the 46th to the 60th volume. Mr. R. was a person of very honourable character and conduct, being greatly respected by the more learned and best characters among the members of the Royal Society; on most occasions his advice in the council was much regarded; and he had the honour to be one of the committee chosen to inspect and report on the government's powder-magazine at Purfleet, concerning its damage and security from lightning. In his mode of teaching, and arranging the matter in his publications, Mr. R. was remarkably neat and methodical; a habit which he probably in some measure acquired in imitation of his good friend and master, William Jones, Esq. many of whose papers, on his decease, came into the possession of Mr. R. which were sold by auction, along with the valuable library of the latter, after his death, on which occasion many of them were purchased by myself.

ROBERVAL (Giles-Personne), an eminent French mathematician, was born in 1602, at Roberval, a parish in the diocese of Beauvais. He was first professor of mathematics at the College of Maitre-Gervais, and afterwards at the College-royal. A similarity of taste connected him with Gassendi and Morin; the latter of whom he succeeded in the mathematical chair at the Royal College, without quitting however that of Ramus.

Roberval made experiments on the Torricellian vacuum: he invented two new kinds of balance, one of which was proper for weighing air; and made many other curious experiments. He was one of the first members of the ancient Academy of Sciences of 1666; but died in 1675, at 73 years of age. His principal works are,

I. A Treatise on Mechanics.

II. A work entitled Aristarchus Samos.

He had several memoirs inserted in the volumes of the Academy of Sciences of 1666, viz, 1. Experiments concerning the Pressure of the Air. 2. Observations on the Composition of Motion, and on the Tangents of Curve Lines. 3. The Recognition of Equations. 4. The Geometrical Resolution of Plane and Cubic Equations. 5. Treatise on Indivisibles. 6. On the Trochoid, or Cycloid. 7. A Letter to Father Mersenne. 8. Two Letters from Torricelli. 9. A new kind of Balance.

ROBERVALLIAN *Lines*, a name given to certain lines, used for the transformation of figures: thus called from their inventor Roberval. These lines bound spaces that are infinitely extended in length, which are nevertheless equal to other spaces that are terminated on all sides.

The abbot Gallois, in the Memoirs of the Royal Academy, anno 1693, observes, that the method of transforming figures, explained at the latter end of Roberval's treatise of Indivisibles, was the same with that afterwards published by James Gregory, in his Geometria Universalis, and also by Barrow in his Lectiones Geometricæ; and that, by a letter of Torricelli, it appears, that Roberval was the inventor of this method of transforming figures, by means of certain lines, which Torricelli therefore called Robervallian Lines. He adds, that it is highly probable, that J. Gregory first learned the method in the journey he made to Padua in 1668, the method itself having been known in Italy from the year 1646, though the book was not published till the year 1692.

This account David Gregory has endeavoured to refute, in vindication of his uncle James. His answer is inserted in the Philos. Trans. of 1694, and the abbot rejoined in the French Memoirs of the Academy of 1703.

ROBINS (Benjamin), an English mathematician and philosopher of great genius and eminence, was born at Bath in Somersetshire, 1707. His parents were Quakers of low condition; and consequently neither able from their circumstances, nor willing from their religious profession, to have him much instructed in that kind of learning which they are taught to despise as human. Nevertheless, he made an early and surprising progress in various branches of science and literature, particularly in the mathematics; and his friends being desirous that he might continue his pursuits, and that his merit might not be buried in obscurity, wished that he could be properly recommended to teach that science in London. Accordingly, a specimen of his abilities in this way was sent up thither, and shown to Dr. Pemberton, the author of the "View of Sir Isaac Newton's Philosophy;" who, thence conceiving a good opinion of the writer, for a farther trial of his skill sent him some problems, which Robins resolved very much to his satisfaction. He then came to London, where he confirmed the opinion which had been preconceived of his abilities and knowledge.

But though Robins was possessed of much more skill than is usually required in a common teacher; yet being very young, it was thought proper that he should employ some time in perusing the best writers upon the sublimer parts of the mathematics, before he should publicly undertake the instruction of others. In this interval, besides improving himself in the modern languages, he had opportunities of reading in particular the works of Archimedes, Apollonius, Fermat, Huygens, De Witt, Slusius, Gregory, Barrow, Newton, Taylor, and Cotes. These authors be readily understood without any assistance, of which he gave frequent proofs to his friends: one was, a demonstration of the last proposition of Newton's treatise on Quadratures, which was thought not undeserving a place in the Philosophical Transactions for 1727.

Not long after, an opportunity occurred of exhibiting to the public a specimen also of his knowledge in Natural Philosophy. The Royal Academy of Sciences at Paris had proposed, among their prize questions in 1724 and 1726, to demonstrate the laws of motion in bodies impinging on one another. John Bernoulli here condescended to be a candidate; and as his dissertation lost the reward, he appealed to the learned world by printing it in 1727. In this piece he endeavoured to establish Leibnitz's opinion of the force of bodies in motion from the effects of their striking against springy materials; as Poleni had before attempted to evince the same thing from experiments of bodies falling on soft and yielding substances. But as the insufficiency of Poleni's arguments had been demonstrated in the Philosophical Transactions, for 1722; so Robins published in the Present State of the Republic of Letters, for May 1728, a Confutation of Bernoulli's performance, which was allowed to be unanswerable.

Robins now began to take scholars; and about this time he quitted the garb and profession of a Quaker; for, having neither enthusiasm nor superstition in his nature, as became a mathematician, he soon shook off the prejudices of such early habits. But though he professed to teach the mathematics only, he would frequently assist particular friends in other matters; for he was a man of universal knowledge: and the confinement of this way of life not suiting his disposition, which was active, he gradually declined it, and went into other courses, that required more exercise. Hence he tried many laborious experiments in gunnery; believing that the resistance of the air had a much greater effect on swift projectiles, than was generally supposed. And hence he was led to consider those mechanic arts that depend upon mathematical principles, in which he might employ his invention: as, the constructing of mills, the building of bridges, draining of fens, rendering of rivers navigable, and making of harbours. Among other arts of this kind, fortification very much engaged his attention; in which he met with opportunities of perfecting himself, by a view of the principal strong places of Flanders, in some journeys he made abroad with persons of distinction.

On his return home from one of these excursions, he found the learned here amused with Dr. Berkeley's treatise, printed in 1734, entitled, "The Analyst;" in which an examination was made into the grounds of the doctrine of Fluxions, and occasion thence taken to explode that method. Robins was therefore advised to clear up this affair, by giving a full and distinct account of Newton's doctrines, in such a manner, as to obviate all the objections, without naming them, which had been advanced by Berkeley; and accordingly he published, in 1735, A Discourse concerning the Nature and Certainty of Sir Isaac Newton's Method of Fluxions, and of Prime and Ultimate Ratios. This is a very clear, neat, and elegant performance: and yet some persons, even among those who had written against The Analyst, taking exception at Robins's manner of defending Newton's doctrine, he afterwards wrote two or three additional discourses.

In 1738, he defended Newton against an objection, contained in a note at the end of a Latin piece, called "Matho, sive Cosmotheoria puerilis," written by Baxter, author of the "Inquiry into the Nature of the Human Soul:" and the year after he printed Remarks on Euler's Treatise of Motion, on Smith's System of Optics, and on Jurin's Discourse of Distinct and Indistinct Vision, annexed to Dr. Smith's work.

In the mean time Robins's performances were not confined to mathematical subjects: for, in 1739, he published three pamphlets on political affairs, which did him great honour. The first was entitled, Observations on the present Convention with Spain: the second, A Narrative of what passed in the Common Hall of the Citizens of London, assembled for the Election of a Lord Mayor: the third, An Address to the Electors and other free Subjects of Great Britain, occasioned by the late Succession; in which is contained a Particular Account of all our Negociations with Spain, and their Treatment of us for above ten years past. These were all published without our author's name; and the first and last were so universally esteemed, that they were generally reputed to have been the production of the great man himself, who was at the head of the opposition to Sir Robert Walpole. They proved of such consequence to Mr. Robins, as to occasion his being employed in a very honourable post; for, the patriots at length gaining ground against Sir Robert, and a committee of the House of Commons being appointed to examine into his past conduct, Robins was chosen their secretary. But after the committee had presented two reports of their proceedings, a sudden stop was put to their farther progress, by a compromise between the contending parties.

In 1742, being again at leisure, he published a small treatise, entitled, New Principles of Gunnery; containing the result of many experiments that he had made, by which are discovered the force of gunpowder, and the difference in the resisting power of the air to swift and slow motions. To this treatise was prefixed a full and learned account of the progress which modern fortification had made from its first rise; as also of the invention of gunpowder, and of what had already been performed in the theory of gunnery. It seems that the occasion of this publication, was the disappointment of a situation at the Royal Military Academy at Woolwich. On the new modelling and establishing of that Academy, in 1741, our author and the late Mr. Muller were competitors for the place of professor of fortification and gunnery. Mr. Muller held then some post in the Tower of London, under the Board of Ordnance, so that, notwithstanding the great knowledge and abilities of our author, the interest which Mr. Muller had with the Board of Ordnance carried the election in his favour. On this disappointment Mr. Robins, indignant at the affront, determined to show them, and the world, by his military publications, what sort of a man he was that they had rejected.

On a discourse containing certain experiments being published in the Philosophical Transactions, with a view to invalidate some of Robins's opinions, he thought proper, in an account he gave of his book in the same Transactions, to take notice of those experiments: and in consequence of this, several dissertations of his on the resistance of the air were read, and the experiments exhibited before the Royal Society, in 1746 and 1747; for which he was presented with the annual gold medal by that Society.

In 1748 came out Anson's Voyage round the World; which, though it bears Walter's name in the title-page, was in reality written by Robins. Of this voyage the public had for some time been in expectation of seeing an account, composed under that commander's own inspection: for which purpose the reverend Richard Walter was employed, as having been chaplain on board the Centurion the greatest part of the expedition. Walter had accordingly almost finished his task, having brought it down to his own departure from Macao for England; when he proposed to print his work by subscription. It was thought proper that an able judge should first review and correct it, and Robins was appointed; when, on examination, it was resolved, that the whole should be written entirely by Robins, and that what Walter had done, being mostly taken verbatim from the journals, should serve as materials only. Hence it was that the whole of the introduction, and many dissertations in the body of the work, were composed by Robins, without receiving the least hint from Walter's manuscript; and what he had transcribed from it regarded chiefly the wind and weather, the currents, courses, bearings, distances, offings, soundings, moorings, the qualities of the ground they anchored on, and such particulars as usually fill up a seaman's account. No production of this kind ever met with a more favourable reception, four large impressions having been sold off within a year: it was also translated into most of the European languages; and it still supports its reputation, having been repeatedly reprinted in various sizes. The fifth edition at London in 1749 was revised and corrected by Robins himself; and the 9th edition was printed there in 1761.

Thus becoming famous for his elegant talents in writing, he was requested to compose an apology for the unfortunate affair at Prestonpans in Scotland. This was added as a preface to the Report of the Proceedings and Opinion of the Board of General Officers on their Examination into the Conduct of Lieutenant-General Sir John Cope, &c, printed at London in 1749; which preface was esteemed a master-piece of its kind.

Robins had afterwards, by the favour of lord Anson, opportunities of making farther experiments in Gunnery; which have been published since his death, in the edition of his works by his friend Dr. Wilson. He also not a little contributed to the improvements made in the Royal Observatory at Greenwich, by procuring for it, through the interest of the same noble person, a second mural quadrant, and other instruments; by which it became perhaps the most complete of any observatory in the world.

His reputation being now arrived at its meridian, he was offered the choice of two very considerable employments. The first was to go to Paris, as one of the commissaries for adjusting the limits in Acadia; the other, to be engineer general to the East India Company, whose forts, being in a most ruinous condition, wanted an able person to put them into a proper state of defence. He accepted the latter, as it was suitable to his genius, and as the Company's terms were both advantageous and honourable. He designed, if he had remained in England, to have written a second part of the Voyage round the World; as appears by a letter from lord Anson to him, dated Bath, Oct. 22, 1749, as follows.

"Dear sir—When I last saw you in town, I forgot to ask you, whether you intended to publish the second volume of my Voyage before you leave us; which I confess I am very sorry for. If you should have laid aside all thoughts of favouring the world with more of your works, it will be much disappointed, and no one in it more than your very obliged humble servant,

"Anson."

Robins said, a little before his death, that the only thing he had to regret during his life, was writing lord Anson's voyage. Hence it has been supposed the *expectation* induced him to *heighten* the narrative; but it seems that his principal reward consisted in *promises*.

Robins was also preparing an enlarged edition of his New Principles of Gunnery: but, having provided himself with a complete set of astronomical and other instruments, for making observations and experiments in the Indies, he departed hence at Christmas in 1749; and after a voyage, in which the ship was near being cast away, he arrived there in July following. He immediately set about his proper business with the greatest diligence, and formed complete plans for Fort St. David and Madras: but he did not live to put them into execution. For the great difference of the climate from that of England being beyond his constitution to support, he was attacked by a fever in September the same year; and though he recovered out of this, yet about eight months after he fell into a languishing condition, in which he continued till his death, which happened the 29th of July 1751, at only 44 years of age.

By his last will, Mr. Robins left the publishing of his Mathematical Works to his honoured and intimate friend Martin Folkes, esq. president of the Royal Society, and to Dr. James Wilson; but the former of these gentlemen being incapacitated by a paralytic disorder, for some time before his death, they were afterwards published by the latter, in 2 volumes 8vo, 1761. To this collection, which contains his mathematical and philosophical pieces only, Dr. Wilson has prefixed an account of Mr. Robins, from which this memoir is chiefly extracted. He added also a large appendix at the end of the second volume, containing a great many curious and critical matters in various interesting parts of the mathematics. As to Mr. Robins's own papers in these two volumes, they are as follow: viz, in vol. I,

1. New Principles of Gunnery. First printed in 1742.
2. An account of that book. Read before the Royal Society, April the 14th and 21st, 1743.
3. Of the Resistance of the Air. Read the 12th of June, 1746.
4. Of the Resistance of the Air; together with the Method of computing the Motions of Bodies projected in that Medium. Read June 19, 1746.
5. Account of Experiments relating to the Resistance of the Air. Read the 4th of June, 1747.
6. Of the Force of Gunpowder, with the Computation of the Velocities thereby communicated to military Projectiles. Read the 25th of June, 1747.
7. A Comparison of the Experimental Ranges of Cannon and Mortars, with the Theory contained in the preceding papers. Read the 27th of June, 1751.
8. Practical Maxims relating to the Effects and Management of Artillery, and the Flight of Shells and Shot.
9. A Proposal for increasing the Strength of the British Navy. Read the 2d of April, 1747.
10. A Letter to Martin Folkes, esq. President of the Royal Society. Read the 7th of January, 1748.
11. A Letter to Lord Anson. Read the 26th of October, 1749.
12. On Pointing, or Directing of Cannon to strike distant Objects.
13. Observations on the Height to which Rockets ascend. Read the 4th of May 1749.
14. An Account of some Experiments on Rockets, by Mr. Ellicott.
15. Of the Nature and Advantage of Rifled Barrel Pieces, by Mr. Robins. Read the 2d of July, 1747.

In volume II are,

16. A Discourse concerning the Nature and Certainty of Sir Isaac Newton's Methods of Fluxions, and of Prime and Ultimate Ratios.
17. An Account of the preceding Discourse.
18. A Review of some of the principal Objections, that have been made to the Doctrine of Fluxions and Ultimate Proportions, with some Remarks on the different Methods, that have been taken to obviate them.
19. A Dissertation, showing that the Account of the Doctrines of Fluxions and of Prime and Ultimate Ratios, delivered in Mr. Robins's Discourse, is agreeable to the real Meaning of their great Inventor.
20. A Demonstration of the Eleventh Proposition of Sir Isaac Newton's Treatise of Quadratures.
21. Remarks on Bernoulli's Discourse upon the Laws of the Communication of Motion.
22. An Examination of a Note concerning the Sun's Parallax, published at the end of Baxter's Matho.
23. Remarks on Euler's Treatise of Motion; Dr. Smith's System of Optics; and Dr. Jurin's Essay on Distinct and Indistinct Vision.
24. Appendix by the Publisher.

It is but justice to say, that Mr. Robins was one of the most accurate and elegant mathematical writers that our language can boast of; and that he made more real improvements in Artillery, the flight and the resistance of projectiles, than all the preceding writers on that subject. His New Principles of Gunnery were translated into several other languages, and commented on by several eminent writers. The celebrated Euler translated the work into the German, accompanied with a large and critical commentary; and this work of Euler's was again translated into English in 1774, by Mr. Hugh Brown, with Notes, in one volume 4to.

ROBINS, or ROBYNS (JOHN), an English mathematician, was born in Staffordshire about the close of the 15th century, as he was entered a student at Oxford in 1516, where he was educated for the church. But the bent of his genius lay to the sciences, and he soon made such a progress, says Wood, in "the pleasant studies of mathematics and astrology, that he became the ablest person in his time for those studies, his friend Record not excepted, whose learning was of a nature more general. At length, taking the degree of bachelor of divinity in 1531, he was the year following made by King Henry the 8th (to whom he was chaplain), one of the canons of his college in Oxon, and in December 1543 canon of Windsor, and finally chaplain to Queen Mary, who held him in great veneration for his learning. Among several things that he wrote relating to astrology (or astronomy) I find these following:

"De Culminatione Fixarum Stellarum, &c.
De Ortu & Occasu Stellarum Fixarum, &c.
Annotationes Astrologicæ, &c. lib. 3.
Annotationes Edwardo VI.
Tractatus de Prognosticatione per Eclipsin.

"All which books, that are in MS, were some time in the choice library of Mr. Thomas Allen, of Glocester Hall. After his death, coming into the hands of Sir Kenelm Digby, they were by him given to the Bodleian library, where they yet remain. It is also said, that he, the said Robyns, hath written a book intitled, De Portentosis Cometis, but such a thing I have not yet seen, nor do I know any thing else of the author, only that, paying his last debt to nature the 25th of August 1558, he was buried in the chappel of St. George at Windsore."

ROBISON (JOHN), LL.D. an eminent philosopher, was born in Scotland, about 1733. After receiving a liberal education in his native country, he went to Russia, on the appointment of director of the marine cadet academy, at Cronstadt, a situation which he held for several years. On his return to Scotland he was appointed professor of chemistry in the university of Glasgow; and shortly afterwards he was invited to fill the chair of natural philosophy professor at Edinburgh; an office which he held with much honour to himself, and benefit to the students of that university, till his death, which happened early in the year 1805.

Though Dr. Robison laboured under a most painful and distressing complaint during the last 18 years of his life, still his mind was always active, and generally directed to the most useful purposes. He was well known as the author of most of the mathematical and philosophical articles in the third edition of the Encyclopedia Britannica, and the Supplement to that valuable work. Those articles are of established character; and, though several of them are written in a very desultory manner, yet they are rich in important remarks and useful information. They appear to have been the substance of his lectures delivered in the college; and some of them were afterwards thrown into an improved form, and published under the title of Elements of Mechanical Philosophy, of which it seems only one large 8vo volume has been published. In 1797 Dr. R. astonished the world by a publication which he called, Proofs of a Conspiracy against all Religions and Governments of Europe, carried on in the Secret Meetings of Free-Masons, Illuminati, and Reading-Societies; and in 1803 he published a valuable edition of Dr. Black's Lectures on the Elements of Chemistry, accompanied with much interesting disquisition and history, by the editor.

Altogether, Dr. R. may justly be considered as one of the most eminent philosophers ever produced in Scotland; though perhaps inferior to Gregory and Maclaurin. He certainly possessed a very extensive acquaintance with chemistry, as well as with both pure and mixed mathematics; and he doubtless enjoyed a most happy talent at converting and applying the knowledge he possessed to important practical purposes.

ROCKET, in Pyrotechny, an artificial firework, usually consisting of a cylindrical case of paper filled with a composition of certain combustible ingredients; which being tied to a rod, mounts into the air to a considerable height, and there bursts. These are called Sky Rockets. Besides which, there are others called Water Rockets, from their acting in water.

The composition with which rockets are filled, consists of the three following ingredients, viz, saltpetre, charcoal, and sulphur, all well ground; and in the smaller sizes, gunpowder dust is also added. But the proportions of all the ingredients vary with the weight of the rocket, as in the following table.

Composition for Rockets of various Sizes.

The general composition for rockets is,

Saltpetre	4lb.
Sulphur	1lb.
Charcoal	1lb.

But for large rockets,

Saltpetre	4lb.
Sulphur	1lb.
Mealpowder	1lb.

For rockets of a middle size,

Saltpetre	3lb.
Sulphur	2lb.
Mealpowder	1lb.
Charcoal	1lb.

When rockets are intended to mount upwards, they have a long slender rod fixed to the lower end, to direct their motion.

Theory of the Flight of Rockets.—Mariotte takes the rise of rockets to be owing to the impulse or resistance of the air against the flame. Desaguliers accounts for it thus. Conceive the rocket to have no vent at the choke, and to be set on fire in the conical bore; the consequence would be, either that the rocket would burst in the weakest place, or that, if all parts were equally strong, and able to sustain the impulse of the flame, the rocket would burn out immoveable. Now, as the force of the flame is equable, suppose its action downwards, or that upwards, sufficient to lift 40 pounds; as these forces are equal, but their directions contrary, they will destroy each other's action.

Imagine then the rocket opened at the choke; by this means the action of the flame downwards is taken away, and there remains a force equal to 40 pounds acting upwards, to carry up the rocket, and the stick or rod it is tied to. Accordingly we find that if the composition of the rocket be very weak, so as not to give an impulse greater than the weight of the rocket and stick, it does not rise at all; or if the composition be slow, so that a small part of it only kindles at first, the rocket will not rise.

The stick serves to keep it perpendicular; for if the rocket should begin to tumble, moving round a point in the choke, as being the common centre of gravity of rocket and stick, there would be so much friction against the air, by the stick between the centre and the point, and the point would beat against the air with so much velocity, that the reaction of the medium would restore it to its perpendicularity. When the composition is burnt out, and the impulse upwards has ceased, the common centre of gravity is brought lower towards the middle of the stick; by which means the velocity of the point of the stick is decreased, and that of the point of the rocket is increased; so that the whole will fall down, with the rocket end foremost.

During the time the rocket burns, the common centre of gravity is shifting and getting downwards, and still the faster and the lower as the stick is lighter; so that it sometimes begins to tumble before it is quite burnt out; but when the stick is too heavy, the common centre of gravity will not get so low, but that the rocket will rise straight, though not so fast.

From the experiments of Mr. Robins, and other gentlemen, it appears that the rockets of 2, 3, or 4 inches diameter, rise the highest; and they found them rise to all heights in the air, from 400 to 1254 yards, which is about ¾th of a mile. See Robins's Tracts, vol. 2, pa. 317, and the Philos. Trans. vol. 46, pa. 578.

ROD, or *Pole*, is a long measure, of 16½ feet, or 5½ yards, or the 4th part of a Gunter's chain, for land-measuring.

ROEMER (OLAUS), a noted Danish astronomer and mathematician, was born at Arhusen in Jutland, 1644;

and at 18 years of age was sent to the university of Copenhagen. He applied assiduously to the study of the mathematics and astronomy, and became so expert in those sciences, that when Picard was sent by Lewis the 14th, in 1671, to make observations in the north, he was greatly surprised and pleased with him. He engaged him to return with him to France, and had him presented to the king, who honoured him with the dauphin as a pupil in mathematics, and settled a pension on him. He was joined with Picard and Cassini, in making astronomical observations; and in 1672 he was admitted a member of the academy of sciences.

During the ten years he resided at Paris, he gained great reputation by his discoveries; yet it is said he complained afterwards, that his coadjutors ran away with the honour of many things which belonged to him. Here it was that Roemer, first of any one, found out the velocity with which light moves, by means of the eclipses of Jupiter's satellites. He had observed for many years that, when Jupiter was at his greatest distance from the earth, the emersions of his first satellite happened constantly 15 or 16 minutes later than the calculation gave them. Hence he concluded that the light reflected by Jupiter took up this time in running over the excess of distance, and consequently that it took up 16 or 18 minutes in running over the diameter of the earth's orbit, and 8 or 9 in coming from the sun to us, provided its velocity was nearly uniform. This discovery had at first many opposers; but it was afterwards confirmed by Dr. Bradley in the most ingenious and beautiful manner. See Aberration.

In 1681 Roemer was recalled back to his own country by Christian the 5th, king of Denmark, who made him professor of astronomy at Copenhagen. The king employed him also in reforming the coin and the architecture, in regulating the weights and measures, and in measuring and laying out the high roads throughout the kingdom; offices which he discharged with the greatest credit and satisfaction. In consequence he was honoured by the king with the appointment of chancellor of the exchequer and other dignities. Finally he became counsellor of state and burgomaster of Copenhagen, under Frederic the 4th, the successor of Christian. Roemer was preparing to publish the result of his observations, when he died the 19th of September 1710, at 66 years of age: but this loss was supplied by Horrebow, his disciple, then professor of astronomy at Copenhagen, who published, in 4to, 1735, various observations of Roemer, with his method of observing, under the title of Basis Astronomiæ.—He had also printed various astronomical observations and pieces, in several volumes of the Memoirs of the Royal Academy of Sciences at Paris, of the institution of 1666, particularly vols. 1 and 10 of that collection.

ROHAULT (James), a French philosopher, was the son of a rich merchant at Amiens, where he was born in 1620. He cultivated the languages and belles-lettres in his own country, and then was sent to Paris to study philosophy. He read the ancient and modern philosophers, but Descartes was the author who most engaged his notice. Accordingly he became a zealous follower of that great man, and drew up an abridgment and explanation of his philosophy with great clearness and method. In the preface to his Physics, for so his work is called, he makes no scruple to say, that "the abilities and accomplishments of this philosopher must oblige the whole world to confess, that France is at least as capable of producing and raising men versed in all arts and branches of knowledge, as ancient Greece." Clerselier, well known for his translation of many pieces of Descartes, conceived such an affection for Rohault, on account of his attachment to this philosopher, that he gave him his daughter in marriage, against all the remonstrances of his family.

Rohault's Physics were written in French, but have been translated into Latin by Dr. Samuel Clarke, with notes, in which the Cartesian errors are corrected on the Newtonian system. The 4th and best edition of Rohault's Physica, by Clarke, is that of 1718, in 8vo. He wrote also,

Elemens de Mathematiques,
Traité de Mechanique, and
Entretiens sur la Philosophie.

But these dialogues are founded and carried on upon the principles of the Cartesian philosophy, which has now little other merit, than that of having corrected the errors of the ancients. Rohault died in 1675, and left behind him the character of an amiable, as well as a learned and philosophic man.

His posthumous works were collected and printed in two neat little volumes, first at Paris, and then at the Hague in 1690. The contents of which are, 1. The first 6 books of Euclid. 2. Trigonometry. 3. Practical Geometry. 4. Fortification. 5. Mechanics. 6. Perspective. 7. Spherical Trigonometry. 8. Arithmetic.

ROLLE (Michel), a French mathematician, was born at Ambert, a small town in Auvergne, the 21st of April 1652. His first studies and employments were under notaries and attorneys; occupations but little suited to his genius. He went to Paris in 1675, with the only resource of fine penmanship, and subsisted by giving lessons in writing. But as his inclination for the mathematics had drawn him to that city, he attended the masters in this science, and soon became one himself. Ozanam proposed a question in arithmetic to him, to which Rolle gave so clear and good a solution, that the minister Colbert made him a handsome gratuity, which at last grew into a fixed pension. He then abandoned penmanship, and gave himself up entirely to algebra and other branches of the mathematics. His conduct in life gained him many friends; in which his scientific merit, his peaceable and regular behaviour, with an exact and scrupulous probity of manners, were his only solicitors.

Rolle was chosen a member of the ancient academy of Sciences in 1685, and named second geometrical-pensionary on its renewal in 1699; an honour which he enjoyed till his death, which happened the 5th of July 1719, at 67 years of age.

The works published by Rolle, were,

I. A Treatise of Algebra; in 4to, 1690.

II. A Method of resolving Indeterminate Questions in Algebra; in 1699. Besides a great many curious pieces inserted in the Memoirs of the Academy of Sciences, as follow:

1. A Rule for the Approximation of Irrational Cubes: an. 1666, vol. 10.—2. A Method of resolving Equations of all Degrees which are expressed in General Terms: an. 1666, vol. 10.—3. Remarks on Geometric Lines: 1702 and 1703.—4. On the New System of Infinity: 1703.—5. On the Inverse Method of Tangents: 1705, pa. 25, 171, 222.—6. Method of finding the Foci of Geometric Lines of all kinds: 1706, pa. 284.—7. On Curves, both Geometrical and Mechanical, with their Radii of Curvature: 1707, pa. 370.—8. On the Construction of Equa-

tions: 1708, and 1709.—9. On the Extermination of the Unknown Quantities in the Geometrical Analysis: 1709, pa. 419.—10. Rules and Remarks for the Construction of Equations: 1711, pa. 86.—11. On the Application of Diophantine Rules to Geometry: 1712.—12. On a Paradox in Geometric Effections: 1713, pa. 243.—13. On Geometric Constructions: 1713, pa. 261, and 1714, pa. 5.

ROLLING, or *Rotation*, in Mechanics, a kind of circular motion, by which the moveable body turns round its own axis, or centre, and continually applies new parts of its surface to the body it moves upon. Such is that of a wheel, a sphere, a garden roller, or the like.

The motion of rolling is opposed to that of sliding; in which latter motion the same surface is continually applied to the plane it moves along.

In a wheel, it is only the circumference that properly and simply rolls; the rest of the wheel proceeds in a compound angular kind of motion, and partly rolls, partly slides. The want of distinguishing between which two motions, occasioned the difficulty of that celebrated problem of Aristotle's Wheel. See ROTA *Aristotelica*.

The friction of a body in rolling, is much less than the friction in sliding. And hence arises the great use of wheels, rolls, &c, in machines; as much of the action as possible being laid upon it, to make the resistance the less. See ROTATION.

ROMAN *Order*, in Architecture, is the same as the Composite. It was invented by the Romans, in the time of Augustus: it is composed of the Ionic and Corinthian orders, being more ornamental than either.

RONDEL, in Fortification, a round tower, sometimes erected at the foot of a bastion.

ROOD, a square measure, being a quantity of land equal to the 4th part of an acre, or equal to 40 perches or square poles.

ROOF, in Architecture, the uppermost part of a building; being that which forms the covering of the whole. In this sense, the roof comprises the timber work, together with its furniture, of slate, or tile, or lead, or whatever else serves for a covering: though the carpenters usually restrain roof to the timber-work only.

The form of a roof is various: viz, 1. Pointed, when the ridge, or angle formed by the two sides, is an acute angle.—2. Square, when the pitch or angle of the ridge is a right angle, called the true pitch.—3. Flat or pediment roof, being only pediment pitch, or the angle very obtuse. There are also various other forms, as hip roofs, valley roofs, hopper roofs, double ridges, platforms, round, &c.—In the true pitch, when the sides form a square or right angle, the girt over both sides of the roof, is accounted equal to the breadth of the building and the half of the same.

ROOKE (LAWRENCE), an English astronomer and geometrician, was born at Deptford in Kent, 1623, and educated at Eton school. Hence he removed to King's College, Cambridge, in 1639; and after taking the degree of master of arts in 1647, he retired into the country. But in the year 1650 he went to Oxford, and settled in Wadham College, that he might have the company of, and receive improvement from Dr. Wilkins, and Mr. Seth Ward the Astronomy Professor; and that he might attend Mr. Boyle in his chemical operations.

After the death of Mr. Foster, he was chosen Astronomy Professor in Gresham College, London, in the year 1652. He made some observations on the comet at Oxford, which appeared in the month of December that year; which were printed by Dr. Seth Ward the year following. And, in 1655, Dr. Wallis publishing his treatise on Conic Sections, he dedicated that work to those two gentlemen.

In 1657, Mr. Rooke was permitted to exchange the astronomy professorship for that of geometry. This step might seem strange, as astronomy still continued to be his favourite study; but it was thought to have been from the convenience of the lodgings, which opened behind the reading hall, and therefore were proper for the reception of those gentlemen after the lectures, who in the year 1660 formed the Royal Society there.

Mr. Rooke having thus successively enjoyed those two places some years before the restoration in 1658, most of those gentlemen who had been accustomed to assemble with him at Oxford, coming to London, joined with other philosophical men, and usually met at Gresham College to hear Mr. Rooke's lectures, and afterwards withdrew into his apartment; till their meetings were interrupted by the quartering of soldiers in the college that year. And after the Royal Society was formed and settled into a regular body, Mr. Rooke was very zealous and serviceable in promoting that great and useful institution; though he did not live till it received its establishment by the Royal charter.

The Marquis of Dorchester, who was not only a patron of learning, but learned himself, used to entertain Mr. Rooke at his seat at Highgate after the restoration, and bring him every Wednesday in his coach to the Royal Society, which then met on that day of the week at Gresham College. But the last time Mr. Rooke was at Highgate, he walked from thence; and it being in the summer, he overheated himself, and taking cold after it, was thrown into a fever, which cost him his life. He died at his apartments at Gresham College the 27th of June 1662, in the 40th year of his age.

Another very unfortunate circumstance attended his death, which was, that it happened the very night that he had for some years expected to finish his accurate observations on the satellites of Jupiter. When he found his illness prevented him from making that observation, Dr. Pope says, he sent to the Society his request, that some other person, properly qualified, might be appointed for that purpose; so intent was he to the last on making those curious and useful discoveries, in which he had been so long engaged.

Mr. Rooke made a nuncupatory will, leaving what he had to Dr. Ward, then lately made bishop of Exeter: whom he permitted to receive what was due upon bond, if the debtors offered payment willingly, otherwise he would not have the bonds put in suit: "for," said he, "as I never was in law, nor had any contention with any man, in my life-time; neither would I be so after my death."

Few persons have left behind them a more agreeable character than Mr. Rooke, from every person that was acquainted with him, or with his qualifications; and in nothing more than for his veracity: for what he asserted positively, might be fully relied on: but if his opinion was asked concerning any thing that was dubious, his usual answer was, "I have no opinion." Mr. Hooke has given this copious, though concise character of him: "I never was acquainted with any person who knew more, and spoke less, being indeed eminent for the knowledge and improvement of astronomy." Dr. Wren and Seth Ward describe him, as a man of profound judgment, a vast comprehension, prodigious memory, and solid experience. His skill in the mathematics was reverenced by all the lovers of those studies, and his perfection in many other kinds of learning deserves no less admiration; but above all, as another writer characterises him, his extensive knowledge had a right influence on the temper of his mind, which had all the humility, goodness, calmness, strength, and sincerity, of a sound and unaffected philosopher. These accounts give us his picture only in miniature; but his successor, Dr. Isaac Barrow, has drawn it in full proportion, in his oration at Gresham College; which is too long to be inserted in this place.

His writings were chiefly;

1. Observations on the Comet of Dec. 1652. This was printed by Dr. Seth Ward, in his Lectures on Comets, 4to, 1653.

2. Directions for Seamen going to the East and West Indies. Published in the Philosophical Transactions for Jan. 1665.

3. A Method of Observing the Eclipses of the Moon &c. In the Philos. Trans. for Feb. 1666.

4. A Discourse concerning the Observations of the Eclipses of the Satellites of Jupiter. In the History of the Royal Society, pa. 183.

5. An Account of an Experiment made with Oil in a long Tube. Read to the Royal Soc. April 23, 1662.— By this experiment it was found, that the oil sunk when the sun shone out, and rose when he was clouded; the proportions of which are set down in the account.

ROOT, in Arithmetic and Algebra, denotes a quantity which being multiplied by itself produces some higher power; or a quantity considered as the basis or foundation of a higher power, out of which this arises and grows, like as a plant from its root.

In the involution of powers, from a given root, the root is also called the first power; when this is once multiplied by itself, it produces the square or second power; this multiplied by the root again, makes the cube or 3d power; and so on. And hence the denominations square-root, cube-root, &c, or 2d root, or 3d root, &c, according as the given power or quantity is considered as the square, or cube, or 2d power, or 3d power, &c. Thus, 2 is the square-root or 2d root of 4, and the cube-root or 3d root of 8, and the 4th root of 16, &c.

Hence, the square-root is the mean proportional between 1 and the square or given power; and the cube-root is the first of two mean proportionals between 1 and the given cube; and so on.

Root is also applied sometimes in a different sense; thus we say the root or radix of any system of notation, or the radix of a system of logarithms. The radix of our present scale of notation is 10, and this is also the radix of the modern or Brigges's logarithms. The advantages of which consist in this equality between the roots of the system of notation and logarithms, by which means the tables of the latter are much contracted, and are also much readier in their application.

For the method of extracting the roots of numbers, and algebraic quantities, see the articles EXTRACTION, and BINOMIAL *Theorem*.

Finite approximating rules for the extraction of roots have been given by several authors, as Raphson, De Lagney, Halley, &c. See the articles APPROXIMATION and EXTRACTION. See also Newton's Universal Arith. the Appendix; Philos. Trans. numb. 210; Maclaurin's Alg. pa. 242; Simpson's Alg. pa. 155; or his Essays, pa. 82, or his Dissertations, pa. 102, or his Select Exerc. pa. 215: where various general theorems for approximating to the roots of pure powers are given. See also EQUATION and REDUCTION of Equations, APPROXIMATION, and CONVERGING.

But the most commodious and general rule of any, for such approximations, I believe, is that which has been invented by myself, and explained in my Tracts, vol. 1, pa. 210: which theorem is this;

$\frac{\overline{n+1}.N + \overline{n-1}.a^n}{\overline{n-1}.N + \overline{n+1}.a^n} a = \sqrt[n]{N}$. That is, having to extract the nth root of the given number N; take a^n the nearest rational power to that given quantity N, whether greater or less, its root of the same kind being a; then the required root, or $\sqrt[n]{N}$, will be as is expressed in this formula above; or the same expressed in a proportion will be thus:

$(n-1).N + (n+1).a^n : (n+1).N + (n-1).a^n :: a : \sqrt[n]{N}$ the root sought very nearly.

This rule includes all the particular rational formulæs of De Lagney, and Halley, which were separately investigated by them; and yet this general formula is perfectly simple and easy to apply, and more easily kept in mind than any one of the said particular formulas.

Ex. Suppose it be required to double the cube, or to extract the cube root of the number 2.

Here $N = 2$, $n = 3$, the nearest root $a = 1$, also $a^3 = 1$; hence, for the cube root the formula becomes $\frac{4N+2a^3}{2N+4a^3} a$ or $\frac{2N+a^3}{N+2a^3} a = \sqrt[3]{N}$.

But $N + 2a^3 = 4$, and $2N + a^3 = 5$; therefore as $4 : 5 :: 1 : \frac{5}{4} = 1{\cdot}25$ = the root nearly by a first approximation.

Again, for a second approximation, take $a = \frac{5}{4}$, and consequently $a^3 = \frac{125}{64}$;

hence $2N + a^3 = 4 + \frac{125}{64} = \frac{381}{64}$,

and $N + 2a^3 = 2 + \frac{250}{64} = \frac{378}{64}$;

therefore as $378 : 381$, or as $126 : 127 :: \frac{5}{4} : \frac{635}{504} =$ $1{\cdot}259921$ &c, for the required cube root of 2, which is true even in the last place of decimals.

ROOT *of an Equation*, denotes the value of the unknown quantity in an equation; which is such a quantity, as being substituted instead of that unknown letter, into the equation, shall make all the terms to vanish, or both sides equal to each other. Thus, of the equation $3x + 5 = 14$, the root or value of x is 3, because substituting 3 for x, makes it become $9 + 5 = 14$. And the root of the equation $2x^2 = 32$ is 4, because $2 \times 4^2 = 32$. Also the root of the equation $x^2 = a^2 + c^2$ is $x = \sqrt{(a^2 + c^2)}$.

For the nature of roots, and for extracting the several roots of equations, see EQUATION.

Every equation has as many roots, or values of the unknown quantity, as are units in the dimensions or highest power in it. So a simple equation has one root, a quadratic two, a cubic three, and so on.

Roots are positive or negative, real or imaginary, rational or radical, &c. See EQUATION.

Cubic ROOT. This is threefold, even for a simple cubic. So the cube root of a^3, is either

a, or $\frac{-1+\sqrt{-3}}{2}a$, or $\frac{-1-\sqrt{-3}}{2}a$.

And even the cube Root of 1 itself is either

1, or $\frac{-1+\sqrt{-3}}{2}$, or $\frac{-1-\sqrt{-3}}{2}$.

Real and Imaginary ROOTS. The odd roots, as the 3d, 5th, 7th, &c roots, of all real quantities, whether positive or negative, are real, and are respectively positive or negative. So the cube root of a^3 is a, and of $-a^3$ is $-a$.

But the even roots, as the 2d, 4th, 6th, &c, are only real when the quantity is positive; being imaginary or impossible when the quantity is negative. So the square root of a^2 is a, which is real; but the square root of $-a^2$, that is, $\sqrt{-a^2}$, is imaginary or impossible; because there is no quantity, neither $+a$ nor $-a$, which by squaring will make the given negative square $-a^2$.

The large Table of Roots, Squares, and Cubes, at the end of vol. 1 of my Tracts, is very useful in many calculations, and will serve to find square roots and cube roots, as well as square and cubic powers, &c.

ROTA, in Mechanics. See WHEEL.

ROTA *Aristotelica*, or *Aristotle's Wheel*, denotes a celebrated problem in mechanics, concerning the motion or rotation of a wheel about its axis; so called because first noticed by Aristotle. The difficulty is this. While a circle makes a revolution on its centre, advancing at the same time in a right line along a plane, it describes, on that plane, a right line which is equal to its circumference. Now if this circle, which may be called the deferent, carry with it another smaller circle, concentric with it, like the nave of a coach wheel; then this little circle, or nave, will describe a line in one revolution, which is equal to that of the large wheel or circumference itself; because its centre advances in a right line as fast as that of the wheel, being in reality the same with it.—The solution given by Aristotle, is no more than a good explication of the difficulty.

Galileo, who next attempted it, had recourse to an infinite number of infinitely little vacuities in the right line described by the two circles: and imagines that the little circle never applies its circumference to those vacuities; but in reality only applies it to a line equal to its own circumference; though it appears to have applied it to a much larger. But all this is nothing to the purpose.

Tacquet says, that the little circle, making its rotation more slowly than the great one, does on that account describe a line longer than its own circumference; yet without applying any point of its circumference to more than one point of its base. But this is no more satisfactory than the former.

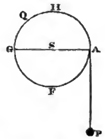
After the fruitless attempts of so many great men, M. Dortous de Meyran, a French gentleman, had the good fortune to hit upon a solution, which he sent to the Academy of Sciences; where being examined by Mess. de Louville and Soulmon, appointed for that purpose, they made their report that it was satisfactory. The solution is to this effect:

The wheel of a coach is only acted on, or drawn in a right line; its rotation or circular motion arises purely from the resistance of the ground upon which it is applied. Now this resistance is equal to the force which draws the wheel in the right line, inasmuch as it defeats that direction; consequently the causes of the two motions, the one right and the other circular, are equal. And hence the wheel describes a right line on the ground equal to its circumference.

As for the nave of the wheel, the case is otherwise. It is drawn in a right line by the same force as the wheel; but it only turns round because the wheel does so, and can only turn in the same time with it. Hence it follows, that its circular velocity is less than that of the wheel, in the ratio of the two circumferences; and therefore its circular motion is less than the rectilinear one. Since then it necessarily describes a right line equal to that of the wheel, it can only do it partly by sliding, and partly by revolving, the sliding part being more or less as the nave itself is smaller or larger. See CYCLOID.

ROTATION, or ROTARY *Motion*, in Mechanics, is the motion of a body, or system of bodies, about a fixed axis; being thus distinguished from rectilinear motion, in which bodies are supposed to describe spaces in the direction of the impelling force, which is always considered as acting in a right line passing through the centre of gravity of the body moved; and therefore, that every particle of such body must partake of the same degree of velocity as that with which the centre of gravity moves. But in numerous instances which occur in practice, a body, or system of bodies, is so situated, that when any force or number of forces are impressed upon it, it cannot take any other motion than one of rotation about a fixed axis, which may either pass through the body or system, or be at an extremity of it: so that the velocity of the constituent moleculæ of the system shall be greater or less according to the greater or less distance of any individual particle from the axis about which the motion is performed. And in such cases, it is necessary to call to our aid other considerations than what are required in discussing the properties of acceleration and retardation.

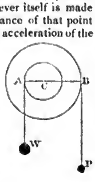
In these considerations, two things are principally to be attended to, i. e. the moving force by which the revolving motion is generated, and the inertia of the parts that compose the system: the moving force exerted on any given particle in the system, as well as its inertia, depends on its distance from the axis of motion, every thing else being the same, and if both these be ascertained, the absolute acceleration will be determined, and consequently the absolute velocity generated in it in a given time. Thus,



Let AFGH represent the circumference of a wheel, which turns in its own plane round an horizontal axis, passing through S its centre, and let a weight P, fixed at the extremity of a line AP, communicate motion to the wheel. Also, let the whole weight of the wheel be Q, and suppose this weight to be collected uniformly into the circumference AFGH; then during the descent of the weight P, each point of the circumference must move with a velocity equal to that with which P descends; and consequently, since the moving force is the weight P, and the mass moved P + Q, the force which accelerates P in its descent, will be that part of the accelerating force of gravity which is expressed by the fraction $\frac{P}{P+Q}$ (see ACCELERATION). The velocity therefore which is generated in P, in any given time, is found by proportion, namely, it will be to the velocity generated by gravity in a falling body in the same time, as this fraction to unity; so, if Q = P, then its velocity to that of gravity, is as 1 to 2. And this is universally true while the axis of the body, or system of bodies, passes through their centre of gravity. But if, instead of this, we suppose all the matter of the wheel to be collected into one point as at Q; then it is manifest, that if the mass Q be acted on by gravity, the force which communicates motion to the system round S, will be variable, it being the greatest when SQ is horizontal, and gradually diminishing till Q has descended to its lowest point. But if, instead of supposing Q to be acted on by gravity, we consider it as destitute of weight, and to possess inertia only, then the moving force will be constant, being equal to P, and the bodies moved will be P + Q, and therefore the accelerating force of the weight P will be represented by $\frac{P}{P+Q}$, the same as before; which ought to be the result, because in the former case the parts of the weight Q being uniformly disposed over the circumference, balance each other round the common centre of gravity S, and their weight therefore has no effect in accelerating or retarding the descent of the weight P.

In general, the accelerating force of the body P will be represented by the motive force divided by the inertia of the bodies moved; and therefore, if the body P be destitute of inertia, the accelerating force will be expressed simply by the fraction $\frac{P}{Q}$.

In what has been said above, we have supposed all the matter of the wheel to be uniformly disposed throughout the circumference of it; but supposing the wheel of uniform thickness and density, or in any other way constituted, before we enter upon the investigation of the law of acceleration, we must first determine the centre of gyration, or that point of it into which, if all the matter of the body be collected, the same angular velocity would be produced, which in a uniform circle is at $r\sqrt{\frac{1}{2}}$ distance from the centre, r being the radius of the wheel. All the matter of the wheel being supposed to be collected in that circumference whose radius is $r\sqrt{\frac{1}{2}}$, we shall have the moving force as rP, because the weight of the wheel, being uniformly distributed, will balance it on its centre, and therefore can neither tend to accelerate nor retard the descent of the body P. But the inertia of bodies being as the square of their distances from the axis of motion, we shall have $\frac{1}{2}r^2$Q for the inertia of the wheel, and r^2P for the inertia of the weight P, and therefore $\frac{rP}{r^2(\frac{1}{2}Q + P)}$ for the accelerating force of the wheel, or of the lever AB; and as the acceleration of any point of a lever must, (besides the accelerating force with which the lever itself is made to revolve) be in proportion to the distance of that point from the axis of suspension, therefore the acceleration of the point P will be as $\frac{r^2P}{r^2(\frac{1}{2}Q + P)} = \frac{P}{\frac{1}{2}Q + P}$.



Let now ABC represent a wheel and axle, the diameters of which are given, W and P two given weights; the former, being fixed to the axle, is drawn up by the descent of the latter attached to the circumference of the wheel; and let it be required to determine the accelerative force of the descending body, the wheel and axle being supposed of no weight.

Put BC = b, AC = a, then from what has been before observed, the moving force will be as bP, and the retarding force as aW, and therefore the motive force will be expressed by bP − aW; also the inertia of the bodies will be as b^2P + a^2W, and hence the accelerating force of the lever will be as $\frac{bP - aW}{b^2P + a^2W}$; also, the acceleration of any point of the lever being as its distance from the axis, we have for the accelerative force of P, $\frac{bP - aW}{b^2P + a^2W} \times b = \frac{b^2P - abW}{b^2P + a^2W}$; and if P be a power of that kind which is not possessed of inertia, the expression becomes simply $\frac{b^2P - abW}{a^2W}$. See Atwood on the Rectilinear Motion and Rotation of Bodies, pa. 183, and Gregory's Mechanics, vol. 1, pa. 257; see also the articles GYRATION, OSCILLATION, CENTRE *of Spontaneous Rotation*, &c, in this Dictionary.

ROTATION, in Geometry, the circumvolution of a surface round an immoveable line, called the Axis of Rotation. By such rotation of planes, the figures of certain regular solids are formed or generated. Such as, a cylinder by the rotation of a rectangle, a cone by the rotation of a triangle, a sphere or globe by the rotation of a semicircle, &c.

The method of cubing solids that are generated by such rotation, is laid down by Demoivre, in his specimen of the use of the doctrine of fluxions, Philos. Trans. numb. 216; and indeed by most of the writers on fluxions. In every such solid, all the sections perpendicular to the axis are circles, and therefore the fluxion of the solid, at any section, is equal to that circle multiplied by the fluxion of the axis. So that, if x denote an absciss of that axis, and y an ordinate to it in the revolving plane, which will also be the radius of that circle; then, putting n = 3·1416, the area of the circle is ny^2, and consequently the fluxion of the solid is $ny^2\dot{x}$; the fluent of which will be the content.

Such solid may also be expressed in terms of the generating plane and its centre of gravity; for the solid is always equal to the product arising from the generating plane multiplied by the path of its centre of gravity, or by the line described by that centre in the rotation of the plane. And this theorem is general, by whatever kind of motion the plane is moved, in describing a solid.

ROTATION, *Revolution*, in Astronomy. See REVOLUTION.

Diurnal ROTATION. See DIURNAL, and EARTH.

ROTONDO, or ROTUNDO, in Architecture, a popular term for any building that is round both withinside and without, whether it be a church, hall, a saloon, a vestibule, or the like.

ROUND, ROUNDNESS, ROTUNDITY, the property of a circle and sphere or globe, &c.

ROWNING (JOHN), an ingenious English mathematician and philosopher, was fellow of Magdalen College, Cambridge, and afterwards rector of Anderby in Lincolnshire, in the gift of that society. He was a constant attendant at the meetings of the Spalding Society, and was a man of a great philosophical turn of mind, though of a cheerful and sociable disposition. He had a good genius for mechanical contrivances in particular. In 1738 he printed at Cambridge, in 8vo, A Compendious System of Natural Philosophy, in 2 vols 8vo; a very ingenious work, which has gone through several editions. He had also two pieces inserted in the Philosophical Transactions, viz, 1. A Description of a Barometer wherein the Scale of Variation may be increased at pleasure; vol. 38, pa. 39. And 2. Direction for making a Machine for finding the Roots of Equations universally, with the Manner of using it; vol. 60, pa. 240.—Mr Rowning died at his lodgings in Carey-street near Lincoln's-Inn Fields, London, the latter end of November 1771, at 72 years of age.

Though a very ingenious and pleasant man, he had rather an unpromising and forbidding appearance: he was tall, stooping in the shoulders, and of a sallow and gloomy countenance.

ROYAL *Oak*, *Robur Carolinum*, in Astronomy, one of the new southern constellations, the stars of which, according to Sharp's catalogue, annexed to the Britannic, are 12.

RUDOLPHINE *Tables*, a set of astronomical tables that were published by the celebrated Kepler, and so called from the emperor Rudolph or Rudolphus.

RULE, *The Carpenter's*, a folding ruler generally used by carpenters and other artificers; and is otherwise called the sliding rule.—This instrument consists of two equal pieces of box-wood, each one foot in length, connected together by a folding joint. One side or face, of the rule, is divided into inches, and half-quarters, or eighths. On the same face also are several plane scales, divided into 12th parts by diagonal lines; which are used in planning dimensions that are taken in feet and inches. The edge of the rule is commonly divided decimally, or into 10ths; viz, each foot into 10 equal parts, and each of these into 10 parts again, or 100th parts of the foot: so that by means of this last scale, dimensions are taken in feet and tenths and hundredths, and multiplied together as common decimal numbers, which is the best way.

On the one part of the other face are four lines, marked A, B, C, D, the two middle ones B and C being on a slider, which runs in a groove made in the stock. The same numbers serve for both these two middle lines, the one line being above the numbers, and the other below them.—These four are logarithmic lines, and the three A, B, C, which are all equal to one another, are double lines, as they proceed twice over from 1 to 10. The lowest line D is a single one, proceeding from 4 to 40. It is also called the girt line, from its use in computing the contents of trees and timber: and on it are marked WG at 17·15, and AG at 18·95, the wine and ale gauge points, to make this instrument serve the purpose of a gauging-rule.—On the other part of this face is a table of the value of a load, or 50 cubic feet, of timber, at all prices, from 6d. to 2s. a foot.

When 1 at the beginning of any line is accounted only 1, then the 1 in the middle is 10, and the 10 at the end 100; but when the 1 at the beginning is accounted 10, then 1 in the middle is 100, and the 10 at the end 1000; and so on. All the smaller divisions being also altered proportionally.

By means of this rule all the usual operations of arithmetic may be easily and quickly performed, as multiplication, division, involution, evolution, finding mean proportionals, 3d and 4th proportionals, or the rule-of-three, &c. For all which, see my Mensuration, part 5, sect. 3.

RULES *of Philosophizing*. See PHILOSOPHIZING.

RULE, in Arithmetic, denotes a certain mode of operation with figures, to find sums or numbers unknown, and to facilitate computations.—Each rule in arithmetic has its particular name, according to the use for which it is intended. The first four, which serve as a foundation of the whole art, are called addition, subtraction, multiplication, and division.

From these arise numerous other rules, which are indeed only applications of these to particular purposes and occasions; as the Rule-of-three, or Golden Rule, or Rule of Proportion; also the Rules of Fellowship, Interest, Exchanges, Position, Progressions, &c, &c. For which, see each article severally.

RULE-*of-Three*, or *Rule of Proportion*, commonly called the *Golden Rule* from its great use, is a rule that teaches how to find a 4th proportional number to three others that are given.

As, if 3 degrees of the equator contain 208 miles, how many are contained in 360 degrees, or the whole circumference of the earth? The rule is this: State, or set the three given terms down in the form of the first three terms of a proportion, stating them proportionally, thus:

```
     deg.  mil.    deg.   miles.
as    3 : 208 : : 360 : 24960
          360
        -----
        12480
         624
       -------
      3)74880
       -------
        24960
```

Then multiply the 2d and 3d terms together, and divide the product by the 1st term, so shall the quotient be the 4th term in proportion, or the answer to the question, which in this example is 24960, or nearly 25,000 miles, for the circumference of the earth.

This rule is often considered as of two kinds, viz, *Direct*, and *Inverse*.

Rule-of-Three Direct, is that in which more requires more, or less requires less. As in this; if 3 men mow 21 yards of grass in a certain time, how much will 6 men mow in the same time? Here more requires more, that is, 6 men, which are more than 3 men, will also perform more work, in the same time. Or if it were thus: if 6 men mow 42 yards, how much will 3 men mow in the same time? Here then less requires less, or 3 men will perform proportionally less work, in the same time. In both these cases then, the rule, or the proportion, is direct; and the stating must be

thus, as 3 : 6 : : 21 : 42,
or thus, as 6 : 3 : : 42 : 21.

Rule-of-Three Inverse, is when more requires less, or less requires more. As in this; if 3 men mow a certain quantity of grass in 14 hours, in how many hours will 6 men mow the like quantity? Here it is evident that 6 men, being more than 3, will perform the same work in less time, or fewer hours; hence then more requires less, and the rule or question is inverse, and must be stated by making the number of men change places, thus, as 6 : 3 : : 14 : 7 hours, the time in which 6 men will perform the work; still multiplying the 2d and 3d terms together, and dividing by the 1st.

For various abbreviations, and other particulars relating to these rules, see my books of arithmetic.

Double RULE-*of-Three*, or *Compound Proportion*, is where two statings are required to be wrought, or to be combined together, to find out the number sought.

This rule may be performed, either by working the two statings or proportions separately, making the result or 4th term of the 1st operation to be the 3d term of the last proportion; or else by reducing the two statings into one, by multiplying the two first terms together, and the two third terms together, and using the products as the 1st and 3d terms of the compound stating. As, if the question be this: If 100*l.* in 2 years yield 9*l.* interest, how much will 500*l.* yield in 6 years. Here, the two statings are,

$$\left.\begin{matrix}100\\2\end{matrix}\right\} : 9 : : \left\{\begin{matrix}500\\6\end{matrix}\right.$$

Then, to work the two statings separately,

as 100 : 9 : : 500 : 45*l.*

and 2 : 6 : : 45 : 135*l.*

so that 135l. is the interest or answer sought. But to work by one stating, it will be thus,

$$\begin{array}{ccccccc}100 & & & & 500 & & \\ \underline{2} & & & & \underline{6} & & \\ \overline{200} & : & 9 & : : & \overline{3000} & : & 135l. \text{ the answer.}\end{array}$$

2·00) 270·00 (135*l.*

See the books of arithmetic for more particulars.

Central Rule. See Central *Rule.*

Parallel Ruler. See Parallel *Ruler.*

RUMB. See Rhumb.

Rumb-*Line*, or *Loxodromie.* See Rhumb-*Line.*

RUSTIC, in Architecture, denotes a manner of building in imitation of simple or rude nature, rather than according to the rules of art.

Rustic *Quoin.* See Quoin.

Rustic *Work* is where the stones in the face &c of a building, instead of being smooth, are hatched or picked with the point of an instrument.

Regular Rustics, are those in which the stones are chamfered off at the edges, and form angular or square recesses of about an inch deep at their jointings, or beds, and ends.

Rustic *Order*, is an order decorated with rustic quoins, or rustic work, &c.

RUTHERFORD (Thomas, d. d.), an ingenious English philosopher, was the son of the Rev. Thomas Rutherford, rector of Papworth Everard in the county of Cambridge, who had made large selections for the history of that county. He was born the 13th of October 1712. He studied at Cambridge, and became fellow of St. John's college, and regius professor of divinity, in that university; afterwards rector of Shenfield in Essex, and of Barley in Hertfordshire, and archdeacon of Essex. He died October 5, 1771, at 59 years of age.

Dr. Rutherford, besides a number of theological writings, published, at Cambridge,

1. Ordo Institutionum Physicarum, 1743, in 4to.

2. A System of Natural Philosophy, in 2 vols, 4to, 1748. A work which has been much esteemed.

3. He communicated also to the Gentleman's Society at Spalding, a curious correction of Plutarch's description of the instrument used to renew the vestal fire, as relating to the triangle with which the instrument was formed. It was nothing more, it seems, than a concave speculum, whose principal focus, which collected the rays, is not in the centre of concavity, but at the distance of half a diameter from its surface. But some of the ancients thought otherwise, as appears from prop. 31 of Euclid's Catoptrics.

S.

S, IN books of Navigation, &c, denotes south. So also s. e. is south-east; s. w. south-west; and s. s. e. south-south-east, &c. See Compass.

SACROBOSCO. See Holywood.

SAGITTA, in Astronomy, the *Arrow* or *Dart*, a constellation of the northern hemisphere near the eagle, and one of the 48 old asterisms. The Greeks say that this constellation owes its origin to one of the arrows of Hercules, with which he killed the eagle or vulture that gnawed the liver of Prometheus. The stars in this constellation, in the catalogues of Ptolemy, Tycho, and Hevelius, are only 5, but in Flamsteed's they are extended to 18.

Sagitta, in Geometry, is a term used by some writers for the absciss of a curve.

Sagitta, in Trigonometry &c, is the same as the versed sine of an arch; being so called because it is like a dart or arrow, standing on the chord of the arch.

SAGITTARIUS, Sagittary, the *Archer*, one of the signs of the zodiac, being the 9th in order, and marked with the character ♐ of a dart or arrow. This constellation is drawn in the figure of a Centaur, or an animal half man and half horse, in the act of shooting an arrow from a bow. This figure the Greeks feign to be Crotus, the son of Eupheme, the nurse of the muses. Among more ancient nations the figure was probably meant for a hunter, to denote the hunting season, when the sun enters this sign. The stars in this constellation are, in Ptolemy's catalogue 31, in Tycho's 14, in Hevelius's 22, and in the Britannic catalogue 69.

SAILING, in a general sense, denotes the movement by which a vessel is wafted along the surface of the water, by the action of the wind upon her sails. Sailing is also used for the art or act of navigating; or of determining all the cases of a ship's motion, by means of sea-charts &c. These charts are constructed either on the supposition that the earth is a large extended flat surface, whence we obtain those that are called plane charts; or on the supposition that the earth is a sphere, whence are derived globular charts. Accordingly, sailing may be distinguished into two general kinds, viz, Plane Sailing, and Globular Sailing. Sometimes indeed a third sort is added, viz, Spheroidical Sailing, which proceeds on the supposition of the spheroidical figure of the earth.

Plane Sailing is that which is performed by means of a plane chart; in which case the meridians are considered as parallel lines, the parallels of latitude are at right angles to the meridians, the lengths of the degrees on the meridians, equator, and parallels of latitude, are every where equal. In plane sailing, the principal terms and circumstances made use of, are, course, distance, departure, difference of latitude, rhumb, &c; for as to longitude, that has no place in plane sailing, but belongs properly to globular or spherical sailing. The explanation of all which terms, are given under the respective articles.

If a ship sails either due north or south, she sails on a meridian, her distance and difference of latitude are the same, and she makes no departure: but where the ship sails either due east or west, she runs on a parallel of latitude, making no difference of latitude, and her departure and distance are the same. It may further be observed, that the departure and difference of latitude always make the legs of a right-angled triangle, whose hypothenuse is the distance the ship has sailed; and the angles are the course, its complement, and the right angle; therefore, among these four things, course, distance, difference of latitude, and departure, any two of them being given, the rest may be found by plane trigonometry. Thus, in the annexed figure, suppose the circle FHFH to represent the horizon of the place A, from whence a ship sails; AC the rhumb she sails upon, and C the place arrived at: then HH represents the parallel of latitude she sailed from, and CC the parallel of the latitude arrived in: so that

AD becomes the dif. of lat.
DC the departure,
AC the distance sailed,
∠DAC is the course, and
∠DCA the comp. of the course.

And all these particulars will be alike represented, whether the ship sails in the NE, or NW, or SE, or SW quarter of the horizon.

From the same figure, in which
AB or AF or AH represents the rad. of the tables,
EB the sine of the course,
AB the cosine of the course,

we may easily deduce all the proportions or canons, as they are usually called by mariners, that can arise in plane sailing; because the triangles ADC and ABE and AFG are evidently similar. These proportions are exhibited in the following table, which consists of 6 cases, according to the varieties of the two parts that can be given.

Case.	Given.	Required.	Solutions.
1	∠A and AC, i. e. course and distance.	AD and DC, i. e. difference of latitude and departure.	AE : AB : : AC : AD, i. e. rad. : s. course : : dist. : dif. lat. AE : EB : : AC : DC, i. e. rad. : cos. course : : dist. : depart.
2	∠A and AD, i. e. course and difference of latitude.	AC and DC, i. e. distance and departure.	AB : AE : : AD : AC, i. e. cos. cour. : rad. : : dif. lat. : dist. AB : BE : : AD : DC, i. e. cos. cour. : s. cour. : : dif. lat. : dep.
3	∠A and DC, i. e. course and departure.	AC and AD, i. e. distance and difference of latitude.	BE : AE : : DC : AC, i. e. s. cour. : rad. : : depart. : dist. BE : AB : : DC : AD, i. e. s. cour. : cos. cour. : : dep. : dif. lat.
4	AC and AD, i. e. distance and difference of latitude.	∠A and DC, i. e. course and departure.	AC : AD : : AE : AB, i. e. dist. : dif. lat. : : rad. : cos. course. AE : EB : : AC : DC, i. e. rad. : s. course : : dist. : depart.
5	AC and DC, i. e. distance and departure.	∠A and AD, i. e. course and difference of latitude.	AC : DC : : AE : EB, i. e. dist. : dep. : : rad. : s. course. AE : AB : : AC : AD, i. e. rad. : cos. cour. : : dist. : dif. lat.
6	AD and DC, i. e. difference of latitude and departure.	∠A and AC i. e. course and distance.	AD : DC : : AF : FG, i. e. dif. lat. : dep. : : rad. : tang. course. BE : AB : : DC : AC, i. e. s. cour. : rad. : : dep. : distance.

For the ready working of any single course, there is a table, called a Traverse Table, usually annexed to books of navigation; which is so contrived, that by finding the given course in it, and a distance not exceeding 100 or 120 miles, the usual extent of the table; then the difference of latitude and the departure are had by inspection. And the same table will serve for greater distances, by doubling, or trebling, or quadrupling, &c, or taking proportional parts. See TRAVERSE *Table*.

An ex. to the first case may suffice to show the method. Thus, a ship from the latitude 47° 30′ N, has sailed SW by S 98 miles; required the departure made, and the latitude arrived in.

1. *By the Traverse Table.* In the column of the course, viz. 3 points, against the distance 98, stands the number 54·45 miles for the departure, and 81·5 miles for the diff. of lat; which is 1° 21½′; and this being taken from the given. lat. 47° 30′, leaves 46° 8½′ for the lat. come to.

2. *By Construction.* Draw the meridian AD; and drawing an arc, with the chord of 60, make PQ or angle A equal to 3 points; through Q draw the distance AQE = 98 miles, and through E the departure ED perp. to AD. Then, by measuring, the diff. of lat. AD measures about 81½ miles, and the departure DE about 54½ miles.

3. *By Computation.*

First, as radius	- - - - - -	10·00000
to sin. course 33° 45′	- - -	9·74474
so dist. 98	- - - - - - - -	1·99123
to depart. 54·45	- - - - -	1·73597

Again, as radius - - - - - 10·00000
to cos. course - - - - - - 9·91985
so dist. 98 - - - - - - - - 1·99123
to diff. of lat. 81·48 - - - 1·91108

4. *By Gunter's Scale.* The extent from radius, or 8 points, to 3 points, on the line of sine rhumbs, applied to the line of numbers, will reach from 98 to 54½ the departure. And the extent from 8 points to 5 points, of the rhumbs, reaches from 98 to 81½ on the line of numbers, for the difference of latitude.

And in like manner for other cases.

Traverse SAILING, or *Compound Courses*, is the uniting of several cases of plane sailing into one; as when a ship sails in a zigzag manner, certain distances upon several different courses, to find the whole difference of latitude and departure made good on all of them. This is done by working all the cases separately, by means of the traverse table, and constructing the figure as in the following example.

Ex. A ship sailing from a place in latitude 24° 32′ N, has run five different courses and distances, as set down in the 1st and 2d columns of the following traverse table; required her present latitude, with the departure, and the direct course and distance, between the place sailed from, and the place come to.

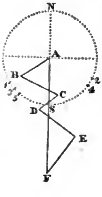
Traverse Table.

Courses.	Dist.	N.	S.	E.	W.
SWbS	45		25·0		37·4
ESE	50		19·1	46·2	
SW	30		21·2		21·2
SE b E	60		33·3	49·9	
SW b S ½ W	63		50·6		37·5
			149·2	96·1	96·1

Here, by finding, in the general traverse table, the difference of latitude and departure answering to each course and distance, they are set down on the same lines with each course, and in their proper columns of northing, southing, easting, or westing, according to the quarter of the compass the ship sails in, at each course. As here, there is no northing, the differences of latitude are all southward, also two departures are eastward, and three are westward. Then, adding up the numbers in each column, the sum of the eastings appears to be exactly equal to the sum of the westings, consequently the ship is arrived in the same meridian, without making any departure; and the southings, or difference of latitude being 149·2 miles or minutes,

that is - - - - - - - - - - 2° 29′,
which taken from - - - - 24 32,
the latitude dep. from,
leaves - - - - - - - - - 22 3N,
the latitude come to.

To Construct this Traverse. With the chord of 60 degrees describe the circle N S &c, and quarter it by the two perpendicular diameters; then from S set upon it the several courses, to the points marked 1, 2, 3, 4, 5, through which points draw lines from the centre A, or conceive them to be drawn; lastly, upon the first line lay off the first distance 45

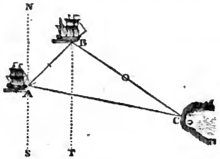


from A to B, also draw BC = 50 and parallel to A 2, and CD = 30 parallel to A 3, and DE = 60 parallel to A 4, and EF = 63, parallel to A 5; then it is found that the point F falls exactly on the meridian NAF produced, thereby showing that there is no departure; and by measuring AF, it gives 149 miles for the difference of latitude.

Oblique SAILING, is the resolution of certain cases and problems in sailing by oblique triangles, or in which oblique triangles are concerned. In this kind of sailing, it may be observed, that *to set an object*, means to observe what rhumb or point of the nautical compass is directed to it. And the *bearing* of an object is the rhumb on which it is seen; also the bearing of one place from another, is reckoned by the name of the rhumb passing through those two places.

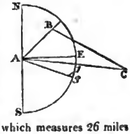
In every figure relating to any case of plane sailing, the bearing of a line, not running from the centre of the circle or horizon, is found by drawing a line parallel to it, from the centre, and towards the same quarter.

Ex. A ship sailing at sea, observed a point of land to bear E by S; and then after sailing NE 12 miles, its bearing was found to be SE by E. Required the place of that point, and its distance from the ship at the last observation.



Construction. Draw the meridian line NAS, and, assuming A for the first place of the ship, draw AC the E by S rhumb, and AB the NE one, upon which lay off 12 miles from A to B; then draw the meridian BT parallel to NS, from which set off the SE by E point BC, and the point C will be the place of the land required; then the distance BC measures 26 miles.

Or thus, describe the circle NES &c, and draw NS and AE cutting each other at right angles in the centre A; which is supposed to be the place of the ship. Draw also AB the NE line, A 1 the E by S, and A 3, the SE by E line. Take AB = 12, and draw BC parallel to A 3, then produce A 1 till it cuts BC in C, so shall C be the point of land, which measures 26 miles as above.



By Computation. Here are given the side AB, and the two angles A and B, viz, the ∠A = 5 points or 56° 15′, and the ∠B = 9 points or 101° 15′; consequently the ∠C = 2 points or 22° 30′. Then, by plane trigonometry,

As sin. ∠C 22° 30′ - - - - 9·58284
To sin. ∠B 56 15 - - - - 9·91985

So is AB 12 miles - - - - 1·07918
To BC 26·073 miles - - - - 1·41619

SAILING *to Windward*, is working the ship towards that quarter of the compass from which the wind blows.

For rightly understanding this part of navigation, it will be necessary to explain the terms that occur in it, though most of them may be seen in their proper places in this work. When the wind is directly, or partly, against a ship's direct course for the place she is bound to, she reaches her port by a kind of zigzag or z like course; which is made by sailing with the wind first on one quarter, and then on the other.

In a ship, when you look towards the head,
Starboard denotes the right hand side;
Larboard, the left hand side;
Forwards, or afore, is towards the head;
Aft, or abaft, is towards the stern. The Beam means athwart or across the middle of the ship.

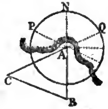
When a ship sails the same way that the wind blows, she is said to sail or run before the wind; and the wind is said to be right aft, or right astern; and her course is then 16 points, or the farthest possible, from the wind, that is, from the point the wind blows from.—When the ship sails with the wind blowing directly across her, she is said to have the wind on the beam; and her course is 8 points from the wind.—When the wind blows obliquely across the ship, the wind is said to be abaft the beam when it pursues her, or blows more on the hinder part, but before the beam when it meets or opposes her course, her course being more than 8 points from the wind in the former case, but less than 8 points in the latter case.—When a ship endeavours to sail towards that point of the compass from which the wind blows, she is said to sail on a wind, or to ply to windward.—And a vessel sailing as near as she can to the point from which the wind blows, is said to be close hauled. Most ships will lie within about 6 points of the wind; but sloops, and some other vessels, will lie much nearer. To know how near the wind a ship will lie; observe the course she goes on each tack, when she is close hauled; then half the number of points between the two courses, will show how near the wind the ship will lie.

The windward, or weather side, is that side of the ship on which the wind blows; and the other side is called the leeward, or lee-side.—Tacks and sheets are large ropes fastened to the lower corners of the fore and main sails; by which either of these corners is hauled fore or aft.—When a ship sails on a wind, the windward tacks are always hauled forwards, and the leeward sheets aft.—The starboard tacks are aboard, when the starboard side is to windward, and the larboard side to leeward. And the larboard tacks are aboard, when the larboard side is to windward, and the starboard to leeward.

The most common cases in turning to windward may be constructed by the following precepts. Having drawn a circle with the chord of 60°, to represent the horizon of the place, quarter it by drawing the meridian and parallel of latitude perpendicular to each other, and both through the centre; mark the place of the wind in the circumference; draw the rhumb passing through the place bound to, and lay on it, from the centre, the distance of that place. On each side of the wind lay off, in the circumference, the points or degrees showing how near the wind the ship can lie; and draw these rhumbs. Now the first course will be on one of these rhumbs, according to the tack the ship leads with. Draw a line through the place bound to, parallel to the other rhumb, and meeting the first; and this will show the course and distance on the other tack.

Ex. The wind being at north, and a ship bound to a port 25 miles directly to windward; beginning with the starboard tacks, what must be the course and distance on each of two tacks to reach the port?

Construction. Having drawn the circle &c, as above described, where A is the port, AP and AQ the two rhumbs, each within 6 points of AN; in NA produced take AB = 25 miles, then B is the place of the ship; draw BC parallel to AP, and meeting QA produced in C; so shall BC and CA be the distances on the two tacks; the former being WNW, and the latter ENE.



Computation.

Here $\angle$B = NAP = 6 points,
and $\angle$A = NAQ = 6 points,
theref. $\angle$C = 4 points.

So that all the angles are given, and the side AB, to find the other two sides AC and BC, which are equal to each other, because their opposite angles A and B are equal. Hence, as sin. C : AB : : sin. A : BC,
i. e. s. 45° : 25 : : s. 67° 30′ : $32\frac{2}{3}$ = BC or AC, the distance to be run on each tack.

SAILING *in Currents*, is the method of determining the true course and distance of a ship when her own motion is affected and combined with that of a current.

A current or tide is a progressive motion of the water, causing all floating bodies to move that way towards which the stream is directed.—The setting of a tide, or current, is that point of the compass towards which the waters run; and the drift of the current is the rate at which it runs per hour.

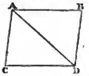
The drift and setting of the most remarkable tides and currents, are pretty well known; but for unknown currents, the usual way to find the drift and setting, is thus: Let three or four men take a boat a little way from the ship; and by a rope, fastened to the boat's stem, let down a heavy iron pot, or loaded kettle, into the sea, to the depth of 80 or 100 fathoms, when it can be done: by which means the boat will ride almost as steady as at anchor. Then heave the log, and the number of knots run out in half a minute will give the rate of the current, or the miles which it runs per hour; and the bearing of the log shows the setting of the current.

A body moving in a current, may be considered in three cases: viz,

1. Moving with the current, or the same way it sets.
2. Moving against it, or the contrary way it sets.
3. Moving obliquely to the current's motion.

In the 1st case, or when a ship sails with a current, its velocity will be equal to the sum of its proper motion, and the current's drift. But in the 2d case, or when a ship sails against a current, its velocity will be equal to the difference of her own motion and the drift of the current: so that if the current drives stronger than the wind, the ship will drive astern, or lose way. In the 3d case, when the current sets oblique to the course of the ship, her real course, or that made good, will be somewhere between that in which the ship endeavours to go, and the direction of the current; and indeed it will always be along the diagonal of a parallelogram, of which one side represents the ship's course set, and the other adjoining side the current's drift.

Let AB be the direction of the wind, or the direction of the vessel when acted on by wind only, and AB the distance the ship would run in any given time, by the action of this force; also let AC be the direction of the current, and the distance the ship would be carried, in the same time as above, by this force only. Draw BD parallel to AC, and CD parallel to AB, meeting BD in D, and join AD; then will AD represent the real course of the vessel when acted on by those two forces conjointly. For the wind neither accelerates nor retards the motion of the ship towards the line CD, the current therefore will bring her there in the same time as if the wind did not act. And in the same manner, the current will have no effect on the motion of the ship in the direction AB, the wind therefore will bring her to the line BD in the same time as if the current did not act. Therefore the ship at the end of that time, will be found in both those lines, that is, in their point of meeting D. Consequently the ship must have passed from A to D in the diagonal AD.



Hence, drawing the rhumbs for the proper course of the ship and of the current, and setting the distances off upon them, according to the quantity run by each in the given time; then forming a parallelogram of these two, and drawing its diagonal, this will be the real course and distance made good by the ship.

Ex. 1. A ship sails E. 5 miles an hour, in a tide setting the same way 4 miles an hour: required the ship's course, and the distance made good.

The ship's motion is 5m. E.
The current's motion is 4m. E.
Theref. the ship's run is 9m. E.

Ex. 2. A ship sails SSW. with a brisk gale, at the rate of 9 miles an hour, in a current setting NNE. 2 miles an hour: required the ship's course, and the distance made good.

The ship's motion is SSW. 9m.
The current's motion is NNE. 2m.
Theref. ship's true run is SSW. 7m.

Ex. 3. A ship running south at the rate of 5 miles an hour, in 10 hours crosses a current, which all that time was setting east at the rate of 3 miles an hour; required the ship's true course and distance sailed.

Here the ship is first supposed to be at A, her imaginary course is along the line AB, which is drawn south, and equal to 50 miles, the run in 10 hours; then draw BC east, and equal to 30 miles, the run of the current in 10 hours. Then the ship is found at C, and her true path is in the line AC = 58·31 her distance, and her course is the angle at A = 30° 58′ from the south towards the east.

Globular SAILING is the estimating the ship's motion and run on principles derived from the globular figure of the earth, viz. her course, distance, and difference of latitude and longitude.

The principles of this method are explained under the articles RHUMB-*line*, *Mercator's* CHART, and MERIDIONAL *Parts*; which see.

Globular Sailing, in the extensive sense here applied to the term, comprehends Parallel Sailing, Middle-latitude Sailing, and Mercator's Sailing; to which may be added Circular Sailing, or Great-circle Sailing. Of each of which it may be proper to give a brief account in this place.

Parallel SAILING is the art of finding what distance a ship should run due east or west, in sailing from the meridian of one place to that of another, in any parallel of latitude.

The computations in parallel sailing depend on the following rule:

As radius,
To cosine of the lat. of any parallel;
So are the miles of long. between any two meridians,
To the dist. of these meridians in that parallel.

Also, for any two latitudes,
As the cosine of one latitude,
Is to the cosine of another latitude;
So is a given meridional dist. in the 1st parallel,
To the like meridional dist. in the 2d parallel.

Hence, counting 60 nautical miles to each degree of longitude, or on the equator; then, by the first rule the number of miles in each degree on the other parallels, will be found as in the following table.

Table of Meridional Distances.

Lat.	Miles.	Lat.	Miles.	Lat.	Miles.
1	59·99	31	51·43	61	29·09
2	59·96	32	50·88	62	28·17
3	59·92	33	50·32	63	27·24
4	59·85	34	49·74	64	26·30
5	59.77	35	49·15	65	25·36
6	59·67	36	48·54	66	24·41
7	59·56	37	47·92	67	23·44
8	59·42	38	47·28	68	22·48
9	59·26	39	46·63	69	21·50
10	59·09	40	45·96	70	20·52
11	58·89	41	45·28	71	19·53
12	58·69	42	44·59	72	18·54
13	58·46	43	43·88	73	17·54
14	58·22	44	43·16	74	16·54
15	57·95	45	42·43	75	15·53
16	57·67	46	41·68	76	14·61
17	57·38	47	40·92	77	13·50
18	57·06	48	40·15	78	12·48
19	56·73	49	39·36	79	11·45
20	56·38	50	38·57	80	10·42
21	56·01	51	37·76	81	9·38
22	55·63	52	36·94	82	8·35
23	55·23	53	36·11	83	7·32
24	54·81	54	35·27	84	6·28
25	54·38	55	34·41	85	5·23
26	53·93	56	33·55	86	4·18
27	53·46	57	32·68	87	3·14
28	52·97	58	31·79	88	2·09
29	52·47	59	30·90	89	1·05
30	51·96	60	30·00	90	0·00

See another table of this kind, allowing $69\frac{1}{11}$ English miles to one degree, under the article DEGREE.

To find the meridional distance to any number of minutes between any of the whole degrees in the table, as for instance in the parallel of 48° 26′; take out the tabular distances for the two whole degrees between which the parallel or the odd minutes lie, as for 48° and 49°; subtract the one from the other, and take the proportional part of the remainder for the odd minutes, by multiplying it by those minutes, and dividing by 60; and lastly, subtract this proportional part from the greater tabular number. Thus,

Lat. 48° - -	40·15	
Lat. 49. - -	39·36	
As 60′ : 26′ : :	0·79	rem. : 0·34
	26	
	474	
	158	
60)	20·54	
	0·34	pro. part
Taken from - -	40·15	for lat. 48°
Leaves merid. dist.	39·81	for lat. 48° 26′.

And, in like manner, by the counter operation, to find what latitude answers to a given meridional distance. As, for ex. in what latitude 46·08 miles answer to a degree of longitude.

From 46·63 for 39°	from 46·63 for 39°
Take 45·96 for 40°	take 46·08 given number.
Then as 0·67 : 60′ : :	0·55 : 49′
	60
	67) 3300
	49′ pro. part.

Therefore the latitude sought is 39° 49′.

Ex. 3. Given the latitude and meridional distance; to find the corresponding difference of longitude. As, if a ship, in latitude 53° 36′, and longitude 10° 18′ east, sail due west 236 miles; required her present longitude.

Here, by the first rule,

As cos. lat.	53° 36′ comp.	0·22664
To radius -	90 00 - -	10·00000
So merid. dist.	236 m. -	2·37291
To diff. long. 397·7	- -	2·59955
Its 60th gives	6° 38′ w. diff. long.	
Taken from	10 18 E. long. from	
Leaves - -	3 40 E. long. come to.	

By the table; the length of a degree on the parallel of 53° 36′ is 35·6.

Then as 35·6 : 60 : : 236 : 397·7, the diff. of long. the same as before.

Middle-latitude SAILING, is a method of resolving the cases of globular sailing by means of the middle latitude between the latitude departed from, and that come to. This method is not quite accurate, being only an approximation to the truth, and it makes use of the principles of plane sailing and parallel sailing conjointly.

The method is founded on the supposition that the departure is reckoned as a meridional distance in that latitude which is a middle parallel between the latitude sailed from, and that arrived at. But the method is not quite accurate, because the arithmetical mean, or half sum of the cosines of two distant latitudes, is not exactly the cosine of the middle latitude, or half the sum of those latitudes; nor is the departure between two places, on an oblique rhumb, equal to the meridional distance in the middle latitude; as is presumed in this method. Yet when the parallels are near the equator, or near to each other, in any latitude, the error is not considerable.

This method seems to have been invented on account of the easy manner in which the several cases may be resolved by the traverse table, and when a table of meridional parts is wanting. The computations depend on the following rules:

1. Take half the sum, or the arithmetical mean, of the two given latitudes, for the middle latitude. Then,

2. As cosine of middle latitude,
   Is to the radius;
   So is the departure,
   To the diff. of longitude. And,
3. As cosine of middle latitude,
   Is to the tangent of the course;
   So is the difference of latitude,
   To the difference of longitude.

Mercator's SAILING, is the art of resolving the several cases of globular sailing, by plane trigonometry, with the assistance of a table of meridional parts, or of logarithmic tangents. And the computations are performed by the following rules:

1. As meridional diff. lat.
   To diff. of longitude;
   So is the radius,
   To tangent of the course.
2. As the proper diff. lat.
   To the departure;
   So is merid. diff. lat.
   To diff. of longitude.
3. As diff. log. tang. half colatitudes,
   To tang. of 51° 38′ 09″;
   So is a given diff. longitude,
   To tangent of the course.

The manner of working with the meridional parts and logarithmic tangents, will appear from the two following cases.

1. Given the latitudes of two places; to find their meridional difference of latitude.

By the Merid. Parts. When the places are both on the same side of the equator, take the difference of the meridional parts answering to each latitude; but when the places are on opposite sides of the equator, take the sum of the same parts, for the meridional difference of latitude sought.

By the Log. Tangents. In the former case, take the difference of the log. tangents of the half colatitudes; but in the latter case, take the sum of the same; then the said difference or sum divided by 12·63, will give the meridional difference of latitude sought.

2. Given the latitude of one place, and the meridional difference of latitude between that and another place; to find the latitude of this latter place.

By the Merid. Parts. When the places have like names, that is both north or both south, take the sum of the merid. parts of the given lat. and the given diff.; but take the difference between the same when they have unlike names; then the result, being found in the table of meridional parts, will give the latitude sought.

By the Log. Tangents. Multiply the given meridional diff. of lat. by 12·63; then in the former case subtract the product from the log. tangent of the given half colatitude, but in the latter case add them; then seek the degrees and minutes answering to the result among the log.

tangents, and these degrees, &c. doubled, will be the co-latitude sought.

Circular SAILING, or *Great-circle* SAILING, is the art of finding what places a ship must go through, and what courses to steer, that her track may be in the arc of a great circle on the globe, or nearly so, passing through the place sailed from and the place bound to.

This method of sailing has been proposed, because the shortest distance between two places on the sphere, is an arc of a great circle intercepted between them, and not the spiral rhumb passing through them, unless when that rhumb coincides with a great circle, which can only be on a meridian, or on the equator.

The solutions of the cases in Mercator's sailing are performed by plane triangles, but in great-circle sailing they are resolved by means of spherical triangles. A great variety of cases might be here proposed, but those that are the most useful, and more commonly occur, pertain to the following problem.

Problem I. Given the latitudes and longitudes of two places on the earth; to find their nearest distance on the surface, together with the angles of position from either place to the other.

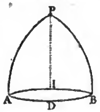
This problem comprehends 6 cases.

Case 1. When the two places lie under the same meridian; then their difference of latitude will give their distance, and the position of one from the other will be directly north and south.

Case 2. When the two places lie under the equator; their distance is equal to their difference of longitude, and the angle of position is a right angle, or the course from one to the other is due east or west.

Case 3. When both places are in the same parallel of latitude. Ex. gr. The places both in 37° north, but the longitude of the one 25° west, and of the other 76° 23′ west.

Let P denote the north pole, and A and B the two places on the same parallel BDA, also BIA their distance asunder, or the arc of a great circle passing through them. Then is the angle A or B that of position, and the angle BPA = 51° 23′ the difference of longitude, and the side PA or PB = 53° the colatitude.



Draw PI perp. to AB, or bisecting the angle at P. Then in the triangle API, right-angled at I, are given the hypothenuse AP = 53°, and the angle APT = 25° 41′ 30″; to find the angle of position A or B = 73° 51′; and the half distance AI = 20° 15′¼; this doubled gives 40° 31′ for the whole distance AB, or 2431 nautical miles, which is 31 miles less than the distance along ADB, or by parallel sailing.

Case 4. When one place has latitude, and the other has none, or is under the equator. For example, suppose the Island of St. Thomas, lat. 0°, and long. 1° 0′ east, and Port St. Julian, in lat. 48° 51′ south, and long. 65° 10′ west.

Port St. Julian, lat.	48° 51′ S.	- long.	65° 10′ W.
Isle St Thomas -	0 00	- - - -	1 00 E.
Julian's colat. -	41 09	Diff. long.	66 10

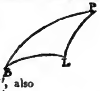
Hence, if S denote the south pole, A the Isle St. Thomas at the equator, and B St. Julian; then in the triangle are given SA a quadrant or 90°, BS = 41° 9′ the colat. of St. Julian, and the ∠S = 66° 10′ the dif. of longitude; to find AB = 74° 85′ = 4475 miles, which is less by 57 miles than th distance found by Mercator's sailing; also the angle of position at A = 51° 22′, and the angle of position B = 108° 24.

Case 5. When the two given places are both on the same side of the equator; for example the Lizard, and the island of Bermudas.

The Lizard, lat.	49° 57′ N.	- long.	5° 21′ W.
Bermudas,	32 35 N.	- -	63 32 W.
			58 11

Here, if P be the north pole, L the Lizard, and B Bermudas; there are given,

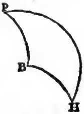
PL = 40° 03′ colat. of the Lizard,
PB = 57 25 colat. of Bermudas,
∠P = 58 11 diff. of longitude; to find BL = 45° 44′ = 2744 miles the distance, and
∠ of position B = 49° 27′, also
∠ of position L = 90° 31′.



Case 6. When the places lie on different sides of the equator; as suppose St. Helena and Bermudas. Here

PB = 57° 25′ polar dist. Bermudas,
PH = 105 55 polar dist. St. Helena,
∠P = 57 43 diff. long.

To find BH = 73° 26′ = 4406 miles, the distance, also the angle of position H = 48° 0′, and the angle of position B = 121° 59′.



From the solutions of the foregoing cases it appears, that to sail on the arc of a great circle, the ship must continually alter her course; but as this is a difficulty too great to be admitted into the practice of navigation, it has been thought sufficiently exact to employ a kind of approximation, that is, by a method which nearly approaches to the sailing on a great circle: namely, on this principle, that in small arcs, the difference between the arc and its chord or tangent is so small, that they may be taken for each other in any nautical operations: and accordingly it is supposed that the great circles on the earth are made up of short right lines, each of which is a segment of a rhumb line. On this supposition the solution of the following problem is deduced.

Problem II. Having given the latitudes and longitudes of the places sailed from and bound to; to find the successive latitudes on the arc of a great circle in those places where the alteration in longitude shall be a given quantity; together with the courses and distances between those places.

1. Find the angle of position at each place, and their distance, by one of the preceding cases.

2. Find the greatest latitude the great circle runs through, i. e. find the perpendicular from the pole to that circle; and also find the several angles at the pole, made by the given alterations of longitude between this perpendicular and the successive meridians come to.

3. With this perpendicular and the polar angles severally, find as many corresponding latitudes, by saying, as radius : tang. greatest lat. : : cos. 1st polar angle : tang. 1st lat. : : cos. 2d polar angle : tang. of 2d lat. &c.

4. Having now the several latitudes passed through, and the difference of longitude between each, then by Merca-

tor's sailing find the courses and distances between those latitudes. And these are the several courses and distances the ship must run, to keep nearly on the arc of a great circle.

The smaller the alterations in longitude are taken, the nearer will this method approach to the truth; but it is sufficient to compute to every 5 degrees of difference of longitude; as the length of an arc of 5 degrees differs from its chord, or tangent, only by 0 002.

The track of a ship, when thus directed nearly in the arc of a great circle, may be delineated on the Mercator's chart, by marking on it, by means of the latitudes and longitudes, the successive places where the ship is to alter her course; then those places or points, being joined by right lines, will show the path along which the ship is to sail, under the proposed circumstances.—On the subject of these articles, see Robertson's Elements of Navigation, vol. 2.

Spheroidical SAILING, is computing the cases of navigation on the supposition or principles of the spheroidical figure of the earth. See Robertson's Navigation, vol. 2, b. 8, sect. 8.

Sailing, *in a more confined sense*, is the art of conducting a ship from place to place, by the working or handling of her sails and rudder.—To bring sailing to certain rules, M. Renau computes the force of the water, against the ship's rudder, stem, and side; and the force of the wind against her sails. In order to this, he first considers all fluid bodies, such as the air, water, &c, to be composed of little particles, which when they act upon any surface, all move parallel to one another, or strike against the surface after the same manner. Secondly, that the motion of any body, with regard to the surface it strikes, must be either perpendicular, parallel, or oblique. From these principles he computes, that the force of the air or water, striking perpendicularly upon a sail or rudder, is to the force of the same striking obliquely, in the duplicate ratio of radius to the sine of the angle of incidence: and consequently that all oblique forces of the wind against the sails, or of the water against the rudder, will be to each other in the duplicate ratio of the sines of the angles of incidence.—Such are the conclusions from theory; but it is very different in real practice, or experiments, as appears from the tables inserted in the article RESISTANCE.

Further, when the different degrees of velocity are considered, it is also found that the forces are as the squares of the velocities of the moving air or water nearly; that is, a wind that blows twice as swift, as another, will act with 4 times the force upon the sail; and when 3 times as swift, 9 times the force, &c. And it being also indifferent, whether we consider the motion of a solid in a fluid at rest, or of the fluid against the solid at rest; therefore, the reciprocal impressions being always the same, if a solid be moved with different velocities in the same fluid matter, as water, the different resistances which it will receive from that water, will be in the same proportion as the squares of the velocities of the moving body.

He then applies these principles to the motions of a ship, both forwards and sideways, through the water, when the wind, with certain velocities, strikes the sails in various positions. After which, the author proceeds to demonstrate, that the best position or situation of a ship, so that she may make the least lee-way, or side motion, but go to windward as much as possible, is this: that, let the sail have what situation it will, the ship must be always in a line bisecting the complement of the wind's angle of incidence on the sail. That is, supposing the sail in the position BC, and the wind blowing from A to B, and consequently the angle of the wind's incidence on the sail is ABC, the complement of which is CBE: then must the ship be put in the position BK, or move in the line BL, bisecting the ∠CBE.

He shows further, that the angle which the sail ought to make with the wind, i. e. the angle ABC, ought to be but 24 degrees; that being the most advantageous situation for working to windward.

To this might be added many curious particulars from Borelli de Vi Percussionis, concerning the different directions given to a vessel by the rudder, when sailing with a wind, or floating without sails in a current: in the former case, the head of the ship always coming to the rudder, and in the latter always flying off from it; as also from Euler, Bouguer, and Juan, who have all written learnedly on this subject.

SALIANT, in Fortification, is said of an angle that projects its point outwards; in opposition to a re-entering angle, which has its point turned inwards. Instances of both kinds of these occur in tenailles and star-works.

SALON, or SALOON, in Architecture, a grand, lofty, spacious kind of hall, vaulted at top, and usually comprehending two stories, with two ranges of windows: and may be either square, round, oval, or octagonal.

SAP, or SAPP, in Building, as to sap a wall, &c, is to dig out the ground from beneath it, so as to bring it down all at once for want of support.

SAP, in the Military Art, denotes a work carried on under cover of gabions and fascines on the flank, and mantlets or stuffed gabions on the front, to gain the descent of a ditch, or the like. It is performed by digging a deep trench, descending by steps from top to bottom, under a corridor, carrying it as far as the bottom of the ditch, when that is dry; or as far as the surface of the water, when wet.

SAROS, in Chronology, a period of 223 lunar months. The etymology of the word is said to be Chaldean, signifying restitution, or return of eclipses; that is, conjunctions of the sun and moon in nearly the same place of the ecliptic. The Saros was a cycle like to that of Meto.

SARRASIN, or SARRAZIN, in Fortification, a kind of port cullis, otherwise called a herse, which is hung with ropes over the gate of a town or fortress, to be let fall in case of a surprise.

SATELLITES, in Astronomy, are certain secondary planets, moving round the other planets, as the moon does round the earth. They are so called because always found attending them, from rising to setting, and making the tour about the sun together with them. The words moon and satellite are sometimes used indifferently: thus we say, either Jupiter's moons, or Jupiter's satellites; but usually we restrain the term moon to the earth's attendant, and apply that of satellite to the little moons discovered about Jupiter, Saturn, and Uranus, by the assistance of the telescope, which is necessary to render them visible.

The satellites move about their primary planets, as a centre, by the same laws as those primary ones do round their centre the sun; viz, in such a manner that, in the satellites of the same planet, the squares of the periodic times are proportional to the cubes of their distances from the primary planet. For the physical cause of their motions, see Gravity. See also Planets.

We know not of any satellites besides those above mentioned; what other discoveries may be made by further improvements in telescopes, time only can bring to light.

Satellites *of Jupiter*. There are 4 little moons, or satellites now known to perform their evolutions about Jupiter, as that planet does about the sun.

Simon Marius, mathematician of the elector of Brandenburg, about the end of November 1609, is said to have observed three little stars moving round Jupiter's body, and proceeding along with him; and in January 1610, he found a 4th. In January 1610 Galileo also observed the same in Italy, and in the same year published his observations. And indeed Montucla gives the honour of the first discovery entirely to Galileo. These satellites were also observed in the same month of January 1710, by Thomas Harriot, the celebrated author of a work on algebra, and who made constant observations of them, from that time till the 26th of February 1612; as appears by his curious astronomical papers, lately discovered by Dr. Zach, at the seat of the earl of Egremont, at Petworth in Sussex.

When Jupiter is in a line with any of his satellites and the sun, the satellite disappears, being then eclipsed, or involved in his shadow.—When the satellite goes behind the body of Jupiter, with respect to an observer on the earth, it is then said to be occulted, being hid from our sight by his body, whether in his shadow or not.—And when the satellite comes into a position between Jupiter and the sun, it casts a shadow upon the face of that planet, which we see as an obscure round spot.—Lastly, when the satellite is in a line between Jupiter and us, it is said to transit the disc of the planet, upon which it appears as a round black spot.

The periods or revolutions of Jupiter's satellites, are found out from their conjunctions with that planet; after the same manner, as those of the primary planets are discovered from their oppositions to the sun. And their distances from the body of Jupiter are measured by a micrometer, and estimated in semidiameters of that planet, and thence in miles. By the latest and most exact observations, the periodical times and distances of these satellites, and the angles under which their orbits are seen from the earth, at its mean distance from Jupiter, are as below:

Satellites *of* Jupiter.

Satellites.	Periodic Time.	Distances in		Angles of Orbit.
		Semidiameters.	Miles.	
1	1ᵈ 18ʰ 27ᵐ 34ˢ	$5\frac{2}{3}$	266,000	3′ 55″
2	3 13 13 42	$9\frac{4}{15}$	423,000	6 14
3	7 3 42 33	$14\frac{4}{17}$	676,000	9 58
4	16 16 31 50	$25\frac{3}{10}$	1,189,000	17 30

The eclipses of the satellites, especially of those of Jupiter, are of very great use in astronomy. First, in determining pretty exactly the distance of Jupiter from the earth. A second advantage still more considerable, which is drawn from these eclipses, is the proof which they give of the progressive motion of light. It is demonstrated by these eclipses, that light does not come to us in an instant, as the Cartesians pretended, though its motion is extremely rapid. For if the motion of light were infinite, or came to us in an instant, it is evident that we should see the commencement of an eclipse of a satellite at the same moment, at whatever distance we might be from it; but, on the contrary, if light move progressively, then it is as evident, that the farther we are from a planet, the later we shall be in seeing the moment of its eclipse, because the light will take up a longer time in arriving at us; and so it is found in fact to happen, the eclipses of these satellites appearing always later and later than the true computed times, as the earth removes farther and farther from the planet. When Jupiter and the earth are nearest to each other; that is, when they are in conjunction on the same side of the sun; then the eclipses are observed to happen about $7\frac{1}{2}$ minutes before the computed time for the mean distance; and when those two planets are at their greatest distance, being then in opposition, the eclipses happen about $7\frac{1}{2}$ minutes after the time predicted by calculation. Now the difference between the least and greatest distance being equal to the diameter of the earth's orbit, it therefore follows that light takes up a quarter of an hour in travelling across the orbit of the earth, or near 8 minutes in passing from the sun to the earth; which gives about 12 millions of miles per minute, or 200,000 miles per second, for the velocity of light. A discovery that was first made by M. Roemer.

The third and greatest advantage derived from the eclipses of Jupiter's satellites, (and which was hinted at by Galileo on the first discovery of them,) is the knowledge of the longitudes of places on the earth. Suppose two observers of an eclipse, the one, for example, at London, the other at the Canaries; it is certain that the eclipse will appear at the same moment to both observers; but as they are situated under different meridians, they count different hours, being perhaps 9 o'clock to the one, when it is only 8 to the other; by which observations of the true time of the eclipse, on communication, they find the difference of their longitude to be one hour in time, which answers to 15 degrees of longitude.

To the above we may also add, that this discovery had a very considerable influence in eradicating the errors of the ancient astronomers, and consequently in firmly establishing the Copernican system; as a supporter of which, the venerable discoverer, Galileo, was, at this time, smarting under the recollection of the condemnation which had been passed upon him, by that most detestable of all tyrannies, the inquisition.

Satellites *of Saturn*, are 7 in number revolving about him. One of them, which till lately was reckoned the 4th in order from Saturn, was discovered by Huygens, the 25th of March 1655, by means of a telescope 12 feet long, and the 1st, 2d, 3d, and 5th, at different times, by Cassini; viz, the 5th in October 1671, by a telescope of 17 feet; the 3d in December 1672, by a telescope of Campani's, 35 feet long; and the first and second in March 1684, by help of Campani's Glasses, of 100 and 136 feet. Finally, the 6th and 7th satellites have lately been discovered by Dr. Herschel, with his 40 feet reflecting telescope, viz, the 6th on the 19th of August 1787, and the 7th on the 17th of September 1788. These two he has called the 6th and 7th satellites, though they are nearer to the planet Saturn than any of the former five, that the names or numbers of these might not be mistaken or confounded, with regard to former observations of them.

Moreover, the great distance between the 4th and 5th satellite gave occasion to Huygens to suspect that there might be some intermediate one, or else that the 5th might have some other satellite moving round it, as its centre. Dr. Halley, in the Philos. Trans. (No. 145,) gives a correction of the theory of the motions of the 4th or Huygenian satellite. Its true period he makes 11d 22h 41m 6s.

The periodical revolutions, and distances of these satellites from the body of Saturn, expressed in semidiameters of that planet, and in miles, are as follow.

SATELLITES *of* SATURN.

Satellites.	Periods.	Distances in		Diameter of Orbit.
		Semidiameters.	Miles.	
1	$1^d\,21^h\,18'\,26''$	$4\frac{3}{8}$	170,000	$1'\ 27''$
2	2 17 44 51	$5\frac{5}{8}$	217,000	1 52
3	4 12 25 11	8	303,000	2 36
4	15 22 41 14	18	704,000	6 18
5	79 7 54 37	54	2,050,000	17 4
6	1 8 53 9	$3\frac{5}{8}$	135,000	1 14
7	0 22 37 30	2 [illegible]	107,000	0 57

The first four describe ellipses like to those of the ring, and are in the same plane. Their inclination to the ecliptic is from 30 to 31 degrees. The 5th describes an orbit inclined from 17 to 18 degrees with the orbit of Saturn; his plane lying between the ecliptic and those of the other satellites, &c. Dr. Herschel observes that the 5th satellite turns once round its axis exactly in the time in which it revolves about the planet Saturn; in which respect it resembles our moon, which does the same thing. And he makes the angle of its distance from Saturn, at his mean distance, 17′ 2″. Philos. Trans. 1792, pa. 22. See a long account of observations of these satellites, with tables of their mean motions, by Dr. Herschel, Philos. Trans. 1790, pa. 427 &c.

SATELLITES *of Herschel*, or *Uranus*, are 6 little moons that revolve about him, like those of Jupiter and Saturn. These satellites were discovered by Dr. Herschel, who gave an account of them in the Philos. Trans, from which it appears that their synodical periods, and angular distances from their primary, are as follow:

Satellite.	Sidereal Revolution.	Mean Dist.
1	$5^d\,21^h\,25^m\,21^s$	$0'\ 25{\cdot}5''$
2	8 16 57 48	0 33·0
3	10 23 3 59	0 38·6
4	13 10 56 30	0 44·2
5	38 1 48 0	0 88·4
6	107 16 39 56	0 176·8

The orbits of these satellites are nearly perpendicular to the ecliptic, and contrary to the order of the signs. In magnitude they are probably not less than those of Jupiter.

SATELLITE *of Venus*. Cassini thought he saw one, and Mr. Short and other astronomers have suspected the same thing. (Hist. de l'Acad. 1741, Philos. Trans. No. 459.) But the many fruitless searches that have been since made to discover it, leave room to suspect that it has been only an optical illusion, formed by the glasses of telescopes; as appears to be the opinion of F. Hell, at the end of his Ephemeris for 1766, and Boscovich, in his 5th Optical Dissertation.—Neither has it been discovered that either of the other planets have any satellites revolving about them. It is remarkable that our moon, and some of the other satellites, as far as they have been observed, keep always the same face or side towards their respective primaries; around which they appear to be moved as a stone is whirled round in a sling.

SATURDAY, the 7th or last day of the week, so called, as supposed, from the idol Seater, worshipped on this day by the ancient Saxons, and thought to be the same as the Saturn of the Latins. In astronomy, every day of the week is denoted by some one of the planets, and this day is marked with the planet ♄ Saturn. Saturday answers to the Jewish sabbath.

SATURN, one of the primary planets, being the 10th in order of distance from the sun, and the outermost of all, except the planet Herschel, is marked with the character ♄, denoting an old man supporting himself with a staff, representing the ancient god Saturn.

Saturn shines with but a feeble light, partly on account of his great distance, and partly from his dull red colour. This planet is perhaps one of the most engaging objects that astronomy offers to our view; it is surrounded with a double ring, one without the other, and beyond these by 7 satellites, most of them in the plane of the rings; the rings and planets being all dark and dense bodies, like Saturn himself, these bodies casting their shadows mutually upon each other; though the reflected light of the rings is usually brighter than that of the planet itself.

Saturn has also certain obscure zones, or belts, appearing at times across his disc, like those of Jupiter, which are changeable, and are probably obscurations in his atmosphere. Dr. Herschel, Philos. Trans. 1790, shows that Saturn has a dense atmosphere; that he revolves about an axis, which is perpendicular to the plane of the rings; that his figure is, like the other planets, the oblate spheroid, being flatted at the poles, the polar diameter being to the equatorial one as 10 to 11; that his ring has a motion of rotation in its own plane, its axis of motion being the same as that of Saturn himself, and its periodical time equal to 10h 32m 15s·4. See also RING, and SATELLITE.

Concerning the discovery of the ring and figure of Saturn, we find that Galileo first perceived that his figure is not round: but Huygens showed, in his Systema Saturniana 1659, that this was owing to the positions of his ring; for his spheroidical form could only be seen by Herschel's telescope; though indeed Cassini, in an observation made June 19, 1692, saw the oval figure of Saturn's shadow upon his ring.

Mr. Bugge determines (Philos. Trans. 1787, pa. 42) the heliocentric longitude of Saturn's descending node to be $9^s\,21^\circ\,5'\,8''\frac{1}{4}$; and that the planet was in that node August 21, 1784, at $18^h\,20^m\,10^s$ time, at Copenhagen.

The annual period of Saturn about the sun, is 10759 days 7 hours, or almost 30 years; and his diameter is about 67000 miles, or near $8\frac{1}{2}$ times the diameter of the earth; also his distance is about $9\frac{1}{2}$ times that of the earth. Hence some have concluded that his light and heat are entirely unfit for rational inhabitants. But that their light is not so weak as we imagine, is evident from its brightness in the night-time. Besides, allowing the sun's light to be 45000 times as strong, with respect to us, as the light of the moon when full, the sun will afford 500 times as much light to Saturn as the full moon does to us, and 1600 times as much to Jupiter. So that these two planets, even without any moon, would be much more enlightened than we at first imagine; and by having so many, they may be very comfortable places of residence. Their heat, so far as it depends on the force of the sun's rays, is certainly much less than ours; to which no doubt the bodies of their inhabitants are as well adapted as ours are to the seasons we enjoy. And if it be considered that Jupiter never has any winter, even at his poles, which probably is also the case with Saturn, the cold cannot be so intense on these two planets as is generally imagined. To this may be added, that there may be something in the nature of their soil warmer than in that of our earth; and we find that all our heat does not depend on the rays of the sun; for if it did, we should always have the same months equally hot or cold at their annual return, which is very far from being the case.

See the articles PLANET, PERIOD, RING, SATELLITE.

SAUCISSE, in Artillery, a long train of powder inclosed in a roll or pipe of pitched cloth, and sometimes of leather, about 2 inches in diameter; serving to set fire to mines or caissons. It is usually placed in a wooden pipe, called an auget, to prevent its growing damp.

SAUCISSON, in Fortification, a kind of faggot, made of thick branches of trees, or of the trunks of shrubs, bound together, for the purpose of covering the men, and to serve as epaulements; and also to repair breaches, stop passages, make traverses over a wet ditch, &c. The saucisson differs from the fascine, which is only made of small branches; and by its being bound at both ends, and in the middle.

SAVILLE (Sir HENRY), a very learned Englishman, the second son of Henry Saville, esq. was born at Bradley, near Halifax, in Yorkshire, November the 30th, 1549. He was entered of Merton-college, Oxford, in 1561, where he took the degree B. A., and was chosen fellow. He became master of arts in 1570, having read for that degree on the Almagest of Ptolemy, which procured him the reputation of a man eminently skilled in mathematics and the Greek language; in the former of which he gratuitously read a public lecture in the university for some time.

In 1578 he travelled into France and other countries; where, diligently improving himself in all useful learning, in languages, and the knowledge of the world, he became a most accomplished gentleman. At his return, he was made tutor in the Greek tongue to queen Elizabeth, who had a great esteem for him.

In 1585 he was made warden of Merton-college, which he governed six-and-thirty years with great honour, and improved it by all the means in his power.—In 1596 he was chosen provost of Eton-college; which he filled with many learned men.—James the First, on his accession to the crown of England, expressed a great regard for him, and would have preferred him either in church or state; but Saville declined these offers, and only accepted the ceremony of knighthood from the king at Windsor in 1604. His only son Henry dying about that time, he thenceforth devoted his fortune to the promoting of learning. Among other things, in 1619, he founded, in the university of Oxford, two lectures, or professorships, one in geometry, the other in astronomy; which he endowed with a salary of 160l. a year each, besides a legacy of 600l. to purchase more lands for the same use. He also furnished a library with mathematical books near the mathematical school, for the use of his professors; and gave 100l. to the mathematical chest of his own appointing: adding afterwards a legacy of 40l. a year to the same chest, to the university, and to his professors jointly. He likewise gave 120l. towards the new building of the schools, besides several rare manuscripts and printed books to the Bodleian library; and a good quantity of Greek types to the printing-press at Oxford.

After a life thus spent in the encouragement and promotion of science and literature in general, he died at Eton-college the 19th of February 1622, in the 73d year of his age, and was buried in the chapel there. On this occasion, the university of Oxford paid him the greatest honours, by having a public oration and verses made in his praise, which were published soon after in 4to, under the title of Ultima Linea Savilii.

As to the character of Saville, the highest encomiums are bestowed on him by all the learned of his time: by Casaubon, Mercerus, Meibomius, Joseph Scaliger, and especially the learned bishop Montague; who, in his Diatribæ upon Selden's History of Tythes, styles him, "that magazine of learning, whose memory shall be honourable amongst not only the learned, but the righteous for ever."

Several noble instances of his munificence to the republic of letters have already been mentioned; in the account of his publications many more, and even greater, will appear. These are,

1. Four Books of the Histories of Cornelius Tacitus, and the Life of Agricola; with Notes upon them, in folio, dedicated to Queen Elizabeth, 1581.

2. A View of certain Military Matters, or Commentaries concerning Roman Warfare, 1598.

3. Rerum Anglicarum Scriptores post Bedam, &c. 1596. This is a collection of the best writers of our English history; to which he added chronological tables at the end, from Julius Cæsar to William the Conqueror.

4. The Works of St. Chrysostom, in Greek, in 8 vols. folio, 1613. This is a very fine edition, and composed with great cost and labour. In the preface he says, "that having himself visited, about 12 years before, all the public and private libraries in Britain, and copied out thence whatever he thought useful to this design, he then sent some learned men into France, Germany, Italy, and the East, to transcribe such parts as he had not already, and to collate the others with the best manuscripts." At the same time, he makes his acknowledgments to several eminent men for their assistance; as Thuanus, Velserus, Schottus, Casaubon, Ducæus, Gruter, Hoeschelius, &c. In the 8th volume are inserted Sir Henry Saville's own notes, with those of other learned men. The whole charge of this edition, including the several sums paid to learned men, at home and abroad, employed in finding out, transcribing, and collating the best manuscripts, is said to have amounted to no less than 8000l. A still more sumptuous and voluminous edition was afterwards printed at Paris, in 13 folio volumes, by the Benedictines and the learned Montfaucon, the 1st vol. in 1718, and the last in 1738.

5. In 1618 he published a Latin work, written by Thomas Bradwardin, abp. of Canterbury, against Pelagius, intitled, De Causa Dei contra Pelagium, et de vir-

tute causarum; to which he prefixed the life of Bradwardin.

6. In 1621 he published a collection of his own Mathematical Lectures on Euclid's Elements; in 4to.

7. Oratio coram Elizabetha Regina Oxoniæ habita, anno 1592. Printed at Oxford in 1658, in 4to.

8. He translated into Latin king James's Apology for the Oath of Allegiance. He also left several manuscripts behind him, written by order of king James; all which are in the Bodleian library. He wrote notes also on the margin of many books in his library, particularly Eusebius's Ecclesiastical History; which were afterwards used by Valesius, in his edition of that work in 1659.—Four of his letters to Camden are published by Smith, among Camden's Letters, 1691, 4to.

Sir Henry Saville had a younger brother, THOMAS SAVILLE, who was admitted probationer fellow of Merton-college, Oxford, in 1580. He afterwards travelled abroad into several countries. On his return he was chosen fellow of Eton-college; but he died at London in 1593. Thomas Saville was also a man of great learning, and an intimate friend of Camden; among whose letters, just mentioned, there are 15 of Mr. Saville's to him.

SAUNDERSON (Dr. NICHOLAS), an eminent professor of mathematics in the university of Cambridge, and a fellow of the Royal Society, was born at Thurlston in Yorkshire in 1682. When he was but twelve months old, he lost not only his eye-sight, but his very eye-balls, by the small-pox; so that he could retain no more ideas of vision than if he had been born blind. At an early age, however, being of very promising parts, he was sent to the free-school at Penniston, and there laid the foundation of that knowledge of Greek and Latin languages, which he afterwards improved so far, by his own application to the classic authors, as to hear the works of Euclid, Archimedes, and Diophantus read in their original Greek.

Having acquired a grammatical education, his father, who was in the excise, instructed him in the common rules of arithmetic. And here it was that his excellent mathematical genius first appeared: for he very soon became able to work the common questions, to make long calculations by the strength of his memory, and to form new rules to himself for the better resolving of such problems as are often proposed to learners as trials of skill.

At the age of 18, our author was introduced to the acquaintance of Richard West, of Underbank, Esq. a lover of mathematics, who, observing Mr. Saunderson's uncommon capacity, took the pains to instruct him in the principles of algebra and geometry, and gave him every encouragement in his power to the prosecution of these studies. Soon after this he became acquainted also with Dr. Nettleton, who took the same pains with him. And it was to these two gentlemen that Mr. Saunderson owed his first institution in the mathematical sciences: they furnished him with books, and often read and expounded them to him. But he soon surpassed his masters, and became fitter to teach, than to learn any thing from them.

His father, otherwise burdened with a numerous family, finding a difficulty in supporting him, his friends began to think of providing both for his education and maintenance. His own inclination led him strongly to Cambridge, and it was at length determined that he should try his fortune there, not as a scholar, but as a master: or, if this design should not succeed, they promised themselves success in opening a school for him at London. Accordingly he went to Cambridge in 1707, being then 25 years of age, and his fame in a short time filled the university. Newton's Principia, Optics, and Universal Arithmetic, were the foundations of his lectures, and afforded him a noble field for the display of his genius; and great numbers came to hear a blind man give lectures on optics, discourse on the nature of light and colours, explain the theory of vision, the effect of glasses, the phenomenon of the rainbow, and other objects of sight.

As he instructed youth in the principles of the Newtonian philosophy, he soon became acquainted with its incomparable author, though he had several years before left the university; and frequently conversed with him on the most difficult parts of his works: he also held a friendly communication with the other eminent mathematicians of the age, Halley, Cotes, Demoivre, &c.

Mr. Whiston was during this time in the mathematical professor's chair, and read lectures in the manner proposed by Mr. Saunderson on his settling at Cambridge; so that an attempt of this kind looked like an encroachment on the privilege of his office; but, as a good-natured man, and an encourager of learning, he readily consented to the application of friends made in behalf of so uncommon a person.

On the removal of Mr. Whiston from his professorship, Mr. Saunderson's merit was thought so much superior to that of any other competitor, that an extraordinary step was taken in his favour, to qualify him with a degree, which the statute requires: in consequence he was chosen, in 1711, Mr. Whiston's successor in the Lucasian professorship of mathematics, Sir Isaac Newton interesting himself greatly in his favour. His first performance, after he was seated in the chair, was an inaugural speech made in very elegant latin, and a style truly Ciceronian; for he was well versed in the writings of Tully, who was his favourite in prose, as Virgil and Horace were in verse. From this time he applied himself closely to the reading of lectures, and gave up his whole time to his pupils. He continued to reside among the gentlemen of Christ-college till the year 1723, when he took a house in Cambridge, and soon after married a daughter of Mr. Dickens, rector of Boxworth in Cambridgeshire, by whom he had a son and a daughter.

In the year 1728, when king George visited the university, he expressed a desire of seeing so remarkable a person; and accordingly our professor attended his majesty in the senate, and by his favour was there created doctor of laws.

Dr. Saunderson was naturally of a strong healthy constitution; but being too sedentary, and constantly confining himself to the house, he became a valetudinarian: and in the spring of the year 1739 he complained of a numbness in his limbs, which ended in a mortification in his foot, of which he died the 19th of April that year, in the 57th year of his age.

There was scarcely any part of the mathematics on which Dr. Saunderson had not composed something for the use of his pupils. But he discovered no intention of publishing any thing till, by the persuasion of his friends, he prepared his Elements of Algebra for the press, which after his death were published by subscription in 2 vols 4to, 1740.

He left many other writings, though none perhaps prepared for the press. Among these were some valuable comments on Newton's Principia, which not only explain the more difficult parts, but often improve upon the doctrine itself. These are published in Latin at the end of his posthumous Treatise on Fluxions, a valuable work, published in 8vo, 1756.—His manuscript lectures too, on most parts of natural philosophy, which I have seen, might make a considerable volume, and prove an acceptable present to the public if printed.

Dr. Saunderson, as to his character, was a man of much wit and vivacity in conversation, and esteemed an excellent companion. He was endued with a great regard to truth; and was such an enemy to disguise, that he thought it his duty to speak his thoughts at all times with unrestrained freedom. Hence his sentiments on men and opinions, his friendship or disregard, were expressed without reserve; a sincerity which raised him many enemies.

A blind man, moving in the sphere of a mathematician, seems a phenomenon difficult to be accounted for, and has excited the admiration of every age in which it has appeared. Tully mentions it as a thing scarce credible in his own master in philosophy, Diodotus; that he exercised himself in it with more assiduity after he became blind; and what he thought next to impossible to be done without sight, that he professed geometry, describing his diagrams so exactly to his scholars, that they could draw every line in its proper direction. St. Jerome relates a still more remarkable instance in Didymus of Alexandria, who, though blind from his infancy, and therefore ignorant of the very letters, not only learned logic, but geometry also to very great perfection, which seems most of all to require sight. But, if we consider that the ideas of extended quantity, which are the chief objects of mathematics, may as well be acquired by the sense of feeling as that of sight, that a fixed and steady attention is the principal qualification for this study, and that the blind are by necessity more abstracted than others (for which reason it is said that Democritus put out his eyes, that he might think more intensely), we shall perhaps find reason to suppose that there is no branch of science so much adapted to their circumstances.

At first, Dr. Saunderson acquired most of his ideas by the sense of feeling; and this, as is commonly the case with the blind, he enjoyed in great perfection. Yet he could not, as some are said to have done, distinguish colours by that sense; for, after having made repeated trials, he used to say, it was pretending to impossibilities. But he could with great nicety and exactness observe the smallest degree of roughness or defect of polish in a surface. Thus, in a set of Roman medals, he distinguished the genuine from the false, though they had been counterfeited with such exactness as to deceive a connoisseur who had judged by the eye. By the sense of feeling also, he distinguished the least variation; and he has been seen in a garden, when observations have been making on the sun, to take notice of every cloud that interrupted the observation almost as justly as they who could see it. He could also tell when any thing was held near his face, or when he passed by a tree at no great distance, merely by the different impulse of the air on his face.

His ear was also equally exact. He could readily distinguish the 5th part of a note. By the quickness of this sense he could judge of the size of a room, and of his distance from the wall. And if ever he walked over a pavement, in courts or piazzas which reflected a sound, and was afterwards conducted thither again, he could tell in what part of the walk he stood, merely by the note it sounded.

Dr. Saunderson had a peculiar method of performing arithmetical calculations, by an ingenious machine and method, which is particularly described in a piece prefixed to the first volume of his Algebra. That he was able to make long and intricate calculations, both arithmetical and algebraical, is a thing as certain as it is wonderful. He had contrived for his own use, a commodious notation for any large numbers, which he could express on his abacus, or calculating table, and with which he could readily perform any arithmetical operations, by the sense of feeling only, for which reason it was called his Palpable Arithmetic.

His calculating table was a smooth thin board, a little more than a foot square, raised upon a small frame so as to lie hollow; which board was divided into a great number of little squares, by lines intersecting one another perpendicularly, and parallel to the sides of the table, and the parallel ones only one-tenth of an inch from each other; so that every square inch of the table was thus divided into 100 little squares. At every point of intersection the board was perforated by small holes, capable of receiving a pin; for it was by the help of pins, stuck up to the head through these holes, that he expressed his numbers. He used two kinds of pins, a larger and a smaller sort; at least their heads were different, and might easily be distinguished by feeling. Of these pins he had a large quantity in two boxes, with their points cut off, which always stood ready before him when he calculated. The writer of that account describes particularly the whole process of using the machine, and concludes, "He could place and displace his pins with incredible nimbleness and facility, much to the pleasure and surprize of all the beholders. He could even break off in the middle of a calculation, and resume it when he pleased, and could presently know the condition of it, by only drawing his fingers gently over the table."

SAURIN (Joseph), an ingenious French mathematician, was born in 1659, at Courtaison, in the principality of Orange. His father, minister at Grenoble, was a man of a very studious disposition, and was the first preceptor or instructor to our author; who made a rapid progress in his studies, and at a very early age was admitted a minister at Eure in Dauphiny: but preaching an offensive sermon, he was obliged to quit France in 1683. On this occasion he retired to Geneva; whence he went into the State of Berne, and was appointed to a living at Yverdun. He was no sooner established in this his situation, than certain theologians raised a clamour against him. Saurin, disgusted with the controversy, and still more with the Swiss, where his talents were buried, passed into Holland, and from thence into France, where he put himself under the protection of the celebrated Bossu, to whom he made his abjuration in 1690, as it is suspected, that he might find protection, and have an opportunity of cultivating the sciences at Paris. And in this he was not disappointed: he met with many flattering encouragements; was even much noticed by the king, had a pension from the court, and was admitted of the Academy of Sciences in 1707, in the quality of geometrician. This science was now his chief study and delight; with many writings upon which he enriched the volums of the Journal des Savans, and the Memoirs of the Academy of Sciences. These were the only works of this kind that he published:

he was author of several other pieces of a controversial nature, against the celebrated Rousseau, and other antagonists, over whom, with the assistance of government, he was enabled to triumph. The latter part of his life was spent more peaceably in cultivating the mathematical sciences. He died the 29th of December 1737, of a lethargic fever, at 78 years of age.

The character of Saurin was lively and impetuous, endued with a considerable degree of that noble independence and loftiness of manner, which is apt to be mistaken for haughtiness or insolence; in consequence of which, his memory was attacked after his death, as his reputation had been during his life; and it was even said he had been guilty of crimes, by his own confession, that ought to have been punished with death.

Saurin's mathematical and philosophical papers, printed in the Memoirs of the Academy of Sciences, which are pretty numerous, are to be found in the volumes for the years following; viz, 1709, 1710, 1713, 1716, 1718, 1720, 1722, 1723, 1725, 1727.

SAUSSURE, (Horace Benedict de), an ingenious philosopher, who was born at Geneva in 1740, and died in 1799. At the age of 21 he was elected philosophical professor at Geneva, where he taught for 25 years, with great public benefit. He first visited Paris in 1768, and next examined the discoveries of Montgolfier at Lyons; he then travelled through Holland, Belgium, England, and Italy. He visited the island of Elba, examined Vesuvius, and measured the crater of Ætna. He invented several instruments, in scientific operations. In his excursions among the Alps, he crossed them 14 times, at 8 different places; and he ascended to the summit of Mont Blanc, where he could hardly breathe. He was made member of the Academy of Sciences at Paris, &c. In the French revolution he was elected, on the union of his country to France, to the National Assembly; but the disorders of the times ruined his little fortune, and broke his heart.

Saussure was author of an Eulogy on his friend Bonnet, 8vo: Dissertatio Physica de Igne: Inquiry on the Bark of Leaves, &c: Dissertatio Physica de Electricitate, 8vo: Plan of Reform for the College of Geneva: Description of the Electrical Effects of Thunder: Essay on Hygrometry, 4to: Travels in the Alps, 4 vols. 4to, a valuable work: and other pieces.

SAUVEUR (Joseph), an eminent French mathematician, was born at La Fleche the 24th of March 1653. He was absolutely dumb till he was seven years of age; and then the organs of speech did not disengage so effectually, but that he was ever after obliged to speak very slowly and with difficulty. He very early discovered a great turn for mechanics, and was always inventing and constructing something or other in that way.

He was sent to the college of the Jesuits to study polite literature, but made very little progress in poetry and eloquence. Virgil and Cicero had no charms for him; but he read with eagerness books of arithmetic and geometry. However, he was prevailed on to go to Paris in 1670, and, being intended for the church, there he applied himself for a time to the study of philosophy and theology; but still succeeded no better. In short, mathematics was the only study he had any relish for, and this he cultivated with extraordinary success; for during his course of philosophy, he learned the first six books of Euclid in the space of a month, without the help of a master.

As he had an impediment in his voice, though otherwise endued with extraordinary abilities, he was advised by M. Bossuet, to give up all designs for the church, and to apply himself to the study of physic: but this being utterly against the inclination of his uncle, from whom he drew his principal resources, Sauveur determined to devote himself to his favourite science, and to perfect himself in it, so as to teach it for his support; and in effect he soon became the fashionable preceptor in mathematics, so that at 23 years of age he had prince Eugene for his scholar.—He had not yet read the geometry of Descartes; but a foreigner of the first quality desiring to be taught it, he made himself master of it in an inconceivably small space of time.—Basset being a fashionable game at that time, the marquis of Dangeau asked him for some calculations relating to it, which gave such satisfaction, that Sauveur had the honour to explain them to the king and queen.

In 1681 he was sent with M Mariotte to Chantilli, to make some experiments upon the waters there, which he did with much applause. The frequent visits he made to this place inspired him with the design of writing a treatise on fortification; and, in order to join practice with theory, he went to the siege of Mons in 1691, where he continued all the while in the trenches. With the same view also he visited all the towns of Flanders; and on his return he became the mathematician in ordinary at the court, with a pension for life.—In 1680 he had been chosen to teach mathematics to the pages of the Dauphiness. In 1686 he was appointed mathematical professor in the Royal College. And in 1696 admitted a member of the Academy of Sciences, where he was in high esteem with the members of that society.—He became also particularly acquainted with the prince of Condé, from whom he received many marks of favour and affection. Finally, M. Vauban having been made marshal of France, in 1703, he proposed Sauveur to the king as his successor in the office of examiner of the engineers; to which his majesty agreed, and honoured him with a pension, which our author enjoyed till his death, which happened the 9th of July 1716, in the 64th year of his age.

Sauveur, in his character, was of a kind obliging disposition, of a sweet, uniform, and unaffected temper; and though his fame was pretty generally spread abroad, it did not alter his humble deportment, and the simplicity of his manners. He used to say, that what one man could accomplish in mathematics, another might do also, if he chose it.

An extraordinary part of Sauveur's character is, that though he had neither a musical voice nor ear, yet he studied no science more than music, of which he composed an entire new system. And though he was obliged to borrow other people's voice and ears, yet he amply repaid them with such demonstrations as were unknown to former musicians. He also introduced a new diction in music, more appropriate and extensive. He invented a new doctrine of sounds; and was the first that discovered, by theory and experiment, the velocity of musical strings, and the spaces they describe in their vibrations, under all circumstances of tension and dimensions. It was he also who first invented for this purpose the monochord and the echometer. In short, he pursued his researches even to the music of the ancient Greeks and Romans, to the Arabs, and to the very Turks and Persians; so jealous was he, lest any thing should escape him in the science of sounds.

Sauveur's writings, which consist of pieces rather than of set works, are all inserted in the volumes of the Memoirs of the Academy of Sciences, from the year 1700 to the year 1716, on various geometrical, mathematical, philosophical, and musical subjects.

SCALE, a mathematical instrument, consisting of certain lines drawn on wood, metal, ivory, &c, divided into various parts, either equal or unequal. It is of great use in laying down distances in proportion, or in measuring distances already laid down. There are scales of various kinds, accommodated to the several uses: the principal are the Plane Scale, the Diagonal Scale, Gunter's Scale, and the Plotting Scale.

Plane or Plain SCALE, a mathematical instrument of very extensive use and application; which is commonly made of 2 feet in length; and the lines usually drawn upon it are the following, viz,

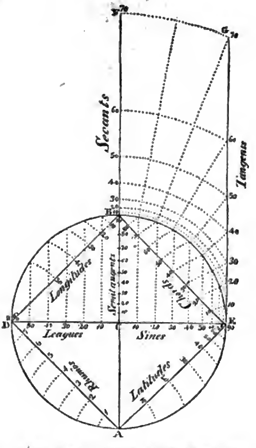
1	Lines of Equal Parts, and marked	E. P.
2	Chords	Cho.
3	Rhumbs	Ru.
4	Sines	Sin.
5	Tangents	Tan.
6	Secants	Sec.
7	Semitangents	S. T.
8	Longitude	Long.
9	Latitude	Lat.

1. The lines of equal parts are of two kinds, viz, simply divided, and diagonally divided. The first of these are formed by drawing three lines parallel to one another, and dividing them into any number of equal parts by short lines drawn across them, and in like manner subdividing the first division or part into 10 other equal small parts; by which, numbers or dimensions of two figures may be taken off. On some rulers, several of these scales of equal parts are ranged parallel to each other, with figures set to them to show into how many equal parts they divide the inch; as 20, 25, 30, 35, 40, 45, &c. The 2d or diagonal divisions are formed by drawing eleven long parallel and equidistant lines, which are divided into equal parts, and crossed by other short lines, as the former; then the first of the equal parts have the two outermost of the eleven parallels divided into 10 equal parts, and the points of division being connected by lines drawn diagonally, the whole scale is thus divided into dimensions or numbers of three places of figures.

The other lines upon the scales are such as are commonly used in trigonometry, navigation, astronomy, dialling, projection of the sphere, &c, &c; and their constructions are mostly taken from the divisions of a circle, as follow:

Describe a circle with any convenient radius, and quarter it by drawing the diameters AB and DE at right angles to each other; continue the diameter AB out towards F, and draw the tangent line EG parallel to it; also draw the chords AD, DB, BE, EA. Then,

2. For the line of chords, divide a quadrant BE into 90 equal parts; on E as a centre, with the compasses transfer these divisions to the chord line EB, which mark with the corresponding numbers, and it will become a line of chords, to be transferred to the ruler.



3. For the line of rhumbs, divide the quadrant AD into 8 equal parts: then with the centre A transfer the divisions to the chord AD, for the line of rhumbs.

4. For the line of sines, through each of the divisions of the arc BE, draw right lines parallel to the radius BC, which will divide the radius CE into the sines, or versed sines, numbering it from C to E for the sines, and from E to C for the versed sines.

5. For the line of tangents, lay a ruler on C, and the several divisions of the arc BE, and it will intersect the line EG, which will become a line of tangents, and numbered from E to G with 10, 20, 30, 40, &c.

6. For the line of secants, transfer the distances between the centre C and the divisions on the line of tangents to the line BF, from the centre C, and these will give the divisions of the line of secants, which must be numbered from B towards F, with 10, 20, 30, &c.

7. For the line of semitangents, lay a ruler on D and the several divisions of the arc EB, which will intersect the radius CB in the divisions of the semitangents, which are to be marked with the corresponding figures of the arc EB.

The chief uses of the sines, tangents, secants, and semitangents, are to find the poles and centres of the several circles represented in projections of the sphere.

8. For the line of longitude, divide the radius CD into 60 equal parts; through each of these, parallels to the radius BC will intersect the arc BD in as many points: from D as a centre the divisions of the arc BD being trans-

ferred to the chord BD, will give the divisions of the line of longitude.

If this line be laid upon the scale close to the line of chords, both inverted, so that 60° in the scale of longitude be against 0° in the chords, &c; and any degree of latitude be counted on the chords, there will stand opposite to it, in the line of longitude, the miles contained in one degree of longitude, in that latitude; the measure of 1 degree under the equator being 60 geographical miles.

9. For the line of latitude, lay a ruler on B, and the several divisions on the sines on CE, and it will intersect the arc AE in as many points; on A as a centre transfer the intersections of the arc AE to the chord AE, for the line of latitude.

See also Robertson's Description and Use of Mathematical Instruments.

Diagonal SCALE. See the article 1, above.

Decimal, or *Gunter's*, or *Plotting*, or *Proportional*, or *Reducing* SCALE. See the several articles.

SCALE, in Architecture and Geography, a line divided into equal parts, placed at the bottom of a map or draught, to serve as a common measure to all the parts of the building, or all the distances and places of the map

In maps of large tracts, as kingdoms and provinces, &c, the scale usually consists of miles: whence it is denominated a scale of miles.—In more particular maps, as those of manors, &c, the scale is usually of chains &c.—The scales used in draughts of buildings mostly consist of modules, feet, inches, palms, fathoms, or the like.

To find the distance between two towns &c, in a map, the interval is taken in the compasses, and set off in the scale; and the number of divisions it includes gives the distance. The same method serves to find the height of a story, or other part in a design.

Front SCALE, in Perspective, is a right line in the draught, parallel to the horizontal line; divided into equal parts, representing feet, inches, &c.

Flying SCALE, is a right line in the draught, tending to the point of view, and divided into unequal parts, representing feet, inches, &c.

Differential SCALE, is used for the scale of relation subtracted from unity. See SERIES.

SCALE *of Notation*, is the order of progression on which any system of arithmetic is founded; as the Binary Scale, Quartenary, Sexenary, Denary, Duodenary, &c.

The denary, or decimal scale, is that on which our present notation is established, and by which the value of our numerical characters increase in a tenfold proportion, from the right hand towards the left, the number of characters employed being ten. In the binary scale, there are only two characters, namely 1 and 0; and generally, for any scale of notation, the number of characters necessary for expressing a given quantity, will never exceed the radix of that system.

The following examples will give some idea of the use of the different scales.

Scale.	*Numb.*	*Progressions.*	*Common Expression.*
Binary - -	101110	$=1\times2^5+0\cdot2^4+1\times2^3+1\times2^2+1\times2+0$	= 46
Ternary -	121201	$=1\times3^5+2\times3^4+1\times3^3+2\times3^2+0\times3+1$	= 451
Quartenary	123013	$=1\times4^5+2\times4^4+3\times4^3+0\times4^2+1\times4+3$	= 1735
Quinary -	413402	$=4\times5^5+1\times5^4+3\times5^3+4\times5^2+0\times5+2$	=13602
Sexenary -	532412	$=5\times6^5+3\times6^4+2\times6^3+4\times6^2+1\times6+2$	=43352
Decimal -	17844	$=1\times10^4+7\times10^3+8\times10^2+4\times10+4$	=17844
Duodenary	7846	$=7\times12^3+8\times12^2+4\times12+6$	=13302

For more on this subject, see NOTATION.

SCALE *of Relation*, in Algebra, an expression denoting the relation of the terms of recurring series to each other. See SERIES.

Hour SCALE. See HOUR.

SCALE, in Music, is a denomination given to the arrangement of the six syllables, invented by Guido Aratino, *ut re mi fa sol la*; called also gammut. It is called scale, or ladder, because it represents a kind of ladder, by means of which the voice rises to acute, or sinks to grave; each of the six syllables being as it were one step of the ladder.

SCALE is also used for a series of sounds rising or falling towards acuteness or gravity, from any given pitch of tune to the greatest distance that is fit or practicable, through such intermediate degrees as to make the succession most agreeable and perfect, and in which we have all the harmonical intervals most commodiously divided.—The scale is otherwise called an Universal System, as including all the particular systems belonging to music. See SYSTEM.—There were three different scales in use among the ancients, which had their denominations from the three several kinds of music, viz, the Diatonic, Chromatic, and Inharmonic; which see.

SCALENE, or SCALENOUS *Triangle*, is a triangle whose sides and angles are all unequal.—A cylinder or cone, whose axis is oblique or inclined to its base, is also said to be scalenous: though more frequently it is called oblique.

SCALIGER (JOSEPH JUSTUS), a celebrated French chronologer and critic, was the son of Julius Cæsar Scaliger, and born at Agen in France, in 1540. He studied in the college of Bourdeaux; after which his father took him under his own care, and employed him in transcribing his poems; by which means he obtained such a taste for poetry, that before he was 17 years of age he wrote a tragedy on the subject of Oedipus, in which he introduced all the poetical ornaments of style and sentiment.

His father dying in 1558, he went to Paris the year following, with a design to apply himself to the Greek tongue; for which purpose he for two months attended the lectures of Turnebus; but finding that in the usual course he should be a long time in gaining his point, he shut himself up in his closet, and by constant application for two years gained a perfect knowledge of the Greek language. After which he applied himself to the Hebrew, which he learned by himself with great facility. And in like manner he ran through many other languages, till he could speak, it is said, no less than 13 ancient and modern tongues. He made no less progress in the sciences; and his writings procured him the reputation of one of the greatest men of that or any other age. He embraced the reformed religion at 22 years of age: and in 1563, he attached himself to Lewis Casteignier de la Roch Pazay, whom he attended in several journeys. And, in 1593, the curators of the university of Leyden invited him to an honorary professorship in that university, where he lived 16 years, till he died of a dropsy in 1609, at 69 years of age.

Scaliger was a man of great temperance; was never married; and was so close a student, that he often spent whole days in his study without eating: and though his circumstances were always very narrow, he constantly refused the presents that were offered him.

He was author of many ingenious works on various subjects. His elaborate work, De Emendatione Temporum; his exquisite animadversions on Eusebius; with his Canon Isagogicus Chronologiæ; and his accurate comment upon Manilius's Astronomicon, sufficiently evince his knowledge in astronomy, and other branches of learning, among the ancients, and who, according to the opinion of the celebrated Vieta, was far superior to any of that age. And he had no less a character given him by the learned Casaubon.—He wrote Cyclometrica et Diatriba de Equinoctiorum Anticipatione. Also notes upon Seneca, Varro, and Ausonius's Poems. But that which above all things renders the name of Scaliger memorable to posterity, is the invention of the Julian period, which consists of 7980 years, being the continued product of the three cycles, of the sun 28, the moon 19, and Roman indiction 15. This period had its beginning fixed to the 764th year before the creation, and is not yet completed, and comprehends all other cycles, periods, and epochas, with the times of all memorable actions and histories. The collections intitled Scaligeriana, were made from his conversations by one of his friends; and being ranged in alphabetical order, were published by Isaac Vossius.

SCANTLING, a measure, size, or standard, by which the dimensions &c of things are to be determined. The term is particularly applied to the dimensions of any piece of timber, with regard to its breadth and thickness.

SCAPEMENT, in Clock-work, a general term for the manner of communicating the impulse of the wheels to the pendulum. The ordinary scapements consist of the swing-wheel and pallets only; but modern improvements have added other levers or detents, chiefly for the purposes of diminishing friction, or for detaching the pendulum from the pressure of the wheels during part of the time of its vibration. Notwithstanding the very great importance of the scapement to the performance of clocks, no material improvement was made in it from the first application of the pendulum to clocks, to the days of Mr. George Graham; nothing more was attempted before his time, than to apply the impulse of the swing-wheel, in such manner as was attended with the least friction, and would give the greatest motion to the pendulum. Dr. Halley discovered, by some experiments made at the Royal Observatory at Greenwich, that by adding more weight to the pendulum, it was made to vibrate larger arcs, and the clock went faster; by diminishing the weight of the pendulum, the vibrations became shorter, and the clock went slower; the result of these experiments being diametrically opposite to what ought to be expected from the theory of the pendulum, probably first roused the attention of Mr. Graham, and led him to such further trials as convinced him, that this seeming paradox was occasioned by the retrograde motion, which was given to the swing-wheel by every construction of scapement that was at that time in use; and his great sagacity soon produced a remedy for this defect, by constructing a scapement which prevented all recoil of the wheels, and restored to the clock pendulum, wholly in theory, and nearly in practice, all its natural properties in its detached simple state; this scapement was named by its celebrated inventor the Dead Beat, and its great superiority was so universally acknowledged, that it was soon introduced into general use, and still continues in universal esteem. The importance of the scapement to the accurate going of clocks, was by this improvement rendered so unquestionable, that artists of the first rate all over Europe, were forward in producing each his particular construction, as may be seen in the works of Thiout l'ainé, M. J. A. Lepante, M. le Roy, M. Ferdinand Bertoud, and Mr. Cummings' Elements of Clock and Watchwork, in which we have a minute description of several new and ingenious constructions of scapements, with an investigation of the principles on which their claim to merit is founded; also a comparative view of the advantages or defects of the several constructions. Besides the scapements described in the above works, many curious constructions have been produced by eminent artists, who have not published any account of them, nor of the motives which have induced each to prefer his favourite construction: Mr. Harrison, Mr. Hindley of York, Mr. Ellicot, Mr. Mudge, Mr. Arnold, Mr. Whitehurst, and many other ingenious artists of this country, have made scapements of new and peculiar constructions, of which we are unable, for the above reason, to give any further account than that those of Mr. Harrison and Mr. Hindley had scarce any friction, with a certain mode and quantity of recoil; those of all the other gentlemen, we believe, have been on the principle of the dead beat, with such other improvements as they severally judged most conducive to a good performance.

Count Bruhl published, in 1794, a small pamphlet, "On the Investigation of Astronomical Circles," to which he has annexed, "A Description of the Scapement in Mr. Mudge's first Timekeeper, drawn up in August 1771." Before entering upon the description, the count premises a few observations, in one of which he recognizes a hint concerning the nature of Mr. Mudge's scapement, thrown out by this artist in a small tract printed by him in the year 1763, which is this: "The force derived from the mainspring should be made as equal as possible, by making the mainspring wind up another smaller spring at a less distance from the balance, at short intervals of time. I think it would not be impracticable to make it wind up at every vibration, a small spring similar to the pendulum spring, that should immediately act on the balance, by which the whole force acting on the balance would be reduced to the greatest simplicity, with this advantage, that the force would increase in proportion to the arch." From this hint, Count Bruhl is surprised that no other artists have taken up Mr. Mudge's invention. He then gives the description of that invention, in the pamphlet above-mentioned.

For a detailed account of Mudge's scapement, and other inventions of this kind, see Gregory's Mechanics, vol. 2, pa. 329.

SCARP, in Fortification, the interior slope of the ditch of a place; that is, the slope of that side of a ditch which is next to the place, or on the outside of the rampart at its foot, facing the champaign or open country. The slope on the outer side of the ditch is called the Counterscarp.

SCENOGRAPHY, in Perspective, the perspective representation of a body on a plane; or a description and view of it in all its parts and dimensions, such as it appears to the eye in any oblique view. This differs essentially from the ichnography and the orthography. The ichnography of a building, &c, represents the plan or ground work of the building, or section parallel to it; and the orthography the elevation, or front, or one side, also in its natural dimensions; but the scenography exhibits the whole of the building that appears to the eye, front, sides, height, and all, not in their real dimensions or extent, but raised on the geometrical plan in perspective.—In architecture and fortification, scenography is the manner of delineating the several parts of a building or fortress, as they are represented in perspective.

To exhibit the SCENOGRAPHY *of any body.* 1. Lay down the basis, ground-plot, or plan, of the body, in the perspective ichnography, that is, draw the perspective appearance of the plan or basement, by the proper rules of perspective. 2. On the several points of the said perspective plan, raise the perspective heights, and connect the tops of them by the proper slope or oblique lines. So will the scenography of the body be completed, when a proper shade is added. See PERSPECTIVE.

SCHEINER (CHRISTOPHER), a considerable German mathematician and astronomer, was born at Mundelheim in Schwaben in 1575. He entered into the society of the Jesuits at 20 years of age; and afterwards taught the Hebrew tongue and the mathematics at Ingolstadt, Friburg, Brisac, and Rome. At length he became confessor to the archduke Charles, and rector of the college of the Jesuits at Neisse in Silesia, where he died in 1650, at 75 years of age.

Scheiner was chiefly remarkable for being one of the first, though not the very first, who observed the spots in the sun with the telescope; for his observations of those spots were first made, at Ingolstadt, in the latter part of the year 1611, whereas Galileo and Harriot both observed them in the latter part of the year before, or 1610. Scheiner continued his observations on the solar phenomena for many years afterwards at Rome, with great assiduity and accuracy, constantly making drawings of them on paper, describing their places, figures, magnitude, revolutions, and periods, so that Riccioli delivered it as his opinion that there was little reason to hope for any better observations of those spots. Descartes and Hevelius also say, that, in their judgment, nothing can be expected of that kind more satisfactory. These observations were published in one volume folio, 1630, under the title of Rosa Ursina, &c; almost every page of which is adorned with an image of the sun with the spots. He wrote also several smaller pieces relating to mathematics and philosophy, the principal of which are,

2. Oculus, sive Fundamentum Opticum, &c; which was reprinted at London, in 1652, in 4to.

3. Sol Ecliptieus, Disquisitiones Mathematicæ.

4. De Controversiis et Novitatibus Astronomicis.

SCHEME, a draught or representation of any geometrical or astronomical figure, or problem, by lines sensible to the eye; or of the celestial bodies in their proper places for any moment; otherwise called a diagram.

SCHEME *Arches.* See ARCH.

SCHOLIUM, a note, remark, or annotation, occasionally made on some passage, proposition, &c.

The term is much used in geometry, and other parts of the mathematics; where, after demonstrating a proposition, it is used to point out how it might be done some other way; or to give some advice or precaution, in order to prevent mistakes; or to add some particular use or application of it.

Wolfius has given abundance of curious and useful arts and methods, and a good part of the modern philosophy, with the description of mathematical instruments, &c; all by way of scholia to the respective propositions in his Elementa Matheseos.

SCHONER (JOHN), a noted German philosopher and mathematician, was born at Carolostadt in the year 1477, and died in 1547, at 70 years of age.—His early propensity to those sciences may be deemed a just prognostication of the great progress which he afterwards made in them. From his uncommon acquirements, he was chosen mathematical professor at Nuremburg when he was but a young man. He wrote a great many works, and was particularly celebrated for his astronomical tables, which he published after the manner of those of Regiomontanus, and to which he gave the title of Resolutæ, on account of their clearness. But notwithstanding his great knowledge, he was, after the custom of the times, much addicted to judicial astrology, which he took great pains to improve. The list of his writings is chiefly as follows:

1. Three Books of Judicial Astrology.
2. The Astronomical Tables named Resolutæ.
3. De Usu Globi Stelliferi; De Compositione Globi Cœlestis; De Usu Globi Terrestris, et de Compositione ejusdem.
4. Æquatorium Astronomicum.
5. Libellus de Distantiis Locorum per Instrumentum et Numeros Investigandis.
6. De Compositione Torqueti.
7. In Constructionem et Usum Rectanguli sive Radii Astronomici Annotationes.
8. Horarii Cylindri Canones.
9. Planisphærium, seu Meteoriscopium.
10. Organum Uranicum.
11. Instrumentum Impedimentorum Lunæ.

All printed at Nuremburg, in folio, 1551.

Of these, the large treatise of dialling rendered him more known in the learned world than all his other works besides; in which he discovers a surprising genius and fund of learning of that kind.

SCHOOL, a place where languages, or arts and sciences, &c, are taught.

SCHOOL is also used for a whole faculty, university, or sect; as Plato's school, the school of Epicurus, the school of Paris, &c. The school of Tiberias was celebrated among the ancient Jews; and it is to this we owe the Massora, and Massoretes.

SCHOOL *Philosophy*, &c. the same with *scholastic.*

SCHOOTEN (FRANCIS), was a professor of mathematics at Leyden, being a very acute and respectable proficient in that science. He published, in 1649, an edition of Descartes's Geometry, with learned and elaborate annotations on that work, as also those of Beaume Hudde, and Van Heauralt. Schooten published also two very useful and learned works of his own compositions, viz,

1. Principia Matheseos Univers. &c, 4to, 1651.
2. Exercitationes Mathematicæ, 4to, 1657.

SCIAGRAPHY, or SCIOGRAPHY, the profile or vertical section of a building; used to show the inside of it.

SCIAGRAPHY, in Astronomy &c, is a term used by some authors for the art of finding the hour of the day or night, by the shadow of the sun, moon, stars, &c. See DIAL.

SCIENCE, a clear and certain knowledge of any thing, founded on demonstration, or on self-evident principles. In this sense, doubting is opposed to science; and opinion is the middle between the two.

SCIENCE is more particularly used for a formed system of any branch of knowledge, comprehending the doctrine, reason, and theory of the thing, without any immediate application of it to any uses or offices of life. And in this sense, the word is used in opposition to art.

Science may be divided into three classes: First, the knowledge of things, their constitutions, properties, and operations, whether material or immaterial. And this, in a little more enlarged sense of the word, may be called physics, or natural philosophy. Secondly, the skill of rightly applying our own powers and actions for the attainment of good and useful things, as Ethics. Thirdly, the doctrine of signs; as words, logic, &c.

SCIENTIFIC, or SCIENTIFICAL, something relating to the pure and sublimer sciences; or that abounds in science, or knowledge. A work, or method, &c, is said to be scientifical, when it is founded on the pure reason of things, or conducted wholly on the principles of them. In which sense the word stands opposed to narrative, arbitrary, opinionative, positive, tentative, &c.

SCIOPTIC, or SCIOPTRIC *Ball*, a sphere or globe of wood, with a circular hole or perforation, where a lens is placed. It is so fitted that, like the eye of an animal, it may be turned round every way, to be used in making experiments of the darkened room, or camera obscura.

SCIOPTRICS. See CAMERA OBSCURA.

SCIOTHERICUM *Telescopium*, is an horizontal dial, adapted with a telescope for observing the true time both by day and night, to regulate and adjust pendulum clocks, watches, and other time-keepers. It was invented by Mr. Molyneux, who published a book with this title, which contains an accurate description of this instrument, with all its uses and applications.

SCLEROTICA, one of the common membranes of the eye, on its hinder part. It is a large, thick, firm, hard, opaque membrane, extended from the external circumference of the cornea to the optic nerve, and forms much of the greater part of the external globe of the eye. The sclerotica and the cornea compose the case in which all the internal coats of the eye and its humours are contained.

SCONCES, small forts, built for the defence of some pass, river, or other place. Some sconces are made regular, of four, five, or six bastions; others are of smaller dimensions, fit for passes, or rivers; and others for the field.

SCORE, in Music, denotes partition, or the original draught of the whole composition, in which the several parts, viz. the treble, second treble, bass, &c, are distinctly scored, and marked.

SCORPIO, the *Scorpion*, the 8th sign of the zodiac, denoted by the character ♏, being a rude design of the animal of that name.

The Greeks, who would be supposed the founders of astronomy, and who have, with that intent, applied some story or other of their own to every one of the constellations, give a very singular account of the origin of this sign. They tell us that this is the creature which killed Orion; and according to them the famous hunter of that name boasted to Diana and Latona, that he would destroy every animal that was upon the earth; the earth, they say, enraged at this, sent forth the poisonous reptile the scorpion, which insignificant creature stung him, that he died. Jupiter then raised the scorpion to the heavens, giving him this place among the constellations; and that afterwards Diana requested of him to do the same honour to Orion, which he at last consented to, but placed him in such a situation, that when the scorpion rises, he sets.

But the Egyptians, or whatever early nation it was that framed the zodiac, probably placed this poisonous reptile in that part of the heavens to denote that when the sun arrived at it, fevers and sicknesses, the maladies of autumn, would begin to rage. This they represented by an animal whose sting was of such a nature as to occasion some of them; and it was thus they formed all the constellations.

The ancients allotted one of the twelve principal among their deities to be the guardian for each of the 12 signs of the zodiac. The scorpion, as their history of it made it a fierce and fatal animal that had killed the great Orion, fell naturally to the protection of the god of war; Mars is therefore its tutelary deity; and to this single circumstance is owing all that jargon of the astrologers, who tell us that there is a great analogy between the planet Mars and the constellation scorpio. To this also is owing the doctrine of the alchymists, that iron, which they call Mars, is also under the dominion of the same constellation, and that the transmutation of that metal into gold can only be performed when the sun is in this sign.

The stars in scorpio, in Ptolemy's catalogue, are 24; in that of Tycho 10, in that of Hevelius 20, but in that of Flamsteed and Sharp 44.

SCORPION is also the name of an ancient military engine, used chiefly in the defence of the walls, &c. Marcellinus describes the scorpion, as consisting of two beams bound together by ropes; from the middle of which rose a third beam, so disposed, as to be pulled up and let down at pleasure; and on the top of this were fastened iron hooks, where a sling was hung, either of iron or hemp; and under the third beam lay a piece of hair-cloth full of chaff, tied with cords. It had its name Scorpio, because when the long beam or tiller was erected, it had a sharp top like a sting.

To use the engine, a round stone was put into the sling, and four persons on each side, loosening the beams bound by the ropes, drew back the erect beam to the hook; then the engineer, standing on an eminence, gave a stroke with a hammer on the chord to which the beam was fastened with its hook, which set it at liberty; so that hitting against the soft hair-cloth, it struck out the stone with a great force.

SCOTIA, in Architecture, a semicircular cavity or channel between the tores, in the bases of columns; and sometimes under the larmier or drip, in the cornice of the Doric order. The workmen often call it the casement, and it is also otherwise called the Trochilus.

SCOTT (GEORGE LEWIS), a learned and respectable member of the Royal Society, and of the Board of Longitude. He was the eldest son of Mr. Scott of Bristow, in Scotland, who married Miss Stewart, daughter of sir James Stewart, who was lord advocate of Scotland in the time of K. William and Q. Anne. That lady was also his cousin-german, their mothers being sisters, and both daughters of Mr. Robert Trail, one of the ministers of Edinburgh, of the same family as the rev. Dr. Wm. Trail, the learned author of the Account of the Life and Writings of Dr. Rob. Simson, professor of mathematics at Glasgow.

Mr. Scott (the father), with his family, lived many years abroad, in a public character; and he had three sons born while residing at the court of Hanover. The eldest of these was our author George Lewis, named (in both these names) after his godfather the Elector, who was afterwards George the 1st of Britain. Geo. Lewis Scott was a gentleman of respectable talents and general learning; he was well skilled also in all the mathematical sciences; for which he manifested at times a fine and critical taste, as may be particularly seen in some letters which, in the year 1764, passed in a literary correspondence between him and Dr. Simson of Glasgow, and inserted in Dr. Trail's Account of the Life and Writings of Dr. Simson, pa. 113, &c. Mr. G. L. Scott was the author of the Supplement to Chambers's Dictionary, in 2 large folio volumes, which was much esteemed, and for which he received 1500l. from the booksellers, a considerable price at the time of that publication. Mr. Scott was sub-preceptor, for the Latin language, to his present Majesty, George the 3d, when Prince of Wales. After that he was appointed a commissioner of excise; a situation which his friends have considered as not adequate to his past deserts, and inferior to what he probably would have had, but for the freedom of his political opinions. Mr. Scott died the 7th of December, 1780.

SCREW, one of the six mechanical powers; chiefly used in pressing bodies close, though sometimes also in raising weights.

The screw is a spiral thread or groove cut round a cylinder, and everywhere making the same angle with the length of it. So that, if the surface of the cylinder, with this spiral thread upon it, were unfolded and stretched into a plane, the spiral thread would form a straight inclined plane, whose length would be to its height, as the circumference of the cylinder is to the distance between two threads of the screw; as is evident by considering, that in making one round, the spiral rises along the cylinder the distance between the two threads.

Hence the threads of a screw may be traced upon the smooth surface of a cylinder thus: cut a sheet of paper into the form of a right-angled triangle, having its base to its height in the above proportion, viz, as the circumference of the cylinder of the screw is to the intended distance between two threads; then wrap this paper triangle about the cylinder, and the hypothenuse of it will trace out the line of the spiral thread.

When the spiral thread is upon the outside of a cylinder, the screw is said to be a male or convex one. But if the thread be cut along the inner surface of a hollow cylinder, or a round perforation, it is said to be female or concave. And this latter is also sometimes called the box or nut.

When motion is to be given to something, the male and female screw are necessarily conjoined; that is, whenever the screw is to be used as a simple engine, or mechanical power. But when joined with an axis in peritrochio, there is no occasion for a female screw; but in that case it becomes part of a compound engine.

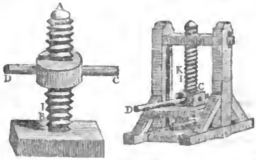
The screw cannot properly be called a simple machine, because it is never used without the application of a lever, or winch, to assist in turning it.

Of the Force and Power of the Screw.

1. The force of a power applied to turn a screw round, is to the force with which it presses upwards or downwards, setting aside the friction, as the distance between two threads, is to the circumference where the power is applied.—For, the screw being only an inclined plane, or half wedge, whose height is the distance between two threads, and its base the said circumference; and the force in the horizontal direction being to that in the vertical one as the lines perpendicular to them, viz, as the height of the plane, or distance of the two threads, is to the base of the plane, or circumference at the place where the power is applied; therefore the power is to the pressure, as the distance of two threads, is to that circumference.

Or the same may be otherwise shown thus. Since the momentum which any power generates, is equal to the momentum of that power; therefore the momentum of the screw, is equal to the momentum of the force applied to move it; which last is measured by the space passed over by the power in a given time. But this space is the circumference of a circle of which the lever is the radius, while the space passed over by the screw, in the same time, is only equal to the breadth of the threads, therefore the force or power of the screw, is to the power applied to move it, as the space passed over by the screw, to the space passed over by the power; that is, as the breadth of the threads to the circumference where the power is applied.

2. Hence, when the screw is put in motion; then the power is to the weight which would keep it in equilibrio, as the velocity of the latter is to that of the former. And hence their two momenta are equal, which are produced by multiplying each weight or power by its own velocity. Two different forms of screw-presses, are as below.

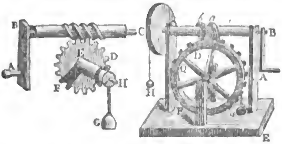


3. Hence we can easily compute the force of any machine turned by a screw. Let the annexed figure represent a press driven by a screw, whose threads are each a quarter of an inch asunder; and let the screw be turned by a handle of 4 feet long from C to D; then if the natural force of a man, by which he can lift, or pull, or draw, be 150 pounds; and it be required to determine with what force the screw will press on the board, when the man turns the handle at C and D with his whole force: the diameter CD of the power being 4 feet, or 48 inches, its circumference is $48 \times 3{\cdot}1416$ or $150\frac{4}{5}$ nearly; and the distance of the threads being $\frac{1}{4}$ of an inch; therefore the power is to the pressure, as $\frac{1}{4}$ to $150\frac{4}{5}$, or as 1 to $603\frac{1}{5}$: but the power is equal to 150lb; therefore as $1 : 603\frac{1}{5} :: 150 : 90480$; and consequently the pressure at the bottom of the screw, is equal to a weight of 90480 pounds, independent of friction.

But the power has to overcome, not only the weight, or other resistance, but also the friction of the screw, which in this machine is very great, in some cases equal to the weight itself, since it is sometimes sufficient to sustain the weight when the power is taken off.

Mr. Hunter has described a new method of applying the screw with advantage in particular cases, in the Philos. Trans. vol. 71, pa. 58 &c. A brief account of which may also be seen in Gregory's Mechanics, vol. 1, pa. 99.

The Endless SCREW, or *Perpetual* SCREW, is one which works in, and turns, a dented wheel DF, without a concave screw; being so called because it may be turned for ever, without coming to an end. From the following figures it is evident, that while the screw turns once round, the wheel only advances the distance of one tooth.



1. If the power applied to the lever, or handle, of an endless screw AB, be to the weight, in a ratio compounded of the periphery of the axis of the wheel EH, to the periphery described by the power in turning the handle, and of the revolutions of the wheel DF to the revolutions of the screw CB, the power will balance the weight. Hence,

2. As the motion of the wheel is very slow, a small power may raise a very great weight, by means of an endless screw. And therefore the chief use of such a screw is, either where a great weight is to be raised through a small space; or where only a slow gentle motion is wanted. For which reason it is very useful in clocks and watches.

3. Having given the number of teeth, the distance of the power from the centre of the screw B, the radius of the axis HE, and the power; to find the weight it will raise. Multiply the distance of the power from the centre of the screw AB, by the number of the teeth, and the product will be the space passed through by the power, while the weight passes through a space equal to the periphery of the axis: then say, as the radius of the axis is to the space of the power just found, so is the power to a 4th proportional, which will be the weight the power is able to sustain. Thus, if $AB = 3$, the radius of the axis $HE = 1$, the power 150 pounds, and the number of teeth of the wheel DF 48; then the weight will be found $= 21600 = 3 \times 150 \times 48$. Whence it appears that the endless screw exceeds all others in increasing the force of a power.

Again, if the endless screw AB be turned by the handle AC of 20 inches, the threads of the screw being each $\frac{1}{2}$ an inch distant; and the screw turns a toothed wheel E, whose pinion L turns another wheel F, and pinion M of this another wheel G, to the pinion or barrel of which is hung a weight W; it is required to determine what weight a man will be able to raise, with this machine, working at the handle C; supposing the diameters of the wheel to be 18 inches, and those of the pinion and barrel 2 inches; the teeth and pinions being all of a size; and the man supposed, as in the former case, to be able to lift 150lbs, by his natural strength.

Here $20 \times 3\cdot1416 \times 2 = 125\cdot664$, is the circumference of the power.

And $125\cdot664 : \frac{1}{2}$, or $251\cdot328 : 1$, is the force of the screw alone.

Also $18 : 2$, or $9 : 1$, being the proportion of wheels to the pinions, and as there are three of them, therefore $9^3 : 1^3$ or $729 : 1$ is the power gained by the wheels. Plate 38, fig. 5.

Consequently $(251\cdot328 \times 729) : 1$ or $183218 : 1$ nearly, is the ratio of the power to the weight, arising from the advantage both of the screw and the wheels. Hence $150 \times 183218 = 27482700$ lbs, is the weight which the man may sustain.

This must, however, only be considered as theoretical; for in practice the friction, which is very great, must of course enter into consideration.

4. A machine for showing the power of the screw may be contrived in the following manner. Let the wheel C (last fig. former column), have a screw *ab* on its axis, working in the teeth of the wheel D, which suppose to be 48 in number. It is plain that for every revolution of the wheel C, and screw *ab*, by the winch A, the wheel D will be moved one tooth by the screw; and therefore in 48 revolutions of the winch, the wheel D will be turned once round. Then if the circumference of a circle, described by the handle of the winch, be equal to the circumference of a groove *e* round the wheel D, the velocity of the handle will be 48 times as great as the velocity of any given point in the groove. Consequently when a line G goes round the groove *e*, and has a weight of 48lb hung to it below the pedestal EF, a power equal to one pound at the handle will balance and support the weight.

Archimedes's SCREW, is a spiral pump, being a machine for raising water, first invented by him. Its structure and use will be understood by the following description of it. ABCD (Pl. 28, fig. 6) is a wheel, which is turned round, according to the order of those letters, by the fall of water EF, which need not be more than 3 feet. The axis G of the wheel is raised so as to make an angle of about 44° with the horizon; and on the top of that axle is a wheel H, which turns such another wheel I of the same number of teeth; the axle K of this last wheel being parallel to the axle G of the two former wheels. The axle G is cut into a double threaded screw, as in the annexed figure (fig. 7), exactly resembling the screw on the axis of the fly of a common jack, which must be what is called a right-handed screw, if the first wheel turns in the direction ABCD; but a left-handed screw, if the stream turns the wheel the contrary way; and the screw on the axle G must be cut in a contrary way to that on the axle K, because these axles turn in contrary directions. These screws must be covered close over with boards, like those of a cylindrical cask; and then they will be spiral tubes. Or they may be made of tubes or pipes of lead, and wrapt round the axles in shallow grooves cut in it, as in figure 8. The lower end of the axle G turns constantly in the stream that turns the wheel, and the lower ends of the spiral tubes are open into the water. So that, as the wheel and axle are turned round, the water rises in the spiral tubes, and runs out at L through the holes M, N, as they come about below the axle. These holes, of which there may be any number, as 4 or 6, are in a broad close ring on the top of the axle, into which ring the water is delivered from the upper open ends of the screw tubes, and falls into the open box N. The lower end of the axle K turns on a gudgeon in the water in N; and the spiral tubes in that axle take up the water from N, and deliver it into another such box under the top of K; on which there may be such another wheel as I, to turn a third axle by such a wheel upon it. And in this manner may water be raised to any proposed height, when there is a stream sufficient for that purpose to act on the broad float boards of the first wheel. Archimedes's screw, or a still simpler form of it, is also represented in fig. 9.

SCROLLS, or SCROWLS, or *Volutes*, a term in Architecture. See VOLUTES.

SCRUPLE, the least of the weights used by the ancients. Among the Romans it was the 24th part of an ounce, or the third part of a drachm.

SCRUPLE is still a small weight among us, equal to 20 grains, or the 3d part of a drachm. Among goldsmiths the scruple is 24 grains.

SCRUPLE, in Chronology, a small portion of time much used by the Chaldeans, Jews, Arabs, and other eastern people, in computations of time. It is the 1080th part of an hour, and by the Hebrews called Helakin.

SCRUPLES, in Astronomy. As

SCRUPLES *Eclipsed*, denote that part of the moon's diameter which enters the shadow, expressed in the same measure in which the apparent diameter of the moon is expressed. See DIGIT.

SCRUPLES *of Half Duration*, an arch of the moon's orbit, described by her from the beginning of an eclipse to its middle.

SCRUPLES *of Immersion*, or *Incidence*, an arch of the moon's orbit, which her centre describes from the beginning of the eclipse, to the time when the centre falls into the shadow. See IMMERSION.

SCRUPLES *of Emersion*, an arch of the moon's orbit, which her centre describes in the time from the first emersion of the moon's limb, to the end of the eclipse.

SEA, in Geography, is frequently used for that vast tract of water encompassing the whole earth, more properly called ocean. But

SEA is more properly used for a particular part or division of the ocean, denominated from the countries it washes, or from other circumstances. Thus we say, the Irish sea, the Mediterranean sea, the Baltic sea, the Red sea, &c.

SEA among sailors is variously applied, to a single wave, or to the agitation produced by a multitude of waves in a tempest, or to their particular progress and direction. Thus they say, a heavy sea broke over our quarter, or we shipped a heavy sea; there is a great sea in the offing; the sea sets to the southward. Hence a ship is said to head the sea, when her course is opposed to the setting or direction of the surges. A Long Sea implies a steady and uniform motion of long and extensive waves. On the contrary, a Short Sea is when they run irregularly, broken, and interrupted, so as frequently to burst over a vessel's side or quarter.

Properties and Affections of the SEA.

1. *General Motion of the Sea.* M. Dassie of Paris, in a work long since published, has been at great pains to prove that the sea has a general motion, independent of winds and tides, and of more consequence in navigation than is usually supposed. He affirms that this motion is from east to west, inclining toward the north when the sun is on the north side of the equinoctial, but toward the south when he is on the south side of it. Philos. Trans. No. 135.

2. *Bason or Bottom of the Sea*, or Fundus Maris, a term used to express the bed or bottom of the sea in general. Mr. Boyle has published a treatise on this subject, in which he has given an account of its irregularities and various depths, founded on the observations communicated to him by mariners.

Count Marsigli has, since Boyle's time, given a more accurate account of this part of the globe. The materials which compose the bottom of the sea, may reasonably be supposed, in some degree, to influence the taste of its waters; and this author has made many experiments to prove that fossil coal, and other bituminous substances, which are found in plenty at the bottom of the sea, may communicate in a great measure its bitterness to it.

It is a general rule among sailors, and is found to hold true in many instances, that the more the shores of any place are steep and high, forming perpendicular cliffs, the deeper the sea is below; and that on the contrary, level shores denote shallow seas. Thus the deepest part of the Mediterranean is generally allowed to be under the height of Malta. And the observation of the strata of earth and other fossils, on and near the shores, may serve to form a good judgment as to the materials to be found in its bottom. For the veins of salt and of bitumen doubtless run on the same, and in the same order, as we see them at land; and the strata of rocks that serve to support the earth of hills and elevated places on shore, serve also, in the same continued chain, to support the immense quantity of water in the bason of the sea.

The coral fisheries have given occasion to observe that there are many, and those very large caverns or hollows in the bottom of the sea, especially where it is rocky; and the same caverns are sometimes found in the perpendicular rocks which form the steep sides of those fisheries. These caverns are often of great depth, as well as extent, and have sometimes wide mouths, and sometimes only narrow entrances into large and spacious hollows.

The bottom of the sea is covered with a variety of matters, such as could not be imagined by any but those who have examined into it, especially in deep water, where the surface only is disturbed by tides and storms, the lower part, and consequently its bed at the bottom, remaining for ages perhaps undisturbed. The soundings, when the plummet first touches the ground on approaching the shores, give some idea of this. The bottom of the plummet is hollowed, and in that hollow there is placed a lump of tallow; which being the part that first touches the ground, the soft nature of the fat receives into it some part of those substances which it meets with at the bottom: this matter, thus brought up, is sometimes pure sand, sometimes a kind of sand made of the fragments of shells, beaten to a kind of powder, sometimes it is made of a like powder of the several sorts of corals, and sometimes it is composed of fragments of rocks; but besides these appearances, which are natural enough, and are what might well be expected, it brings up substances which are of the most beautiful colours. Marsigli Hist. Phys. de la Mer.

Dr. Donati, in an Italian work, containing an essay towards a natural history of the Adriatic sea, printed at Venice in 1750, has related many curious observations on this subject, and which confirm the observations of Marsigli. Having carefully examined the soil and productions of the various countries that surround the Adriatic sea, and compared them with those which he took up from the bottom of the sea; he found that there is very little difference between the former and the latter. At the bottom of the water there are mountains, plains, valleys, and caverns, similar to those upon land. The soil consists of different strata placed one upon another, and mostly parallel and correspondent to those of the rocks, islands, and neighbouring continents. They contain stones of different kinds, minerals, metals, various putrefied bodies, pumice stones, and lavas formed by volcanos.

One of the objects which most excited his attention, was a crust, which he discovered under the water, composed of crustaceous and testaceous bodies, and beds of polypes of different kinds, confusedly blended with earth, sand, and gravel; the different marine bodies which form this crust, are found at the depth of a foot or more, entirely petrified and reduced into marble; these he supposes are naturally placed under the sea when it covers them, and not by means of volcanos and earthquakes, as some have conjectured. On this account he imagines that the bottom of the sea is constantly rising higher and higher, with which other obvious causes of increase concur; and from this rising of the bottom of the sea, that of its level or surface naturally results; in proof of which this writer cites a great number of facts. Philos. Trans. vol. 49, pa. 585.

3. *Luminousness of the Sea.* This is a phenomenon that has been noticed by many nautical and philosophical writers. Mr. Boyle ascribes it to some cosmical law or custom of the terrestrial globe, or at least of the planetary vortex.

Father Bourzes, in his voyage to the Indies, in 1704, took particular notice of this phenomenon, and very minutely describes it, without assigning the true cause.

The Abbé Nollet was long of opinion, that the light of the sea proceeded from electricity; and others have had recourse to the same principle, and shown that the luminous points in the surface of the sea are produced merely by friction.

There are however two other hypotheses, which have been advanced to account for this phenomenon; the one of these ascribes it to the shining of luminous insects or animalcules, and the other to the light proceeding from the putrefaction of animal substances. The Abbé Nollet, who at first considered this luminousness as an electrical phenomenon, having had an opportunity of observing the circumstances of it, when he was at Venice in 1749, relinquished his former opinion, and concluded that it was occasioned either by the luminous aspect, or by some liquor or effluvia of an insect which he particularly describes, though he does not altogether exclude other causes, and especially the spawn or fry of fish.

The same hypothesis had also occurred to M. Vianelli; and both he and Grizellini, a physician in Venice, have given drawings of the insects from which they imagined this light to proceed.

A similar conjecture is proposed by a correspondent of Dr. Franklin, in a letter read at the Royal Society in 1756; the writer of which apprehends, that this appearance may be caused by a great number of little animals, floating on the surface of the sea. And Mr. Forster, in his account of a voyage round the world with captain Cook, in the years 1772, 3, 4, and 5, describes this phenomenon as a kind of blaze of the sea; and, having attentively examined some of the shining water, expresses his conviction that the appearance was occasioned by innumerable minute animals of a round shape, moving through the water in all directions, which appear separately as so many luminous sparks when taken up on the hand: he imagines that these small gelatinous luminous specks may be the young fry of certain species of some medusæ, or blubber. And M. Dagelat and M. Rigaud observed several times, and in different parts of the ocean, such luminous appearances by vast masses of different animalcules; and a few days after the sea was covered, near the coasts, with whole banks of small fish in innumerable multitudes, which they supposed had proceeded from the shining animalcules.

But M. le Roi, after giving much attention to this phenomenon, concludes that it is not occasioned by any shining insects, especially as, after carefully examining with a microscope some of the luminous points, he found them to have no appearance of an animal; and he also found that the mixture of a little spirit of wine with water just drawn from the sea, would give the appearance of a great number of little sparks, which would continue visible longer than those in the ocean: the same effect was produced by all the acids, and various other liquors. M. le Roi is far from asserting that there are no luminous insects in the sea; for he allows that several gentlemen have found them; but he is satisfied that the sea is luminous chiefly on some other account, though he does not so much as offer a conjecture with respect to the true cause.

Other authors, equally dissatisfied with the hypothesis of luminous insects, for explaining the phenomenon which is the subject of this article, have ascribed it to some substance of the phosphoric kind, arising from putrefaction. The observations of F. Bourzes, above referred to, render it very probable, that the luminousness of the sea arises from slimy and other putrescent matter, with which it abounds, though he does not mention the tendency to putrefaction, as a circumstance of any consequence to the appearance. But the experiments of Mr. Canton, which have the advantage of being easily made, seem to leave no room to doubt that the luminousness of the sea is chiefly owing to putrefaction. And his experiments confirm an observation of Sir John Pringle's, that the quantity of salt contained in sea water hastens putrefaction; but since that precise quantity of salt which promotes putrefaction the most, is less than that which is found in sea water, it is probable, Mr. Canton observes, that if the sea were less salt, it would be more luminous. See Philos. Trans. vol. 59, pa. 446, and Franklin's Exper. and Observ. pa. 274.

4. *Of the Depth of the Sea, its Surface, &c.*

What proportion the superficies of the sea bears to that of the land, is not accurately known, though it is said to be somewhat more than two to one. This ratio of the surface of the sea to the land, has been found by experiment thus: taking the printed paper map or covering of a terrestrial globe, with a pair of scissors clip out the parts that are land, and those that are water; then weighing these parts separately in a pair of fine scales, the land is found to be near $\frac{1}{3}$, and the water rather more than $\frac{2}{3}$ of the whole.

With regard to the profundity or depth of the sea, Varenius affirms, that it is in some places unfathomable, and in others very various, being in certain places from $\frac{1}{10}$th of a mile to $4\frac{1}{2}$ miles in depth, in other places deeper, but much less in bays than in oceans. In general, the depths of the sea bear a great analogy to the height of mountains on the land, so far as is hitherto discovered.

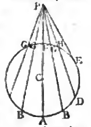
There is very good reason why the sea does not increase by means of rivers, &c, running every where into it; viz, because the vapours raised from the sea, and falling in rain upon the land, only cause a circulation of the water, but no increase of it. It has been found by calculations, founded on experiments, that in a summer's day, there may be raised in vapours from the surface of the Mediterranean sea, 528 millions of tuns of water; and yet this sea does not, from all its nine great rivers, receive more than 183 millions of tuns per day, which is but about a third part of what is exhausted in vapours; and this defect in the supply by the rivers, may serve to account for the continual influx of a current by the mouth or straits at Gibraltar. Indeed it is rather probable, that the waters of the sea suffer a continual slow decrease as to their quantity, by sinking always deeper into the earth, by filtering through the fissures in the strata and component parts; as also by the slow increase and raising of the earth's surface.

SEASONS, certain portions or quarters of the year, distinguished by the signs which the sun then enters at those periods.

The year is divided into four seasons, spring, summer, autumn, winter, which take their beginnings when the sun enters the first point of the signs Aries, Cancer, Libra, Capricorn.

The seasons are well illustrated by fig. 1, plate x; where the candle at I represents the sun in the centre, about which the earth moves in the ecliptic ABCD, which cuts the equinoctial *abcd* in the two equinoxes E and G. When the earth is in these two points, it is evident that the sun equally illuminates both the poles, and makes the days and nights equal in all parts of the earth. But while the earth moves from G by C to ♑, the upper or north pole becomes more and more enlightened, the days become longer, and the nights shorter; so that when the earth is at ♑, or the sun at ♋, our days are at the longest, as at midsummer. While the earth moves from ♑ by D to E, our days continually decrease, by the north pole gradually declining from the sun, till at E or autumn they become equal to the nights, or 12 hours long. Again, while the earth moves from E by A to F, the north pole beomes always more and more involved in darkness, and the days become shorter and shorter, till at F or ♋, when it is midwinter to the inhabitants of the northern sphere. Lastly, while the earth moves from ♋ by B to G, the north parts emerge more out of darkness, and the days grow continually longer, till at G the two poles are equally enlightened, and the days equal to the nights again. And so on continually year after year.

SECANT, in Geometry, a line that cuts another, whether right or curved: Thus the line PA or PB, &c, is a secant of the circle ABD, because of their cutting it in the point F, or G, &c. Properties of such secants to the circle are as follow:



1. Of several secants PA, PB, PD, &c, drawn from the same point P, that which passes through the centre C is the greatest; and from thence they decrease more and more as they recede farther from the centre; viz, PB less than PA, and PD less than PB, and so on, till they arrive at the tangent at E, which is the limit of all the secants.

2. Of these secants, the external parts PF, PG, PH, &c, are in the reverse order, increasing continually from F to E, the greater secant having the less external part, and in such proportion, that any secant and its external part are reciprocals, or the whole is reciprocally as its external part, and consequently that the rectangle of every secant and its external part is equal to a constant quantity, viz, the square of a tangent. Thus,

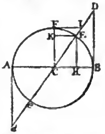
$$PA : \frac{1}{PF} :: PB : \frac{1}{PG} :: PD : \frac{1}{PH} \text{ \&c,}$$

or $PA \times PF = PB \times PG = PD \times PH = PE^2$.

3. The tangent PE is a mean proportional between any secant and its external part; as between PA and PF, or PB and PG, or PD and PH, &c.

4. The angle DPB, formed by two secants, is measured by half the difference of its intercepted arcs DB and GH.

SECANT, in Trigonometry, denotes a right line drawn from the centre of a circle, and, cutting the circumference, proceeds till it meets with a tangent to the same circle. Thus, the line CD, drawn from the centre C, till it meets the tangent BD, is called a secant; and particularly the secant of the arc BE, to which BD is a tangent. In like manner, by producing DC to meet the tangent *Ad* in *d*, then *cd*, equal to CD, is the secant of the arch AE, which is the supplement of the arch BE. So that an arch and its supplement have their secants equal, only the latter one is negative to the former, being drawn the contrary way. And thus the secants in the 2d and 3d quadrant are negative, while those in the 1st and 4th quadrants are positive.



The secant CI of the arc EF, which is the complement of the former arc BE, is called the Cosecant of BE, or the secant of its complement. The cosecants in the 1st and 2d quadrants are affirmative, but in the 3d and 4th negative.

The secant of an arc is reciprocally as the cosine, and the cosecant reciprocally as the sine; or the rectangle of the secant and cosine, and the rectangle of the cosecant and sine, are each equal to the square of the radius.

For CD : CE :: CB : CH, or S : r :: r : c,
and CI : CE :: CF : CK, or σ : r :: r : s;
and consequently $r^2 = cS = s\sigma$; where r denotes the radius, s the sine, c the cosine, S the secant, and σ the cosecant.

Some of the most useful trigonometrical formulæ, into which the secants and cosecants enter, are the following.

$$\text{Sec} = \sqrt{(r^2 + \tan^2)} = \frac{r^2}{\cos} = \frac{r . \tan}{\sin} = \frac{\cot . \tan}{\cos}$$

$$= r\frac{\sqrt{(r^2 + \cot^2)}}{\cot} = \frac{r^3}{\sin . \cot} = \frac{r . \text{cosec}}{\cot}$$

$$= \frac{\tan . \text{cosec}}{r} = \frac{\sin . \text{cosec}}{\cos} = \frac{r . \text{cosec}}{\sqrt{(\text{cosec}^2 - r^2)}}.$$

The secant of the sum or difference of any two arcs a and b may be expressed as follows:

$$\text{Sec } (a \pm b) = \frac{r . \sec a . \sec b}{r^2 \mp \tan a . \tan b}.$$

$$\text{Cosec } (a \pm b) = \frac{\text{cosec } a . \text{cosec } b}{\cot b \pm \cot a}.$$

The secants of the multiple arcs are exhibited in the following formulæ:

$$\text{Sec } a = \sec a$$

$$\text{Sec } 2a = \frac{\sec^2 a}{2 - \sec^2 a}$$

Sec $3a = \frac{\sec^3 a}{4 - 3\sec^2 a}$.

Sec $4a = \frac{\sec^4 a}{8 - 8\sec^2 a + \sec^4 a}$.

Sec $5a = \frac{\sec^5 a}{16 - 20\sec^2 a + 5\sec^4 a}$, &c, &c.

Or generally sec $na =$

$$\frac{\sec^n a}{2^{n-1}\left(r^{n-1} - \frac{nr^{n-3}}{1.2^2}\sec^2 a + \frac{n(n-3)r^{n-5}}{1.2.2^4}\sec.^4 a - \frac{n(n-4)(n-5)r^{n-7}}{1.2.3.2^6}\sec.^6 a, \&c.\right)}$$

Also, an arc a, to the radius r, being given, the secant s, and cosecant σ, and their logarithms, or the logarithmic secant and cosecant, may be expressed in infinite series, as follows, viz,

$$s = r + \frac{a^2}{2r} + \frac{5a^4}{24r^3} + \frac{61a^6}{720r^5} + \frac{277a^8}{8064r^7} \&c.$$

$$\sigma = \frac{r^2}{a} + \frac{a}{6} + \frac{7a^3}{360r^2} + \frac{31a^5}{15120r^4} + \frac{127a^7}{604800r^6} \&c.$$

$$\log. s = m \times \left(\frac{a^2}{2} + \frac{a^4}{12} + \frac{a^6}{45} + \frac{17a^8}{2520} \&c.\right)$$

$$\log. \sigma = -\log. a + m \times \left(\frac{a^2}{6} + \frac{a^4}{180} + \frac{a^6}{2835} + \frac{a^8}{37800} \&c\right)$$

where m is the modulus of the system of logarithms.

SECANTS, *Figure of*. See FIGURE *of Secants*.

SECANTS, *Line of*. See SECTOR, and SCALE.

SECOND, in Geometry, or Astronomy, &c, the 60th part of a prime or minute: either in the division of circles, or in the measure of time. A degree, or an hour, are each divided into 60 minutes, marked thus ′; a minute is subdivided into 60 seconds, marked thus ″; a second into 60 thirds, marked thus ‴; &c.

We sometimes say a second minute, a third minute, &c, but more usually only second, third, &c.

The seconds pendulum, or pendulum that vibrates seconds, in the latitude of London, is $39\frac{1}{8}$ inches long.

SECONDARY *Circles of the Ecliptic*, are circles of longitude of the stars; or circles which, passing through the poles of the ecliptic, are at right angles to it.

By means of these secondary circles, all points in the heavens are referred to the ecliptic; that is, any star, planet, or other phenomenon, is understood to be in that point of the ecliptic, which is cut by the secondary circle that passes through such star, &c.

If two stars be thus referred to the same point of the ecliptic, they are said to be in conjunction; if in opposite points, they are in opposition; if they are referred to two points at a quadrant's distance, they are said to be in a quartile aspect, if the points differ a 6th part of the ecliptic, they are in sextile aspect, &c.

In general, all circles that intersect one of the six greater circles of the sphere at right angles, may be called secondary circles. As the azimuth or vertical circles in respect of the horizon, &c; the meridian in respect of the equator, &c.

SECONDARY *Planets*, or *Satellites*, are those moving round other planets as the centres of their motion, and along with them round the sun.

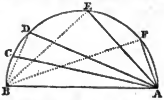
SECTION, in Geometry, denotes the intersection of two planes, or the surface made by a body's being cut by a plane, &c.

The common section of two planes is always a right line: being the line supposed to be drawn by one plane in its cutting or entering the other. If a sphere be cut in any manner by a plane, the figure of the section will be a circle; also the common intersection of the surfaces of two spheres, is the circumference of a circle; and the two common sections of the surfaces of a right cone and a sphere, are the circumferences of circles if the axis of the cone pass through the centre of the sphere, otherwise not; moreover, of the two common sections of a sphere and a cone, whether right or oblique, if the one be a circle the other will be a circle also, otherwise not. See my Tracts, vol. 1, tract 13, prop. 7, 8, 9.

The sections of a cone by a plane, are five; viz, a triangle, circle, ellipse, hyperbola, and parabola. See each of these terms, as also CONIC SECTION.

Sections of buildings and bodies, &c, are either vertical, or horizontal, &c. The

Angular SECTIONS, is a term given by Vieta to the analytical investigation of the law of increase, or decrease, of the sines and chords of multiple and submultiple arcs. Vieta first published this ingenious theory in 1579, with his Canon Mathematicus, which is nothing more than a table of sines constructed according to this principle. He there shows that, if in the semicircle BCD&c, there be taken any number of equal arcs, BD, DE, EF, FG, &c; and if we make the radius equal to 1, and AD $= x$, we shall have the series of supplementary chords AD, AE, AF, &c; which, according to the modern method of expression, will be represented as follows:



AB $= 2$
AD $= x$
AE $= x^2 - 2$
AF $= x^3 - 3x$
AG $= x^4 - 4x^2 + 2$
AH $= x^5 - 5x^3 + 5x$
AI $= x^6 - 6x^4 + 9x^2 - 2$
AK $= x^7 - 7x^5 + 14x^3 - 7x$
&c.

Vieta has also pointed out the law of this progression, by which it may be continued to infinity; that of the powers and signs is evident; and as to the co-efficients, he observes that, the coefficients of the second column are the series of natural numbers, beginning at 2; those of the third columns are triangular numbers, beginning at 2, instead of 1, as in the common form of those numbers; that is, 2, (2+3), (2+3+4), (2+3+4+5), &c: in the fourth column, they are the pyradical numbers, &c.

The ratio of the chords themselves as BD, BE, BF, &c, Vieta has also shown may be expressed in the following manner, by calling the first chord x, and radius $= 1$, as before, then the

2d chord - - - - - $2 - x^2$
3d - - - - - - - $3x - x^3$
4th - - - - - - $2 + 4x^2 - x^4$
5th - - - - - $5x - 5x^3 + x^5$, &c.

The law of the progression being the same as in the former case.

Various other curious and useful formulæ and observations, on the doctrine of angular sections, may be seen in the work above alluded to, and in the Opuscula of Oughtred, first published in 1667.

Vertical SECTION, or simply the SECTION, of a building, denotes its profile, or a delineation of its heights and depths raised on the plan; as if the fabric had been cut asunder by a vertical plane, to discover the inside. And

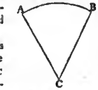
Horizontal SECTION is the ichnography or ground plan, or a section parallel to the horizon.

SECTION *of a Ratio*, or Proportional Section, one of the last works of Apollonius, in 2 books, restored by Snell, in 1607, and by Halley, in 1706, 8vo.

SECTION *of a Space*, another of the last works of Apollonius, in 2 books, restored by Snell in 1607.

SECTION, *Determinate*. See DETERMINATE *Section*.

SECTOR, of a Circle, is a portion of the circle comprehended between two radii and their included arc. Thus, the figure ABC, contained between the two radii AC and BC, and the arc AB, is a sector of the circle.



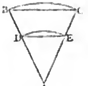
The sector of a circle, as ABC, is equal to a triangle, whose base is the arc AB, and its altitude the radius AC or BC. And therefore the radius being drawn into the arc, half the product gives the area.

Similar SECTORS, are those which have equal angles included between their radii. These are to each other as the squares of their bounding arcs, or as their whole circles.

SECTOR also denotes a mathematical instrument, which is of great use in geometry, trigonometry, surveying, &c, in measuring and laying down and finding proportional quantities of the same kind: as, between lines and lines, surfaces and surfaces, &c: whence it was called the Compass of Proportion, by the French and the Germans, &c.

The great advantage of the sector above the common scales, &c, is, that it is adapted to all radii, and all scales. By the lines of chords, sines, &c, on the sector, we have lines of chords, sines, &c, to any radius between the length and breadth of the sector when open.

The sector is founded on the 4th proposition of the 6th book of Euclid; where it is demonstrated, that similar triangles have their like sides proportional. An idea of the theory of its construction may be conceived thus. Let the lines AB, AC represent the legs of the sector; and AD, AE, two equal sections from the centre: then if the points BC and DE be connected, the lines BC and DE will be parallel; therefore the triangles ABC, ADE will be similar, and consequently the sides AB, BC, AD, DE proportional, that is, as AB : BC :: AD : DE; so that if AD be the half, 3d, or 4th part of AB, then DE will be a half, 3d, or 4th part of BC: and the same holds of all the rest. Hence, if DE be the chord, sine or tangent, of any arc, or of any number of degrees, to the radius AD, then BC will be the same to the radius AB.



The sector, it is supposed, was the invention of Guido Baldo or Ubaldo, about the year 1568. The first printed account of it was in 1584, by Gaspar Mordente at Antwerp, who indeed says that his brother Fabricius Mordente invented it, in the year 1554. It was next treated of by Daniel Speckle, at Strasburgh, in 1589; after that by Dr. Thomas Hood, at London, in 1598; then by Lewin Hulse, at Frankfort on the Maine, 1603, who says it was invented long before by Justus Byrgius, an engineer in the service of the Landgrave of Hesse. But that honour was claimed, and even contended for, by Galileo and by Balthasar Capra of Milan. The former published a Tract on that useful instrument in 1607; and it doubtless received improvements from him, as well as from our countrymen Gunter, Foster, and others. See Wolfii Elem. Math. tom. 5, pa. 49; also Saverien Diction. art. Compass, and Cunn on the Sector, published by Stone, Preface. It was treated on afterwards by many other writers on practical geometry, in all the nations of Europe.

Description of the SECTOR. This instrument consists of two rules or legs, the longer the better, made of box, or ivory, or brass, &c, representing the radii, moveable round an axis or joint, the middle of which represents the centre; from whence several scales are drawn on the faces. See the fig. 1, plate xxxii.

The scales usually set upon sectors, may be distinguished into single and double. The single scales are such as are set upon plane scales: the double scales are those which proceed from the centre; each of these being laid twice on the same face of the instrument, viz, once on each leg. From these scales, dimensions or distances are to be taken, when the legs of the instrument are set in an angular position.

The scales set upon the best sectors are

Single	1	A line of	Inches, each divided into 8 and 10 parts,		
	2		Decimals, containing 100 parts.		
	3		Chords	marked	Cho.
	4		Sines		Sin.
	5		Tangents		Tan.
	6		Rhumbs		Rhum.
	7		Latitude		Lat.
	8		Hours		Hou.
	9		Longitude		Lon.
	10		Inclin. Merid.		In. mer.
	11		the logarithms of Numbers		Num.
	12		Sines		Sin.
	13		Versed sines		V. Sin.
	14		Tangents		Tan.
Double	1	a line of	Lines, or equal parts	marked	Lin.
	2		Chords		Cho.
	3		Sines		Sin.
	4		Tangents to 45°		Tan.
	5		Secants		Sec.
	6		Tangents to above 45°.		Tan.
	7		Polygons		Pol.

The manner in which these scales are disposed on the sector, is best seen in the figure.

The scales of lines, chords, sines, tangents, rhumbs, latitudes, hours, longitude, incl. merid. may be used, with the instrument either shut or open, each of these scales being contained on one of the legs only. The scales of inches, decimals, log. numbers, log. sines, log. versed sines, and log. tangents, are to be used with the sector quite open, with the two rulers or legs stretched out in the same direction, part of each scale lying on both legs.

The double scales of lines, chords, sines, and lower tangents, or tangents under 45°, are all of the same radius or length; they begin at the centre of the instrument, and are terminated near the other extremity of each leg; viz, the lines at the division 10, the chords at 60, the sines at 90, and the tangents at 45; the remainder of the tangents, or those above 45°, are on other scales beginning at $\frac{1}{4}$ of the length of the former, counted from the centre, where they are marked with 45, and run to about 76 degrees.

The secants also begin at the same distance from the centre, where they are marked with 10, and are from thence continued to as many degrees as the length of the sector will allow, which is about 75°.

The angles made by the double scales of lines, of chords, of sines, and of tangents to 45 degrees, are always equal. And the angles made by the scales of upper tangents, and of secants, are also equal.

The scales of polygons are set near the inner edge of the legs; and where these scales begin, they are marked with 4, and from thence are figured backwards, or towards the centre, to 12.

From this disposition of the double scales, it is plain, that those angles that are equal to each other while the legs of the sector were close, will still continue to be equal, though the sector be opened to any distance.

The scale of inches is laid close to the edge of the sector, and sometimes on the very edge; it contains as many inches as the instrument will receive when opened; each inch being usually divided into 8, and also into 10 equal parts. The decimal scale lies next to this: it is of the length of the sector when opened, and is divided into 10 equal parts, or primary divisions, and each of these into 10 other equal parts; so that the whole is divided into 100 equal parts: and by this decimal scale, all the other scales, that are taken from tables, may be laid down. The scales of chords, rhumbs, sines, tangents, hours, &c, are such as are described under Plane Scale.

The scale of logarithmic or artificial numbers, called Gunter's scale, or Gunter's line, is a scale expressing the logarithms of common numbers, taken in their natural order.

The construction of the double scale will be evident by inspecting the instrument. As to the scale of polygons, it usually comprehends the sides of the polygons from 6 to 12 sides inclusive: the divisions are laid down by taking the lengths of the chords of the angles at the centre of each polygon, and laying them down from the centre of the instrument. When the polygons of 4 and 5 sides are also introduced, this line is constructed from a scale of chords, where the length of 90° is equal to that of 60° of the double scale of chords on the sector.

In describing the use of the sector, the terms *lateral distance* and *transverse distance* often occur. By the former is meant the distance taken with the compasses on one of the scales only, beginning at the centre of the sector; and by the latter, the distance taken between any two corresponding divisions of the scales of the same name, the legs of the sector being in an angular position.

Uses of the SECTOR.

Of the Line of Lines. This is useful, to divide a given line into any number of equal parts, or in any proportion, or to make scales of equal parts, or to find 3d and 4th proportionals, or mean proportionals, or to increase or decrease a given line in any proportion. Ex. 1. To divide a given line into any number of equal parts, as suppose 9: make the length of the given line a transverse distance to 9 and 9, the number of parts proposed; then will the transverse distance of 1 and 1 be one of the equal parts, or the 9th part of the whole; and the transverse distance of 2 and 2 will be 2 of the equal parts, or $\frac{2}{9}$ of the whole line; and so on. 2. Again, to divide a given line into any number of parts that shall be in any assigned proportion, as suppose three parts, in the proportion of 2, 3, and 4. Make the given line a transverse distance to 9, the sum of the proposed numbers 2, 3, 4; then the transverse distances of these numbers severally will be the parts required.

Of the Scale of Chords. 1. To open the sector to any angle, as suppose 50 degrees: Take the distance from the joint, or centre, to 50 on the chords, the number of degrees proposed; then open the sector till the transverse distance from 60 to 60, on each leg, be equal to the said lateral distance of 50; so shall the scale of chords make the proposed angle of 50 degrees.—By the converse of this operation, may be known the angle the sector is opened to; viz, taking the transverse distance of 60, and applying it laterally from the joint.

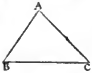
2. To protract or lay down an angle of any given number of degrees. At any opening of the sector, take the transverse distance of 60°, with which extent describe an arc; then take the transverse distance of the number of degrees proposed, and apply it to that arc; and through the extremities of this distance on the arc draw two lines from the centre, and they will form the angle as proposed. When the angle exceeds 60°, lay it off at twice or thrice. —By the converse operation any angle may be measured; viz, With any radius describe an arc from the angular point; set that radius transversely from 60 to 60; then take the distance of the intercepted arc, and apply it transversely to the chords, which will show the degrees in the given angle.

Of the Line of Polygons. 1. In a given circle to inscribe a regular polygon, for example an octagon. Open the legs of the sector till the transverse distance from 6 to 6 be equal to the radius of the circle; then will the transverse distance of 8 and 8 be the side of the inscribed octagon. 2. Upon a line given to describe a regular polygon. Make the given line a transverse dis. to 5 and 5; and at that opening of the sector take the transverse distance of 6 and 6; with which as a radius, from the extremities of the given line describe arcs to intersect each other, and this intersection will be the centre of a circle in which the proposed polygon may be inscribed; then from that centre describe the said circle through the extremities of the given line, and apply this line continually round the circumference, for the several angular points of the polygon. 3. On a given right line as a base, to describe an isosceles triangle, having the angles at the base double the angle at the vertex. Open the sector till the length of the given line fall transversely on 10 and 10 on each leg; then take the transverse distance to 6 and 6, and it will be the length of each of the equal sides of the triangle.

Of the Sines, Tangents, and Secants. By the several lines disposed on the sector, we have scales of several radii. So that, 1. Having a length or radius given, not exceeding the length of the sector when opened, we can find the chord, sine, &c, to the same: for ex. suppose the chord, sine, or tangent of 20 degrees to a radius of 3 inches be required. Make 3 inches the opening or transverse distance to 60 and 60 on the chords; then will the same extent reach from 45 to 45 on the tangents, and from 90 to 90 on the sines; so that to whatever radius the line of chords is set, to the same are all the others set also. In this disposition therefore, if the transverse distance between 20 and 20 on the chords be taken with the compasses, it will give the chord of 20 degrees; and if the transverse of 20 and 20 be in like manner taken on the sines, it will be the sine of 20 degrees; and lastly, if the transverse distance of 20 and 20 be taken on the tangents, it will be the tangent of 20 degrees, to the same radius.—2. If the chord or tangent of 70 degrees were required. For the chord, the transverse distance of half the arc, viz 35, must be taken, as before; which distance taken twice gives the chord of 70 degrees. To find the tangent of 70 degrees, to the same radius, the scale of upper tangents must be used, the under one only reaching to 45: making therefore 3 inches the transverse distance to 45 and 45 at the beginning of that scale, the extent between 70 and 70 degrees on the same, will be the tangent of 70 degrees to 3 inches radius.—3. To find the secant of an arc; make the given radius the transverse distance between 0 and 0 on the secants; then will the transverse distance of 20 and 20, or 70 and 70, give the secant of 20 or 70 degrees.—4. If the radius, and any line representing a sine, tangent, or secant, be given, the degrees corresponding to that line may be found by setting the sector to the given radius, according as a sine, tangent, or secant is concerned; then taking the given line between the compasses, and applying the two feet transversely to the proper scale, and sliding the feet along till they both rest on like divisions on both legs; then the divisions will show the degrees and parts corresponding to the given line.

Use of the Sector in Trigonometry, or in working any other proportions.

By means of the double scales, which are the parts more peculiar to the sector, all proportions are worked by the property of similar triangles, making the sides proportional to the bases, that is, on the sector, the lateral distances proportional to the transverse ones; thus, taking the distance of the first term, and applying it to the 2d, then the distance of the 3d term, properly applied, will give the 4th term: observing that the sides of triangles are taken off the line of numbers laterally, and the angles are taken transversely, off the sines or tangents or secants, according to the nature of the proportion. For example, in a plane triangle ABC, given two sides and an angle opposite to one of them, to find the rest; viz, given AB = 56, AC = 64 and ∠B = 46° 30′, to find BC and the angles A and C. In this case, the sides are proportional to the sines of their opposite angles; hence these proportions,



as AC (64) : sin. ∠B (46° 30′) :: AB (56) : sin. ∠C, and as sin. B : AC :: sin. A :: BC.

Therefore, to work these proportions by the sector, take the lateral distance of 64 = AC from the lines, and open the sector to make this a transverse distance of 46° 30′ = ∠B, on the sines; then take the lateral distance of 56 = AB on the lines, and apply it transversely on the sines, which will give 39° 24′ = ∠C. Hence, the sum of the angles B and C, which is 85° 54′, taken from 180°, leaves 94° 6′ = ∠A. Then, to work the 2d proportion, the sector remaining set at the same opening as before, take the transverse distance of 94° 6′ = ∠A, on the sines, or, which is the same thing, the transverse distance of its supplement 85° 54′; then this applied laterally to the lines, gives 88 = the side BC sought.

For the complete history of the sector, with its more ample and particular construction and uses, see the Introduction to Robertson's Treatise of such Mathematical Instruments, as are usually put into a Portable Case.

SECTOR *of a Sphere*, is the solid generated by the revolution of the sector of a circle about one of its radii; the other radius describing the surface of a cone, and the circular arc a circular portion of the surface of the sphere of the same radius. So that the spherical sector consists of a right cone, and of a segment of the sphere having the same common base with the cone. And hence the solid content of it will be found by multiplying the base or spherical surface by the radius of the sphere, and taking a 3d part of the product.

SECTOR *of an Eclipse*, or *of an Hyperbola*, &c, is a part resembling the circular sector, being contained by three lines, two of which are radii, or lines drawn from the centre of the figure to the curve, and the intercepted arc or part of that curve.

Astronomical SECTOR, an instrument invented by Mr. George Graham, for finding the difference in right ascension and declination between two objects, whose distance is too great to be observed through a fixed telescope, by means of a micrometer. This instrument (fig. 2, pl. 32,) consists of a brass plate, called the sector, formed like a T, having the shank CD, as a radius, about 2½ feet long, and 2 inches broad at the end D, and an inch and a half at C; and the cross-piece AB, as an arch, about 6 inches long, and one and a half broad; upon which, with a radius of 30 inches, is described an arch of 10 degrees, each degree being divided in as many parts as are convenient. Round a small cylinder C, containing the centre of this arch, and fixed in the shank, moves a plate of brass, to which is attached a telescope CE, having its line of collimation parallel to the plane of the sector, and passing over the centre C of the arch AB, and the index of a Vernier's dividing plate, whose length, being equal to 16 quarters of a degree, is divided into 15 equal parts, fixed to the eye end of the telescope, and made to slide along the arch; which motion is performed by a long screw, G, at the back of the arch, communicating with the Vernier through a slit cut in the brass, parallel to the divided arch. Round the centre F of a circular brass plate *abc*, of 5 inches diameter, moves a brass cross KLMN, having the opposite ends O and P of one bar turned up perpendicularly about 3 inches, to serve as supporters to the sector, and screwed to the back of its radius; so that the plane of the sector is parallel to the plane of the circular plate, and can revolve round the centre of that plate in this parallel position. A square iron axis HIF, 18 inches long, is screwed flat to the back of the circular plate along one of its diameters, so that the axis is parallel to the plane of the sector. The whole instrument is supported on a proper pedestal, so that the said axis shall be parallel to the earth's axis, and proper contrivances are annexed to fix it in any position. The instrument, thus supported, can revolve round its axis HI, parallel to the earth's axis, with a motion like that of the stars, the plane of the sector being always parallel to the plane of some hour-circle, and consequently every point of the telescope describing a parallel of declination; and if the sector be turned round the joint F of the circular plate, its graduated arch may be brought parallel to an hour-circle; and consequently any two stars, whose difference of declination does not exceed the degrees in that arch, will pass over it.

To observe their passage, direct the telescope to the preceding star, and fix the plane of the sector a little to the westward of it; move the telescope by the screw G, and observe at the transit of each over the cross wires the time shown by the clock, and also the division upon the arch AB, shown by the index; then is the difference of the arches the difference of the declination; and that of the times shows the difference of the right ascension of those stars. For a more particular description of this instrument, see Smith's Optics, book iii, chap. 9.

SECULAR *Equations*, or Century Equations, in Astronomy, are corrections required to compensate such inequalities, in the celestial motions, as occur in the course of a century or 100 years. Thus, there are secular inequalities in the moon's motion, which require for their correction as many distinct secular equations. For which, see the books on astronomy.

SECULAR *Year*, the same with Jubilee.

SECUNDANS, an infinite series of numbers, beginning from nothing, and proceeding according to the squares of numbers in arithmetical progression, as 0, 1, 4, 9, 16, 25, 36, 49, 64, &c.

SEEING, the act of perceiving objects by the organ of sight; or the sense we have of external objects by means of the eye.

For the apparatus, or diposition of the parts necessary to seeing, see EYE. And for the manner in which seeing is performed, and the laws of it, see VISION.

Our best anatomists differ greatly as to the cause why we do not see double with the two eyes. Galen, and others after him, ascribe it to a coalition, or decussation, of the optic nerve, behind the os sphenoides. But whether they decussate or coalesce, or only barely touch one another, is not well agreed on.—The Bartholines and Vesalius say expressly, they are united by a perfect confusion of their substance; Dr. Gibson allows them to be united by the closest conjunction, but not by a confusion of their fibres. —Alhazen, an Arabian philosopher of the 12th century, accounts for single vision by two eyes, by supposing that when two corresponding parts of the retina are affected, the mind perceives but one image.

Descartes and others account for the effect another way; viz, by supposing that the fibrillæ constituting the medullary part of those nerves, being spread in the retina of each eye, have each of them corresponding parts in the brain, so that when any of those fibrillæ are struck by any part of an image, the corresponding parts of the brain are affected by it. Somewhat like which is the opinion of Dr. Briggs, who takes the optic nerves of each eye to consist of homologous fibres, having their rise in the thalamus nervorum opticorum, and being thence continued to both the retinæ, which are composed of them; and further, that those fabrillæ have the same parallelism, tension, &c, in both eyes; consequently when an image is painted on the same corresponding sympathizing parts of each retina, the same effects are produced, the same notice carried to the thalamus, and so imparted to the mind. Hence it is, that double vision ensues upon an interruption of the parallelism of the eyes; as when one eye is depressed by the finger, or their symphony is interrupted by disease: but Dr. Briggs maintains, that it is but in few subjects there is any decussation; and in none any conjunction more than mere contact; though his notion is by no means consonant to facts, and it is attended with many improbable circumstances.

It was the opinion of Sir Isaac Newton, and of many others, that objects appear single, because the two optic nerves unite before they reach the brain. But Dr. Porterfield shows, from the observation of several anatomists, that the optic nerves do not mix or confound their substance, being only united by a close cohesion; and objects have appeared single, where the optic nerves were found to be disjoined. To account for this phenomenon, this ingenious writer supposes, that, by an original law in our natures, we imagine an object to be situated somewhere in a right line drawn from the picture of it upon the retina, through the centre of the pupil; consequently the same object appearing to both eyes to be in the same place, we cannot distinguish it into two. In answer to an objection to this hypothesis, from objects appearing double when one eye is disturted, he says, the mind mistakes the position of the eye, imagining, that it had moved in a manner corresponding to the other, in which case the conclusion would have been just: in this he seems to have recourse to the power of habit, though he disclaims that hypothesis. This principle however has been thought sufficient to account for this appearance.

Originally, every object making two pictures, one in each eye, is imagined to be double; but, by degrees, we find that when two corresponding parts of the retina are impressed, the object is but one; but if those corresponding parts be changed by the distortion of one of the eyes, the object must again appear double as at the first. This seems to be verified by Mr. Cheselden, who informs us, that a gentleman, who, from a blow on his head, had one eye distorted, found every object to appear double, but by degrees the most familiar ones came to appear single again, and in time all objects did so without amendment of the distortion. A similar case is mentioned by Dr. Smith.—On the other hand, Dr. Reid is of opinion, that the correspondence of the centres of two eyes, on which single vision depends, does not arise from custom, but from some natural constitution of the eye, and of the mind. M. du Tour adopts an opinion, long before suggested by Gassendi, that the eye attends to no more than the image made in one eye at a time; in support of which, he produces several curious experiments; but as M. Buffon observes, it is a sufficient answer to this hypothesis, that we see more distinctly with two eyes than with one; and that when a round object is near us, we plainly see more of the surface in one case than in the other.

With respect to single vision with two eyes, Dr. Hartley observes, that it deserves particular attention, that the optic nerves of man, and such other animals as look the same way with both eyes, unite in the sella turcica in a ganglion, or little brain, as it may be called, peculiar to themselves, and that the associations between synchronous impressions on the two retinas, must be made sooner and cemented stronger on this account; also that they ought to have a much greater power over one another's image, than in any other part of the body. And thus an impression made on the right eye alone by a single object, propagates itself into the left, and there raises up an image almost equal in vividness to itself; and, consequently, when we see with one eye only, we may however have pictures in both eyes.

It is a common observation, says Dr. Smith, that objects seen with both eyes appear more vivid and stronger than they do to a single eye, especially when both of them are equally good. Porterfield on the Eye, vol. ii, pa. 285, 315. Smith's Optics, Remarks, pa. 31. Reid's Inquiry, pa. 267. Mem. Présentes, pa. 514. Acad. Par. 1747. Mem. Pr. 334. Hartley on Man, vol. i, pa. 207. Priestley's Hist. of Light and Colours, pa. 663, &c.

Whence it is that we see objects erect, when it is certain that the images thereof are painted invertedly on the retina, is another difficulty in the theory of seeing. Descartes accounts for it hence, that the notice which the soul takes of the object, does not depend on any image, nor any action coming from the object, but merely on the situation of the minute parts of the brain, whence the nerves arise; ex. gr. the situation of a capillament brain, which occasions the soul to see all those places lying in a right line with it.

But Mr. Molyneux gives another account of this matter. The eye, he observes, is only the organ, or instrument; it is the soul that sees. To enquire then, how the soul perceives the object erect by an inverted image, is to enquire into the soul's faculties. Again, imagine that the eye receives an impulse on its lower part, by a ray from the upper part of an object; must not the visive faculty be hereby directed to consider this stroke as coming from the top, rather than the bottom of the object, and consequently be determined to conclude it the representation of the top?

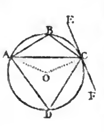
On these principles, we are to consider, that inverted is only a relative term, and that there is a very great difference between the real object, and the means or image by which we perceive it. When all the parts of a distant prospect are painted on the retina (supposing that to be the seat of vision), they are all right with respect to one another, as well as the parts of the prospect itself; and we can only judge of an object being inverted, when it is turned reverse to its natural position with respect to other objects which we see and compare it with.

The eye or visive faculty (says Molyneux) takes no notice of the internal surface of its own parts, but uses them as an instrument only, contrived by nature for the exercise of such a faculty. If we lay hold of an upright stick in the dark, we can tell which is the upper or lower part of it, by moving our hand upward or downward; and very well know that we cannot feel the upper end by moving our hand downward. Just so, we find by experience and habit, that by directing our eyes towards a tall object, we cannot see its top by turning our eyes downward, nor its foot by turning our eyes upward; but must trace the object the same way by the eye to see it from head to foot, as we do by the hand to feel it; and as the judgment is informed by the motion of the hand in one case, so it is also by the motion of the eye in the other.

Molyneux's Dioptr. pa. 105, &c. Musschenbroek's Int. ad Phil. Nat. vol. ii, pa. 762. Ferguson's Lectures, pa. 132. See Visible, Vision, &c.

SEGMENT, in Geometry, is a part cut off the top of a figure by a line or plane; and the part remaining at the bottom, after the segment is cut off, is called a frustum, or a zone. So, a

Segment *of a Circle*, is a part of the circle cut off by a chord, or a portion comprehended by an arch and its chord; and may be either greater or less than a semicircle. Thus, the portion ABCA is a segment less than a semicircle; and ADCA a segment greater.



The angle formed by lines drawn from the extremities of a chord to meet in any point of the arc, is called an angle *in* the segment. So the angle ABC is an angle *in* the segment ABCA; and the angle ADC, an angle *in* the segment ADCA.

Also the angle B is said to be the angle *upon* the segment ADC, and D the angle *on* the segment ABC.

The angle which the chord AC makes with a tangent EF, is called the angle *of* a segment; and it is equal to the angle in the alternate or supplemental segment, or equal to the supplement of the angle in the same segment. So the angle ACE is the angle *of* the segment ABC, and is equal to the angle ADC, or to the supplement of the angle B; also the angle ACF is the angle *of* the segment ADC, and is equal to the angle B, or to the supplement of the angle D.

The area of a segment ABC, is evidently equal to the difference between the sector OABC of the same arc, and the triangle OAC on the same chord; the triangle being subtracted from the sector, to give the segment when less than a semicircle; but to be added when greater. See more rules for the segment in my Mensuration, pa. 99, &c, 4th edition.

Similar Segments, are those that have their chords directly proportional to their radii or diameters, or that have similar arcs, or such as contain the same number of degrees.

Segment *of a Sphere*, is a part cut off by a plane.

The base of a segment is always a circle. And the convex surfaces of different segments, of the same sphere, are to each other as their altitudes, or versed sines. And as the whole convex surface of the sphere is equal to 4 of its great circles, or 4 circles of the same diameter; so the surface of any segment, is equal to 4 circles on a diameter equal to the chord of half the arc of the segment. So that if d denote the diameter of the sphere, or the chord of half the circumference, and c the chord of half the arc of any other segment, also a the altitude or versed sine of the same; then,

$3{\cdot}1416d^2$ is the surface of the whole sphere, and

$3{\cdot}1416c^2$, or $3{\cdot}1416ad$, the surface of the segment.

For the solid content of a segment, there are two rules usually given; viz, 1. To 3 times the square of the radius of its base, add the square of its height; multiply the sum by the height, and the product by ·5236. Or, 2dly, From 3 times the diameter of the sphere, subtract twice the height of the frustum; multiply the remainder by the square of the height, and the product by ·5236. That is, in symbols, the solid content is either

$= {\cdot}5236a \times (3r^2 + a^2)$, or $= {\cdot}5236a^2 \times (3d - 2a)$; where a is the altitude of the segment, r the radius of its base, and d the diameter of the whole sphere.

Line of Segments, are two particular lines, so called, on Gunter's sector. They lie between the lines of sines and superficies, and are numbered with 5, 6, 7, 8, 9, 10. They represent the diameter of a circle, so divided into 100 parts, that a right line drawn through those parts, and perpendicular to the diameter, shall cut the circle into two segments, the greater of which will have the same proportion to the whole circle, as the parts cut off have to 100.

SELENOGRAPHY, the description and representation of the moon, with all the parts and appearances of her disc or face; as geography does those of the earth. Since the invention of the telescope, selenography is very much improved. We have now distinct names for most of the supposed regions, seas, lakes, mountains, &c, visible in the moon's body. Hevelius, a celebrated astronomer of Dantzic, and who published the first selenography, named the several places of the moon from those of the earth. But Riccioli afterwards called them by the names of the most celebrated astronomers and philosophers. Thus, what the one calls Mons Porphyrites, the other calls Aristarchus; what the one calls Ætna, Sinai, Athos, Apenninus, &c, the other calls Copernicus, Posidonius, Tycho, Gassendus, &c.—M. Cassini has published a work called Instructions Seleniques, and has published the best map of the moon.

SELEUCIDÆ, in Chronology, the era of the Seleucidæ, or the Syro-Macedonian era, which is a computation of time, commencing from the establishment of the Seleucidæ, a race of Greek kings, who reigned as successors of Alexander the Great, in Syria, as the Ptolemies did in Egypt. According to the best accounts, the first year of this era falls in the year 311 before Christ, which was 12 years after the death of Alexander.

SELL, in Building, is of two kinds, viz, Ground-Sell, which denotes the lowest piece of timber in a wooden building, and that upon which the whole superstructure is raised. And sell of a window, or of a door, which is the bottom piece in the frame of them, upon which they rest.

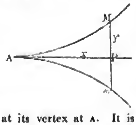
SEMICIRCLE, in Geometry, is half a circle, or a figure comprehended between the diameter of a circle, and half the circumference.

SEMICIRCLE is also an instrument in Surveying, sometimes called the Graphometer. It consists of a semicircular limb or arch, as FIG (fig. 3, pl. 32) divided into 180 degrees, and sometimes subdivided diagonally or otherwise into minutes. This limb is subtended by a diameter FG, having two sights erected at its extremities. In the centre of the semicircle, or the middle of the diameter, is fixed a box and needle; and on the same centre an alidade, or moveable index, carrying two other sights, as H, I: the whole being set on a staff, with a ball and socket, &c.

Hence it appears, that the semicircle is nothing but half a theodolite; with this only difference, that whereas the limb of the theodolite, being an entire circle, takes in all the 360° successively; while in the semicircle the degrees only going from 1 to 180, it is usual to have the remaining 180°, or those from 180° to 360°, graduated in another line on the limb within the former.

To take an Angle with a Semicircle.—Place the instrument in such manner, as that the radius CG may hang over one leg of the angle to be measured, with the centre C over the vertex of the same. The first is done by looking through the sights F and G, at the extremities of the diameter, to a mark fixed up in one extremity of the leg; and the latter is had by letting fall a plummet from the centre of the instrument. This done, turn the moveable index HI on its centre towards the other leg of the angle, till, through the sights fixed in it, you see a mark in the extremity of the leg. Then the degree which the index cuts on the limb, is the quantity or measure of the angle. Other uses are the same as in the theodolite.

SEMICUBICAL PARABOLA, a curve of the 2d order, of such a nature that the cubes of the ordinates are proportional to the squares of the abscisses, its equation being $ay^2 = x^3$. This curve, AM*m*, is one of Newton's five diverging parabolas, being his 70th species; having a cusp at its vertex at A. It is otherwise named the Neilian parabola, from the name of the author who first treated of it, or squared it.



The area of the space APM, is $= \frac{4}{5}xy = \frac{4}{5}$AP × PM, or $\frac{4}{5}$ of the circumscribing rectangle.

The content of the solid generated by the revolution of the space APM about the axis AP, is $\frac{1}{4}pxy^2 = \cdot 7854$AP × PM², or $\frac{1}{4}$ of the circumscribing cylinder. And a circle equal to the surface of that solid may be found from the quadrature of an hyperbolic space.

Also the length of any arc AM of the curve may be easily obtained from the quadrature of a space contained under part of the curve of the common parabola, two semiordinates to the axis, and the part of the axis contained between them.

This curve may be described by a continued motion, viz, by fastening the angle of a square in the vertex of a common parabola; and then carrying the intersection of one side of this square and a long ruler (which ruler always moves perpendicularly to the axis of the parabola) along the curve of that parabola. For the intersection of the ruler, and the other side of the square will describe a semicubical parabola. Maclaurin performs this without a common parabola, in his Geometria Organica.

SEMIDIAMETER, the Radius, or half-diameter of a circle or sphere, is a line drawn from the centre to the circumference. And in any curve that has diameters and a centre, it is the radius, or half-diameter, or a line drawn from the centre to some point in the curve.

The distances, diameters, &c, of the heavenly bodies, are usually estimated by astronomers in semidiameters of the earth; the number of which terrestrial semidiameters, contained in that of each of those planets, is as below.

	Semidiam.		Semidiam.
The Earth - -	1	Juno - - -	
The Sun - -	111·25	Pallas - - -

SEMIDIAPASON, in Music, a defective or imperfect octave; or an octave diminished by a lesser semitone, or 4 commas.

SEMIDIAPENTE, in Music, a defective or imperfect fifth, called usually by the Italians, falsa quinta, and by us a false fifth.

SEMIDIATESSARON, in Music, a defective fourth, called also a false fourth.

SEMIDIATONE, in Music, is the lesser third, having its terms as 6 to 5.

SEMIORDINATES, in Geometry, the halves of the ordinates or applicates, being the lines applied between the absciss and the curve.

SEMIPARABOLA, &c, in the higher geometry, a curve defined by the equation $ax^{n-1} = y^n$; as $ax^2 = y^3$, or $ax^3 = y^4$, &c. In semiparabolas, $y^n : v^n :: ax^{n-1} : az^{n-1} :: x^{n-1} : z^{n-1}$; or the powers of the semiordinates are as the powers of the abscisses one degree lower: for instance, in cubical semiparabolas, the cubes of the ordinates are as the squares of the abscisses; that is, $y^3 : v^3 :: x^2 : z^2$.

SEMIQUADRATE, or SEMIQUARTILE, is an aspect of the planets, when distant from each other one sign and a half, or 45 degrees.

SEMIQUAVER, in Music, the half of a quaver.

SEMIQUINTILE, is an aspect of the planets when distant from each other the half of a 5th of the circle, or by 36 degrees.

SEMISEXTILE, an aspect of two planets, when they are distant from each other 30 degrees, or the half of a sextile, which is 2 signs or 60°. The semisextile is marked *s. s.*

SEMITONE, in Music, a half tone or half note, one of the degrees or intervals of concords. There are three degrees, or less intervals, by which a sound can move upwards and downwards, successively from one extreme of any concord to the other, and yet produce true melody. These degrees are the greater tone, the less tone, and the semitone. The ratios defining these intervals are these, viz, the greater tone 8 to 9, the less tone 9 to 10, and the semitone 15 to 16. Its compass is 5 commas, and it has its name from being nearly half a whole, though it is really somewhat more.

There are several species of semitones; but those that usually occur in practice are of two kinds, distinguished by the addition of greater and less. The first is expressed by the ratio of 16 to 15, or $\frac{16}{15}$; and the second by 25 to 24, or $\frac{25}{24}$. The octave contains 10 semitones major, and 2 dieses, nearly, or 17 semitones minor, nearly; for the measure of the octave being expressed by the log. 100,000, the semitone major will be measured by - 0,09311, and the semitone minor by - - 0,05889. These two differ by a whole enharmonic diesis; which is an interval practicable by the voice. It was much in use among the ancients, and is not unknown among modern practitioners. Euler Tent. Nov. Theor. Mus. pa. 107. See Interval.

These semitones are called fictitious notes; and, with respect to the natural ones, they are expressed by characters called flats and sharps. The use of them is to remedy the defects of instruments, which, having their sounds fixed, cannot always be made to answer to the diatonic scale. By means of these, we have a new kind of scale, called the

SEMITONIC *Scale*, or the *Scale of Semitones*, which is a scale or system of music, consisting of 12 degrees, or 13 notes, in the octave, being an improvement on the natural or diatonic scale, by inserting between each two notes of it, another note, which divides the interval or tone into two unequal parts, called semitones.

The use of this scale is for instruments that have fixed sounds, as the organ, harpsichord, &c, which are exceedingly defective on the foot of the natural or diatonic scale. For the degrees of the scale being unequal, from every note to its octave there is a different order of degrees; so that from any note we cannot find every interval in a series of fixed sounds; which yet is necessary, that all the notes of a piece of music, carried through several keys, may be found in their just tune, or that the same song may be begun indifferently at any note, as may be necessary for accommodating some instrument to others, or to the voice, when they are to accompany each other in unison.

The diatonic scale, beginning at the lowest note, being first settled on an instrument, and the notes of it distinguished by their names *a, b, c, d, e, f, g*; the inserted notes, or semitones, are called fictitious notes, and take the name or letter below with a ♯, as $c^{\sharp}$ called c sharp; signifying that it is a semitone higher than the sound of *c* in the natural series; or this mark ♭ called a flat, with the name of the note above signifying it to be a semitone lower.

Now $\frac{15}{16}$ and $\frac{128}{135}$ being the two semitones the greater tone is divided into, and $\frac{15}{16}$ and $\frac{24}{25}$, the semitones the less tone is divided into, the whole octave will stand as in the following scheme, where the ratios of each term to the next are written fraction-wise between them below.

c. $c^{\sharp}$. *d.* $d^{\sharp}$. *e.* *f.* $f^{\sharp}$. *g.* $g^{\sharp}$. $a^{\flat}$. *b.* *cc.*
$\frac{15}{16}$ $\frac{128}{135}$ $\frac{15}{16}$ $\frac{24}{25}$ $\frac{15}{16}$ $\frac{128}{135}$ $\frac{15}{16}$ $\frac{15}{16}$ $\frac{24}{25}$ $\frac{15}{16}$ $\frac{128}{135}$ $\frac{15}{16}$

For the names of the intervals in this scale, it may be considered, that as the notes added to the natural scale are not designed to alter the species of melody, but leave it still diatonic, and only correct certain defects arising from something foreign to the office of the scale of music, viz, the fixing and limiting the sounds; we see the reason why the names of the natural scale are continued, only making a distinction of each into a greater and less. Thus an interval of one semitone, is called a less second; of two semitones, a greater second; of three semitones, a less third; of four, a greater third, &c.

A second kind of semitonic scale we have from another division of the octave into semitones, which is performed by taking an harmonical mean between the extremes of the greater and less tone of the natural scale, which divides it into two semitones nearly equal. Thus, the greater tone 8 to 9 is divided into two semitones, which are 16 to 17, and 17 to 18; where 16, 17, 18, is an arithmetical division, the numbers representing the lengths of the chords; but if they represent the vibration, the lengths of the chords are reciprocal; viz as 1, $\frac{16}{17}$, $\frac{8}{9}$; which puts the greater semitone $\frac{16}{17}$ next the lower part of the tone, and the lesser $\frac{17}{18}$ next the upper, which is the property of the harmonical division. And after the same manner the less tone 9 to 10 is divided into two semitones, 18 to 19, and 19 to 20; and the whole octave stands thus:

c. $c^{\sharp}$. *d.* $d^{\sharp}$. *e.* *f.* $f^{\sharp}$. *g.* $g^{\sharp}$. $a^{\flat}$. *b.* *c.*
$\frac{16}{17}$ $\frac{17}{18}$ $\frac{18}{19}$ $\frac{19}{20}$ $\frac{15}{16}$ $\frac{16}{17}$ $\frac{17}{18}$ $\frac{18}{19}$ $\frac{19}{20}$ $\frac{16}{17}$ $\frac{17}{18}$ $\frac{15}{16}$.

This scale, Mr. Salmon tells us, in the Philosophical Transactions, he made an experiment of before the Royal Society, on chords, exactly in these proportions, which yielded a perfect concert with other instruments, touched by the best hands. Mr. Malcolm adds, that, having calculated the ratios of them, for his own satisfaction, he found more of them false than in the preceding scale, but then their errors were considerably less, which made amends. Malcolm's Music, chap. 10. § 2.

SENSIBLE *Horizon*, or *Point*, or *Quality*, &c. See the substantives.

SEPTUAGESIMA, in the Calendar, is the 9th Sunday before Easter, so called, as some have supposed, because it is near 70 days, though in reality it is only 63 days, before it.

SERIES, in Algebra, denotes a rank or progression of quantities or terms, which usually proceed according to some certain law.

As the series $1 + \frac{1}{2} + \frac{1}{4} + \frac{1}{8} + \frac{1}{16}$ &c,
or the series, $1 + \frac{1}{2} + \frac{1}{3} + \frac{1}{4} + \frac{1}{5}$ &c,

where the former is a geometrical series, proceeding by the constant division by 2, or the denominators multiplied by 2; and the latter is an harmonical series, being the reciprocals of the arithmetical series 1, 2, 3, 4, &c, or the denominators being continually increased by 1.

The only traces of the doctrine of series found among the ancients are in the works of Archimedes and Pappus. Thus, in comparing the spheroid with the cone and cylinder, Archimedes supposes the terms of a progression to increase constantly by the same difference, and demonstrates several properties of such a progression relating to the sum of the terms, and the sum of their squares; by means of which he compares the parabolic conoid, the spheroid, and hyperbolic conoid, with the cone, and the area of his spiral line with the area of the circle. Again, in his Treatise on the Quadrature of the Parabola, he mentions a progression whose terms decrease constantly in the ratio of 4 to 1: but he does not suppose this progression to be continued to infinity, or mention the sum of an infinite number of terms; though it is plain that all that can be understood by those who assign that sum was fully known to him. He contents himself however, with demonstrating this plain property of such a series, that the sum of the terms continued at pleasure, added to the $\frac{1}{3}$ part of the last term, amounts always to $\frac{4}{3}$ of the first term. See pr. 23 quad. parab.

Pappus touches on a subject nearly allied to the modern doctrine of series, in the 4th book of his mathematical collections, where he treats of the general problem relating to an infinite series of circles inscribed in the space called arbelon, contained between the circumferences of two circles touching inwardly. But both of these authors investigate their respective problems geometrically, and without any reference to the algebraic method.

With regard to series considered algebraically, the first notices are found in the works of Dr. Wallis. Thus, in his arithmetical works, published in 1657, he for the first time reduced the fraction $\frac{A}{1-R}$, by a continued division, into the infinite series $A + AR + AR^2 + AR^3 + AR^4 +$ &c. This, and a few other deductions of similar import, gave the idea to Nic. Mercator, who made some advances in the doctrine. It was afterwards taken up by Brouncker, James Gregory, &c; but the genius of Newton first gave it body and form.

This method is chiefly useful in the quadrature of curves; where, as we often meet with quantities which cannot be expressed by any precise definite numbers, such as is the ratio of the diameter of a circle to the circumference, we are glad to express them by a series, which, infinitely continued, is the value of the quantity sought, and which is called an infinite series.

The Nature, Origin, &c. of SERIES.

Infinite series commonly arise, either from a continued division, as was practised by Mercator, or the extraction of roots, as first performed by Newton, who also explained other general ways for the expanding of quantities into infinite series as by the binomial theorem. Thus, to divide 1 by 3, or to expand the fraction $\frac{1}{3}$ into an infinite series; by division in decimals in the ordinary way, the series is 0·3333 &c, or $\frac{3}{10} + \frac{3}{100} + \frac{3}{1000} + \frac{3}{10000}$ &c, where the law of continuation is manifest. Or, if the same fraction $\frac{1}{3}$ be set in this form $\frac{1}{2+1}$, and division be performed algebraically, the quotient will be

$$\frac{1}{3} = \frac{1}{2+1} = \frac{1}{2} - \frac{1}{4} + \frac{1}{8} - \frac{1}{16} + \frac{1}{32} \text{ \&c.}$$

Or, if it be expressed in this form $\frac{1}{3} = \frac{1}{4-1}$, by a like division there will arise the series,

$$\frac{1}{3} = \frac{1}{4} + \frac{1}{16} + \frac{1}{64} \text{ \&c} = \frac{1}{4} + \frac{1}{4^2} + \frac{1}{4^3} \text{ \&c.}$$

Again, by dividing 1 by 5−2, or 6−3, or 7−4, &c, the series answering to the fraction $\frac{1}{3}$, may be found in an endless variety of infinite series. The finite quantity $\frac{1}{3}$ is called the value or radix of the series, as also its sum, being the number or sum to which the series would amount, or the limit to which it would tend or approximate, by summing up its terms, or by collecting them together one after another.

In like manner, by dividing 1 by the algebraic sum $a+c$, or by $a-c$, the quotient will be in these two cases, as below, viz,

$$\frac{1}{a+c} = \frac{1}{a} - \frac{c}{a^2} + \frac{c^2}{a^3} - \frac{c^3}{a^4} \text{ \&c,}$$

$$\frac{1}{a-c} = \frac{1}{a} + \frac{c}{a^2} + \frac{c^2}{a^3} + \frac{c^3}{a^4} \text{ \&c;}$$

where the terms of each series are the same, and they differ only in this, that the signs are alternately positive and negative in the former, but all positive in the latter.

And hence, by expounding a and c by any numbers whatever, we obtain an endless variety of infinite series, whose sums or values are known. So, by taking a or c equal to 1 or 2 or 3 or 4, &c, we obtain these series, and their values or roots:

$$\frac{1}{1+1} = \frac{1}{2} = 1 - 1 + 1 - 1 + 1 - 1 \text{ \&c,}$$

$$\frac{1}{3-1} = \frac{1}{2} = \frac{1}{3} + \frac{1}{3^2} + \frac{1}{3^3} + \frac{1}{3^4} \text{ \&c,}$$

$$\frac{1}{2+1} = \frac{1}{3} = \frac{1}{2} - \frac{1}{2^2} + \frac{1}{2^3} - \frac{1}{2^4} \text{ \&c,}$$

$$\frac{1}{1+2} = \frac{1}{3} = 1 - 2 + 2^2 - 2^3 \text{ \&c,}$$

$$\frac{1}{3+1} = \frac{1}{4} = \frac{1}{3} - \frac{1}{3^2} + \frac{1}{3^3} - \frac{1}{3^4} \text{ \&c.}$$

And hence it appears, that the same quantity or radix may be expressed by a great variety of infinite series, or that many different series may have the same radix or value.

Another way in which an infinite series arises, is by the extraction of roots. Thus, by extracting the square root of the number 3 in the common way, we obtain its value in a series as follows, viz, $\sqrt{3} = 1{\cdot}73205$ &c $= 1 + \frac{7}{10} + \frac{3}{100} + \frac{2}{1000} + \frac{5}{100000}$ &c; in which way of resolution the law of the progression of the series is not visible, as it is when found by division. Thus, the square root of the algebraic quantity $a^2 + c^2$ gives

$$\sqrt{(a^2 + c^2)} = a + \frac{c^2}{2a} - \frac{c^4}{8a^3} + \frac{c^6}{16a^5} \text{ \&c.}$$

And a 3d way is by Newton's binomial theorem, which is a universal method, that serves for all kinds of quantities, whether fractional or radical ones: and by this means the same root of the last given quantity becomes

$$\sqrt{(a^2 + c^2)} = a + \frac{c^2}{2a} - \frac{1.c^4}{2.4a^3} + \frac{1.3c^6}{2.4.6a^5} \text{ \&c,}$$

where the law of continuation is evident.

See EXTRACTION *of Roots*, and BINOMIAL *Theorem*.

From the specimens above given, it appears that the signs of the terms may be either all plus, or alternately plus and minus. Though they may be varied in many other ways. It also appears that the terms may be either continually smaller and smaller, or larger and larger, or they may be all equal. In the first case therefore the series is said to be a decreasing one, in the 2d case an increasing one, and in the 3d case an equal one. Also the first series is called a converging one, because that by collecting its terms successively, taking in always one term more, the successive sums approximate or converge to the value or sum of the whole infinite series. So, in the series $\frac{1}{3-1} = \frac{1}{2} = \frac{1}{3} + \frac{1}{9} + \frac{1}{27} + \frac{1}{81}$, &c, the first term $\frac{1}{3}$ is too little, or below $\frac{1}{2}$ which is the value or sum of the whole infinite series proposed; the sum of the first two terms $\frac{1}{3} + \frac{1}{9}$ is $\frac{4}{9} = \cdot 4444$ &c, is also too little, but nearer to $\frac{1}{2}$ or $\cdot 5$ than the former; and the sum of three terms $\frac{1}{3} + \frac{1}{9} + \frac{1}{27}$ is $\frac{13}{27} = \cdot 481481$ &c, is nearer than the last, but still too little; and the sum of four terms $\frac{1}{3} + \frac{1}{9} + \frac{1}{27} + \frac{1}{81}$, is $\frac{40}{81} = \cdot 493827$ &c, which is again nearer than the former, but still too little; and this is always the case when the terms are all positive. But when the converging series has its terms alternately positive and negative, then the successive sums are alternately too great and too little, though still approaching nearer and nearer to the final sum or value. Thus in in the series

$$\frac{1}{3+1} = \frac{1}{4} = 0{\cdot}25 = \frac{1}{3} - \frac{1}{9} + \frac{1}{27} - \frac{1}{81} \text{ \&c,}$$

the 1st term $\frac{1}{3} = \cdot 333$ &c, is too great,
two terms $\frac{1}{3} - \frac{1}{9} = \cdot 222$ &c, are too little,
three terms $\frac{1}{3} - \frac{1}{9} + \frac{1}{27} = \cdot 259259$ &c, are too great,
four terms $\frac{1}{3} - \frac{1}{9} + \frac{1}{27} - \frac{1}{81} = \cdot 246913$ &c, are too small, and so on, alternately too great and too small, but every succeeding sum still nearer than the former, or converging.

In the second case, or when the terms become larger and larger, the series is called a diverging one, because that by collecting the terms continually, the successive sums diverge, or go always farther and farther from the true value or radix of the series; being all too great when the terms are all positive, but alternately too great and too little when they are alternately positive and negative. Thus, in the series

$$\frac{1}{1+2} = \frac{1}{3} = 1 - 2 + 4 - 8 \text{ \&c.}$$

the first term $+ 1$ is too great.
two terms $1 - 2 = - 1$ are too little,
three terms $1 - 2 + 4 = + 3$ are too great,
four terms $1 - 2 + 4 - 8 = - 5$ are too little,
and so on continually, after the 2d term, diverging more and more from the true value or radix $\frac{1}{3}$, but alternately too great and too little, or positive and negative. But the alternate sums would be always more and more too great if the terms were all positive, and always too little if negative.

But in the third case, or when the terms are all equal, the series of equals, with alternate signs, is called a neutral one, because the successive sums, found by a continual collection of the terms, are always at the same distance from the true value or radix, but alternately positive and negative, or too great and too little. Thus, in the series

$$\frac{1}{1+1} = \frac{1}{2} = 1 - 1 + 1 - 1 + 1 - 1 \text{ \&c,}$$

the first term 1 is too great,
two terms $1 - 1 = 0$ are too little,
three terms $1 - 1 + 1 = 1$ too great,
four terms $1 - 1 + 1 - 1 = 0$ too little,
and so on continually, the successive sums being alternately 1 and 0, which are equally different from the true value or radix $\frac{1}{2}$, the one as much above it, as the other below it.

A series may be terminated and rendered finite, and accurately equal to its radix, by assuming the supplement or remainder, after any particular term, and combining it with the foregoing terms. So, in the series $\frac{1}{2} - \frac{1}{4} + \frac{1}{8} - \frac{1}{16}$ &c, which is equal to $\frac{1}{3}$, and found by dividing 1 by $2 + 1$, after the first term, $\frac{1}{2}$, of the quotient, the remainder is $- \frac{1}{2}$, which divided by $2 + 1$, or 3, gives $- \frac{1}{6}$ for the supplement, which being combined with the first term $\frac{1}{2}$, gives $\frac{1}{2} - \frac{1}{6} = \frac{1}{3}$ the true sum of the series. Again, after the first two terms $\frac{1}{2} - \frac{1}{4}$, the remainder is $+ \frac{1}{4}$, which divided by the same divisor 3, gives $\frac{1}{12}$ for the supplement, and this combined with those two terms $\frac{1}{2} - \frac{1}{4}$, makes $\frac{1}{2} - \frac{1}{4} + \frac{1}{12} = \frac{1}{4} + \frac{1}{12} = \frac{4}{12}$ or $\frac{1}{3}$ the same sum or value as before. And in general, by dividing 1 by $a + c$, there is obtained

$$\frac{1}{a+c} = \frac{1}{a} - \frac{c}{a^2} + \frac{c^2}{a^3} \cdots\cdots \pm \frac{c^n}{a^{n+1}} \mp \frac{c^{n+1}}{a^{n+1}(a+c)};$$

where, stopping the division at any term as $\frac{c^n}{a^{n+1}}$, the remainder after this term is $\frac{c^{n+1}}{a^{n+1}}$, which being divided by the same divisor $a + c$, gives $\frac{c^{n+1}}{a^{n+1}(a+c)}$ for the supplement as above.

The Law of Continuation.—A series being proposed, one of the chief questions concerning it, is to find the law of its continuation. Indeed, no universal rule can be given for this; but it often happens that the terms, taken two and two, or three and three, or in greater numbers, have an obvious and simple relation, by which the series may be determined and produced indefinitely. Thus, if 1 be divided by $1 - x$, the quotient will be a geometrical progression, viz, $1 + x + x^2 + x^3$ &c, where the succeeding terms are produced by the continual multiplication by x. In like manner, in other cases of division, other progressions are produced.

But in most cases the relation of the terms of a series is not constant, as it is in those that arise by division. Yet their relation often varies according to a certain law, which is sometimes obvious on inspection, and sometimes it is found by dividing the successive terms one by another, &c. Thus, in the series
$1 + \frac{2}{3}x + \frac{8}{15}x^2 + \frac{16}{35}x^3 + \frac{128}{315}x^4$ &c, by dividing the 2d term by the 1st, the 3d by the 2d, the 4th by the 3d, and so on, the quotients will be $\frac{2}{3}x$, $\frac{4}{5}x$, $\frac{6}{7}x$, $\frac{8}{9}x$, &c; and therefore the terms may be continued indefinitely by the successive multiplication by these fractions. Also in the following series $1 + \frac{1}{6}x + \frac{3}{40}x^2 + \frac{5}{112}x^3 + \frac{35}{1152}x^4$ &c, by dividing the adjacent terms successively by each other, the series of quotients is $\frac{1}{6}x$, $\frac{9}{20}x$, $\frac{25}{42}x$, $\frac{49}{72}x$, &c, or
$\frac{1.1}{2.3}x$, $\frac{3.3}{4.5}x$, $\frac{5.5}{6.7}x$, $\frac{7.7}{8.9}x$, &c; and therefore the terms of the series may be continued by the multiplication of these fractions.

Another method of expressing the law of a series, is one that defines the series itself, by its *general term*, showing the relation of the terms generally by their distances from the beginning, or by differential equations. To do this, Mr. Stirling conceives the terms of the series to be placed as so many ordinates on a right line given by position, taking unity as the common interval between these ordinates. The terms of the series he denotes by the initial letters of the alphabet, A, B, C, D, &c; A being the first, B the 2d, C the 3d, &c: and he denotes any term in general by the letter T, and the rest following it in order by T′, T″, T‴, T⁗, &c; also the distance of the term T from any given term, or from any given intermediate point between two terms, he denotes by the indeterminate quantity z: so that the distances of the terms T′, T″, T‴, &c, from the said term or point, will be $z + 1$, $z + 2$, $z + 3$, &c; because the increment of the absciss is the common interval of the ordinates, or terms of the series, applied to the absciss.

These things being premised, let this series be proposed, viz, 1, $\frac{1}{2}x$, $\frac{3}{8}x^2$, $\frac{5}{16}x^3$, $\frac{35}{128}x^4$, $\frac{63}{256}x^5$, &c; in which it is found, by dividing the terms by each other, that the relations of the terms are,

$B = \frac{1}{2}Ax$, $C = \frac{3}{4}Bx$, $D = \frac{5}{6}Cx$, $E = \frac{7}{8}Dx$, &c: then the relation in general will be defined by the equation $T' = \frac{2z+1}{2z+2}Tx$ or $\frac{z+\frac{1}{2}}{z+1}Tx$, where z denotes the distance of T from the first term of the series. For by substituting 0, 1, 2, 3, 4, &c, successively instead of z, the same relations will arise as in the proposed series above. In like manner, if z be the distance of T from the 2d term of the series, the equation will be $T' = \frac{2z+3}{2z+4}Tx$ or $\frac{z+\frac{3}{2}}{z+2}Tx$, as will appear by substituting the numbers − 1, 0, 1, 2, 3, &c, successively for z. Or, if z denote the place or number of the term T in the series, its successive values will be 1, 2, 3, 4, &c, and the equation or general term will be $T' = \frac{2z-1}{2z}Tx$.

It appears therefore, that innumerable differential equations may define one and the same series, according to the different points from whence the origin of the absciss z is taken. And, on the contrary, the same equation defines innumerable different series, by taking different successive values of z. For in the equation $T' = \frac{2z-1}{2z}Tx$, which defines the foregoing series when 1, 2, 3, 4, &c are the successive values of the abscisses; if $1\frac{1}{2}$, $2\frac{1}{2}$, $3\frac{1}{2}$, $4\frac{1}{2}$, &c, be successively substituted for z, the relations of the terms arising will be, $B = \frac{2}{3}Ax$, $C = \frac{4}{5}Bx$, $D = \frac{6}{7}Cx$, &c, from whence will arise the series A, $\frac{2}{3}Ax$, $\frac{8}{15}Ax^2$, $\frac{16}{35}Ax^3$, $\frac{128}{315}Ax^4$, &c, which is different from the former.

And thus the equation will always determine the series from the given values of the absciss and of the first term, when the equation includes but two terms of the series, as in the last example, where the first term being given, all the rest will be given.

But when the equation includes three terms, then two must be given; and three must be given, when it includes four; and so on. So, if there be proposed the series x, $\frac{1}{6}x^3$, $\frac{3}{40}x^5$, $\frac{5}{112}x^7$, $\frac{35}{1152}x^9$, &c, where the relations of the terms are, $B = \frac{1.1}{2.3}Ax^2$, $C = \frac{3.3}{4.5}Bx^2$, $D = \frac{5.5}{6.7}Cx^2$, &c, the equation defining this series will be

$T' = \frac{(2z-1).(2z-1)}{2z.(2z+1)}Tx^2 = \frac{4zz-4z+1}{4zz+2z}Tx^2$, where the successive values of z are 1, 2, 3, 4, &c. See Stirling's Methodus Differentialis, in the introduction.

This may suffice to give a notion of these differential equations, defining the nature of series. But as to the application of these equations in interpolations, and finding the sums of series, it would require a treatise to explain it. We must therefore refer to that excellent one just quoted, as also to Demoivre's Miscellanea Analytica; and several curious papers by Euler in the Acta Petropolitana.

A series often converges so slowly, as to be of no use in practice. Thus, if it were required to find the sum of the series $\frac{1}{1.2} + \frac{1}{3.4} + \frac{1}{5.6} + \frac{1}{7.8} + \frac{1}{9.10}$ &c, which lord Brouncker found for the quadrature of the hyperbola, true to 9 figures, by the mere addition of the terms of the series; Mr Stirling computes that it would be necessary to add a thousand millions of terms for that purpose; for which the life of man would be too short. But by that gentleman's method, the sum of the series may be found by a very moderate computation. See Method. Differ. pa. 26.

Series are of various kinds or descriptions. So,

An *Ascending* SERIES, is one in which the powers of the indeterminate quantity increase; as $1 + ax + bx^2 + cx^3$ &c. And a

Descending SERIES, is one in which the powers decrease, or else increase in the denominators, which is the same thing; as

$1 + ax^{-1} + bx^{-2} + cx^{-3}$ &c, or $1 + \frac{a}{x} + \frac{b}{x^2} + \frac{c}{x^3}$ &c.

A Circular SERIES, which denotes a series whose sum depends on the quadrature of the circle. Such is the series $1 - \frac{1}{3} + \frac{1}{5} - \frac{1}{7} + \frac{1}{9}$ &c: See Demoivre Miscel. Analyt. pa. 111, or my Mensur. pa. 119. Or the sum of the series $1 + \frac{1}{4} + \frac{1}{9} + \frac{1}{16} + \frac{1}{25}$ &c, continued ad infinitum, according to Euler's discovery.

Continued Fraction or *Series*, is a fraction of this kind, to infinity,

$$\cfrac{a}{b + \cfrac{c}{d + \cfrac{e}{f + \cfrac{g}{h \text{ \&c.}}}}}$$

The first series of this kind was given by lord Brouncker, first president of the Royal Society, for the quadrature of the circle, as related by Dr. Wallis, in his Algebra, pa. 317. His series is,

$$1 + \cfrac{1}{2 + \cfrac{9}{2 + \cfrac{25}{2 + \cfrac{49}{2 + \cfrac{81}{2 + \text{\&c,}}}}}}$$

which denotes the ratio of the square of the diameter of a circle to its area. Mr. Euler has treated on this kind of series, in the Petersburg Commentaries, vol. 11, and in his Analys. Infinit. vol. 1, pa. 295, where he shows various uses of it, and how to transform ordinary fractions and common series into continued fractions. A common fraction is transformed into a continued one, after the manner of seeking the greatest common measure of the numerator and denominator, by dividing the greater by the less, and the last divisor always by the last remainder. Thus to change $\frac{1461}{59}$ to a continued fraction.

Theref. $\frac{1461}{59} = 24 + \cfrac{1}{1 + \cfrac{1}{3 + \cfrac{1}{4 + \cfrac{1}{1 + \cfrac{1}{2.}}}}}$

It is not, however, in this form of the series that they are applied to any useful purposes; they must first be reduced to a series of converging fractions, which will be finite when the radix is rational, but infinite when the radix is a surd. The rule for performing this is as follows.

Having divided one number by another, as above directed, till nothing remains, place all the quotients thus arising in one horizontal line, in the order in which they were obtained, proceeding from left to right. Then the first fraction will have 1 for its numerator, and the first quotient figure for its denominator. The second fraction will have the second quotient figure for its numerator; and for its denominator, the product of the first denominator, and the said quotient plus 1.

And all the other terms will then be found as follows. For the numerator, multiply the numerator already found by the next quotient figure, and to the product add the preceding numerator, which will form the new numerator. And the denominators are obtained in exactly the same manner.

Thus, to reduce the above continued fraction to a series of converging fractions, we have

Quotients	24,	1,	3,	4,	1,	2.
Converging fractions	$\frac{24}{1}$,	$\frac{25}{1}$,	$\frac{99}{4}$,	$\frac{421}{17}$,	$\frac{520}{21}$,	$\frac{1461}{59}$.

A surd quantity, such as $\sqrt{19}$, is reduced to a series of converging fractions, which will go on to infinity, in a similar manner, after the series of quotients q, q', q'', q''', &c is obtained, which is done by taking out the greatest square, then the next greatest, and so on, thus,

$$q = \sqrt{19} = 4 + \frac{\sqrt{19}-4}{1}$$
$$q' = \frac{1}{\sqrt{19}-4} = \frac{\sqrt{19}+4}{3} = 2 + \frac{\sqrt{19}-2}{3}$$
$$q'' = \frac{3}{\sqrt{19}-2} = \frac{\sqrt{19}+2}{5} = 1 + \frac{\sqrt{19}-3}{5}$$
$$q''' = \frac{5}{\sqrt{19}-3} = \frac{\sqrt{19}+3}{2} = 3 + \frac{\sqrt{19}-3}{2}$$
$$q^{iv} = \frac{2}{\sqrt{19}-3} = \frac{\sqrt{19}+3}{5} = 1 + \frac{\sqrt{19}-2}{5}$$
$$q^{v} = \frac{5}{\sqrt{19}-2} = \frac{\sqrt{19}+2}{3} = 2 + \frac{\sqrt{19}-4}{3}$$
$$q^{vi} = \frac{3}{\sqrt{19}-4} = \frac{\sqrt{19}+4}{1} = 8 + \frac{\sqrt{19}-4}{1}$$
$$q^{vii} = \frac{1}{\sqrt{19}-4} = \frac{\sqrt{19}+4}{3} = 2 + \text{\&c.}$$

So that the quotients are

4 2 1 3 1 2 8 2; 4, 2, 1, &c.

Converging fractions $\frac{4}{1}$, $\frac{9}{2}$, $\frac{13}{3}$, $\frac{48}{11}$, $\frac{61}{14}$, &c, each of which fractions approximates towards the $\sqrt{19}$; differing from the common series in this, that in those, it is the sum of all the terms that gives the approximate value of the radix, whereas in this each term, singularly, approaches towards the value of the radical.

Converging SERIES, is a series whose terms continually decrease, or the successive sums of whose terms approximate or converge always nearer to the ultimate sum of the whole series. And, on the contrary, a

Diverging SERIES, is one whose terms continually increase, or that has the successive sums of its terms diverging, or going off always the farther, from the sum or value of the series.

Determinate SERIES, is a series whose terms proceed by the powers of a determinate quantity; as

$1 + \frac{1}{2} + \frac{1}{2^2} + \frac{1}{2^3} +$ &c. If that determinate quantity be unity, the series is said to be determined by unity. Demoivre, Miscel. Analyt. pa. 111.

Indeterminate SERIES is one whose terms proceed by the powers of an indeterminate quantity x; as

$x + \frac{1}{2}x^2 + \frac{1}{3}x^3 + \frac{1}{4}x^4$ &c; or sometimes also with indeterminate exponents, or indeterminate coefficients.

The *Form of a* SERIES, is used for that affection of an indeterminate series, such as

$ax^n + bx^{n+r} + cx^{n+2r} + dx^{n+3r}$ &c, which arises from the different values of the indices of x. Thus,

If $n = 1$, and $r = 1$, the series will take the form

$ax + bx^2 + cx^3 + dx^4$ &c.

If $n = 1$, and $r = 2$, the form will be

$ax + bx^3 + cx^5 + dx^7$ &c.

If $n = \frac{1}{2}$, and $r = 1$, the form is

$ax^{\frac{1}{2}} + bx^{\frac{3}{2}} + cx^{\frac{5}{2}} + dx^{\frac{7}{2}}$ &c. And

If $n = 0$, and $r = -1$, the form will be

$a + bx^{-1} + cx^{-2} + dx^{-3}$ &c.

When the value of a quantity cannot be found exactly, it is of use in algebra, as well as in common arithmetic, to seek an approximate value of that quantity, which may be useful in practice. Thus, in arithmetic, as the true value of the square root of 2 cannot be assigned, a decimal fraction is found to a sufficient degree of exactness in any particular case; which decimal fraction is in reality, no more than an infinite series of fractions converging or approximating to the true value of the root sought. For the expression $\sqrt{2} = 1{\cdot}414213$ &c, is equivalent to this $\sqrt{2} = 1 + \frac{4}{10} + \frac{1}{100} + \frac{4}{1000}$ &c; or supposing $x = 10$, to this

$$\sqrt{2} = 1 + \frac{4}{x} + \frac{1}{x^2} + \frac{4}{x^3} + \frac{2}{x^4} \text{ \&c.}$$
$$\text{or } = 1 + 4x^{-1} + x^{-2} + 4x^{-3} + 2x^{-4} \text{ \&c,}$$

which last series is a particular case of the more general indeterminate series $ax^n + bx^{n+r} + cx^{n+2r}$ &c, viz, when $n = 0$, $r = -1$, and the coefficients $a = 1$, $b = 4$, $c = 1$, $d = 4$, &c.

But the application of the notion of approximations in numbers, to species, or to algebra, is not so obvious. Newton, with his usual sagacity, took the hint, and prosecuted it; by which were discovered general methods in the doctrine of infinite series, which had before been treated only in a particular manner, though with great acuteness, by Wallis and a few others. See Newton's Method of Fluxions and Infinite Series, with Colson's Comment; as also the Analysis per Æquationes Numero Terminorum Infinitas, published by Jones in 1711, and since translated and explained by Stewart, together with Newton's Tract on Quadratures, in 1745. To these may be added Maclaurin's Algebra, part. 2, chap. 10, pa. 244; and Cramer's Analyse des Lignes Courbes Algebraiques, chap. 7, pa. 148; and many other authors.

Among the various methods for determinating the value of a quantity by a converging series, that seems preferable to the rest, which consists in assuming an indeterminate series as equal to the quantity whose value is sought, and afterwards determining the values of the terms of this assumed series. For instance, suppose a logarithm were given, to find the natural number answering to it. Suppose the logarithm to be z, and the corresponding number sought $1 + x$: then by the nature of logarithms and fluxions, $\dot{z} = \frac{\dot{x}}{1+x}$, or $\dot{z} + x\dot{z} = \dot{x}$. Now assume a series for the value of the unknown quantity x, and substitute it and its fluxion instead of x and $\dot{x}$ in the last equation, then determine the assumed coefficients, by comparing or equating the like terms of the equation. Thus,

assume $x = az + bz^2 + cz^3 + dz^4$ &c,
then $\dot{x} = a\dot{z} + 2bz\dot{z} + 3cz^2\dot{z} + 4dz^3\dot{z}$ &c;
and $\dot{x} = (\dot{z} + x\dot{z}) = \dot{z} + az\dot{z} + bz^2\dot{z} + cz^3\dot{z}$ &c;

hence, comparing the like terms of these two values of $\dot{x}$, there arises $a = 1$, $b = \frac{1}{2}$, $c = \frac{1}{6}$, $d = \frac{1}{24}$, &c; which values being substituted for a, b, c, &c, in the assumed series $az + bz^2 + cz^3$ &c, it gives

$x = z + \frac{1}{2}z^2 + \frac{1}{6}z^3 + \frac{1}{24}z^4 + \frac{1}{120}z^5$, &c, or

$x = z + \frac{1}{1.2}z^2 + \frac{1}{1.2.3}z^3 + \frac{1}{1.2.3.4}z^4 + \frac{1}{1.2.3.4.5}z^5$ &c;

and consequently the number sought will be

$$1 + x = 1 + z + \tfrac{1}{2}z^2 + \tfrac{1}{6}z^3 \text{ \&c.}$$

But the indeterminate series $az + bz^2 + cz^3$ &c, was here assumed arbitrarily, with regard to its exponents 1, 2, 3, &c, which will not succeed in all cases, because some quantities require other forms for the exponents. For instance, if from a given arc, it were required to find the tangent. Making x = the tangent, and z = arc, the radius being = 1. Then, from the nature of the circle we shall have $\frac{\dot{x}}{1 + x^2} = \dot{z}$, or $\dot{x} = \dot{z} + x^2\dot{z}$. Now if, to find the value of x, we suppose $x = az + bz^2 + cz^3$ &c, and proceed as before, we shall find all the alternate coefficients b, d, f, &c, or those of the even powers of z, to be each = 0; and therefore the series assumed is not of a proper form. But making $x = az + bz^3 + cz^5 + dz^7$, &c, then we find $a = 1$, $b = \frac{1}{3}$, $c = \frac{2}{15}$, $d = \frac{17}{315}$, &c, and consequently $x = z + \frac{1}{3}z^3 + \frac{2}{15}z^5 + \frac{17}{315}z^7$ &c. And other quantities require other forms of series.

Now to find a proper indeterminate series in all cases, tentatively, would often be very laborious, and even impracticable. Mathematicians have therefore endeavoured to find out a general rule for this purpose; though till lately the method has been but imperfectly understood and delivered. Most authors indeed have explained the manner of finding the coefficients a, b, c, d, &c, of the indeterminate series $ax^n + bx^{n+r} + cx^{n+2r}$ &c, which is easy enough; but the values of n and r, in which the chief difficulty lies, have been assigned by many in a manner as if they were self-evident, or at least discoverable by an easy trial or two, as in the last example.

As to the number n, Newton himself has shown the method of determining it, by his rule for finding the first term of a converging series, by the application of his parallelogram and ruler. For the particulars of this method, see the authors above cited; see also PARALLELOGRAM.

Taylor, in his Methodus Incrementorum, investigates the number r; but Stirling observes that his rule sometimes fails. Lineæ Tert. Ordin. Newton. pa. 28. Mr. Stirling gives a correction of Taylor's rule, but says he cannot affirm it to be universal, having only found it by chance. And again,

Gravesande observes, that though he thinks Stirling's rule never leads into an error, yet that it is not perfect. See Gravesande, De Determin. Form. Seriei Infinit. printed at the end of his Matheseos Universalis Elementa. This learned professor has endeavoured to rectify the rule. But Cramer has shown that it is still defective in several respects; and he himself, to avoid the inconveniences to which the methods of former authors are subject, has had recourse to the first principles of the method of infinite series, and has entered into a more exact and instructive detail of the whole method, than is to be met with elsewhere; for which reason, and many others, his treatise deserves to be particularly recommended to beginners. See also my Tracts, v. 3, p. 369, for an easy method of determining the exponents in the assumed indeterminate series.

But it is to be observed, that in determining the value of a quantity by a converging series, it is not always necessary to have recourse to an indeterminate series: for it is often better to find it by division, or by extraction of roots. See Newton's Meth. of Flux. and Inf. Series, above cited. Thus, if it were required to find the arc of a circle from its tangent being given, that is, to find the value of $\dot{z}$ in the given fluxional equation, $\dot{z} = \frac{\dot{x}}{1 + xx}$, by an infinite series: dividing $\dot{x}$ by $1 + xx$, the quotient will be the series $\dot{x} - x^2\dot{x} + x^4\dot{x} - x^6\dot{x}$ &c $= \dot{z}$; and taking the fluents of the terms, there results $z = x - \frac{1}{3}x^3 + \frac{1}{5}x^5 - \frac{1}{7}x^7$ &c, which is the series often used for the quadrature of the circle. If $x = 1$, or the tangent of 45°, then will $z = 1 - \frac{1}{3} + \frac{1}{5} - \frac{1}{7}$ &c = the length of an arc of 45°, or $\frac{1}{8}$ of the circumference, to the radius 1, or $\frac{1}{4}$ of the circumference to the diameter 1. Consequently, if 1 be the diameter, then $1 - \frac{1}{3} + \frac{1}{5} - \frac{1}{7}$ &c will be the area of the circle, because $\frac{1}{4}$ of the circumference multiplied by the diameter, gives the area of the circle. This series was first given by Leibnitz and James Gregory.

See the form of the series for the binomial theorem, determined, both as to the coefficients and exponents, in my Tracts, vol. 1, pa. 228.

Harmonical SERIES, the reciprocal of arithmeticals. See HARMONICAL.

Hyperbolic SERIES, is used for a series whose sum depends on the quadrature of the hyperbola. Such is the series $\frac{1}{2} + \frac{1}{4} + \frac{1}{6} + \frac{1}{8}$ &c. Demoivre's Miscel. Analyt. pa. 111.

Interpolation of SERIES, the inserting of some terms between others, &c. See INTERPOLATION.

Interscendent SERIES. See INTERSCENDENT.

Mixt SERIES, one whose sum depends partly on the quadrature of the circle, and partly on that of the hyperbola. Demoivre, Miscel. Analyt. pa. 111.

Recurring SERIES, is used for a series which is so constituted, that having taken at pleasure any number of its terms, each following term shall be related to the same number of preceding terms by some constant law of relation. Thus, in the following series,

$$\overset{a}{1} + \overset{b}{2x} + \overset{c}{3x^2} + \overset{d}{10x^3} + \overset{e}{34x^4} + \overset{f}{97x^5} \text{ \&c,}$$

in which the terms being respectively represented by the letters a, b, c, &c, set over them, we shall have

$$d = 3cx - 2bx^2 + 5ax^3,$$
$$e = 3dx - 2cx^2 + 5bx^3,$$
$$f = 3ex - 2dx^2 + 5cx^3,$$
&c, &c,

where it is evident that the law of relation between d and c, is the same as between e and f, each being formed in the same manner from the three terms which precede it in the series.

The quantities $3x - 2x^2 + 5x^3$, taken together and connected by their proper signs, form what Demoivre calls the index, or the scale of relation; though sometimes the bare coefficients $3 - 2 + 5$ are called the scale of relation. And the scale of relation subtracted from unity, is called the differential scale. On the subject of Recurring Series, see Demoivre's Miscel. Analyt. pa. 27 and 72, and his Doctrine of Chances, 3d edit. pa. 220; also Euler's Analys. Infinit. tom. 1, pa. 175.

Having given a recurring series, with its scale of relation, the sum of the whole infinite series will also be given. For instance, suppose a series $a + bx + cx^2 + dx^3$ &c, where the relation between the coefficient of any term and the coefficients of any two preceding terms may be expressed by $f - g$; that is, $c = fd - gc$, and $d = fc - gb$, &c; then will the sum of the series, infinitely continued, be $\frac{a + (b - fa)x}{1 - fx + gx^2}$.

Thus, for example, assume 2 and 5 for the coefficients of the first two terms of a recurring series; and suppose f and g to be respectively 2 and 1; then the recurring series will be

$$2 + 5x + 8x^2 + 11x^3 + 14x^4 + 17x^5 \text{ \&c,}$$

and its sum $= \frac{2 + 5x - 4x}{1 - 2x + xx} = \frac{2 + x}{(1 - x)^2}$. For the proof of which divide $2 + x$ by $(1 - x)^2$, and there arises the said series $2 + 5x + 8x^2 + 11x^3$ &c. And similar rules might be derived for more complex cases.

Demoivre's general rule is this: 1. Take as many terms of the series as there are parts in the scale of relation. 2. Subtract the scale of relation from unity, and the remainder is the differential scale. 3. Multiply the terms taken in the series by the differential scale, beginning at unity, and so proceeding orderly, remembering to leave out what would naturally be extended beyond the last of the terms taken. Then will the product be the numerator, and the differential scale will be the denominator of the fraction expressing the sum required.

But it must here be observed, that when the sum of a recurring series extended to infinity, is found by Demoivre's rule, it ought to be supposed that the series converges indefinitely, that is, that the terms may become less than any assigned quantity. For if the series diverge, that is, if its terms continually increase, the rule does not give the true sum. For the sum in such case is infinite, or greater than any given quantity, whereas the sum exhibited by the rule, will often be finite. The rule therefore in this case only gives a fraction expressing the radix of the series, by the expansion of which the series is produced. Thus $\frac{1}{(1 - x)^2}$ by expansion becomes the recurring series $1 + 2x + 3x^2$ &c, whose scale of relation is $2 - 1$, and its sum by the rule will be $\frac{a + bx - fax}{1 - fx + gxx} = \frac{1 + 2x - 2x}{1 - 2x + xx} = \frac{1}{(1 - x)^2}$, the quantity from which the series arose. But this quantity cannot in all cases be deemed equal to the infinite series $1 + 2x + 3x^2$ &c: for stop where you will, there will always want a supplement to make the product of the quotient by the divisor equal to the dividend. Indeed when the series converges infinitely, the supplement, diminishing continually, becomes less than any assignable quantity, or equal to nothing; but in a diverging series, this supplement becomes infinitely great, and the series deviates indefinitely from the truth. See Colson's Comment on Newton's Method of Fluxions and Infinite Series, pa. 152; Stirling's Method. Differ. pa. 36; Bernoulli de Serieb. Infin. pa. 249; and Cramer's Analyse des Lignes Courbes, pa. 174.

A recurring series being given, the sum of any finite number of the terms of that series may be found. This is prob. 3, pa. 73, Demoivre's Miscel. Analyt. and prob. 5, pa. 223 of of his Doctrine of Chances. The solution is effected, by taking the difference between the sums of two infinite series, differing by the terms answering to the given number; viz, from the sum of the whole infinite series, commencing from the beginning, subtract the sum of another infinite number of terms of the same series, commencing after so many of the first terms whose sum is required; and the difference will evidently be the sum of that number of terms of the series. For example, to find the sum of n terms of the infinite geometrical series $a + ax + ax^2 + ax^3$ &c. Here are two infinite series; the one beginning with a, and the other with ax^n, which is the next term after the first n terms of the original series. By the rule, the sum of the first infinite progression will be $\frac{a}{1 - x}$, and the sum of the second $\frac{ax^n}{1 - x}$; the difference of which is $\frac{a - ax^n}{1 - x}$, which is therefore the sum of the first n terms of the series. This quantity $\frac{a - ax^n}{1 - x}$ is equal to $\frac{ax^n - a}{x - 1}$, which last expression, putting $ax^{n-1} = l$, will be equivalent to this, $\frac{lx - a}{x - 1}$, which is the common rule for finding the sum of any geometric progression, having given the first term a, the last term l, and the ratio x. See Miscel. Analyt. pa. 167, 168.

In a recurring series, any term may be obtained whose place is assigned. For after having taken so many terms of the series as there are terms in the scale of relation, the series may be protracted till it reach the place assigned. But when that place is very distant from the beginning of the series, the continuing the terms is very laborious; and therefore other methods have been contrived. See Miscel. Analyt. pa. 33, and Doctrine of Chances, pa. 224.

These questions have been resolved in many cases, besides those of recurring series. But as there is no universal method for the quadrature of curves, neither is there one for the summation of series; indeed there is a great analogy between these things, and similar difficulties arise in both. See the authors above cited.

The investigation of Daniel Bernoulli's method for finding the roots of algebraic equations, which is inserted in the Petersburg Acts, tom. 3, pa. 92, depends on the doctrine of recurring series. See Euler's Analysis Infinitorum, tom. 1, pa. 276.

Reversion of SERIES. See REVERSION *of Series*.

Summable SERIES, is one whose sum can be accurately found. Such is the series $\frac{1}{2} + \frac{1}{4} + \frac{1}{8}$ &c, the sum of which is said to be unity, or to speak more accurately, the limit of its sum is unity or 1.

An indefinite number of summable infinite series may be assigned: such are, for instance, all infinite recurring converging series, and many others, for which, consult Demoivre, Bernoulli, Stirling, Euler, and Maclaurin; viz, Miscel. Analyt. pa. 110; De Serieb. Infinit. passim; Method. Different. pa. 34; Acta Petrop. passim; Fluxions, art. 350.

The obtaining the sums of infinite serieses of fractions has been one of the principal objects of the modern method of computation; and these sums may often be found, and sometimes not. Thus the sums of the two following series of geometrical progressionals are easily found to be

1 and $\frac{1}{2}$, viz, $1 = \frac{1}{2} + \frac{1}{4} + \frac{1}{8} + \frac{1}{16}$ &c,
and $\frac{1}{2} = \frac{1}{3} + \frac{1}{9} + \frac{1}{27} + \frac{1}{81}$ &c.

But the series of fractions that occur in the solution of problems, can seldom be reduced to geometric progressions; nor can any general rule, in cases so infinitely various, be given. The art here, as in most other cases, is only to be acquired by examples, and by a careful observation of the arts used by great authors in the investigation of such series of fractions as they have considered. And the general methods of infinite series, which have been carried so far by Demoivre, Stirling, Euler, &c, are often found necessary to determine the sum of a very simple series of fractions. See the quotations above.

The sum of a series of fractions, though decreasing continually, is not always finite. This is the case of the series $\frac{1}{1} + \frac{1}{2} + \frac{1}{3} + \frac{1}{4} + \frac{1}{5}$ &c, which is the harmonic series, consisting of the reciprocals of arithmeticals, the sum of which exceeds any given number whatever; and this is shown from the analogy between this progression and the space comprehended by the common hyperbola and its asymptote; though the same may be shown also from the nature of progressions. See James Bernoulli, de Seriebus Infin. But, what is curious, the sum of the squares of its terms is finite; for if the same terms of the harmonic series, $\frac{1}{1} + \frac{1}{2} + \frac{1}{3}$ &c, be squared, forming the series $\frac{1}{1} + \frac{1}{4} + \frac{1}{9}$ &c, being the reciprocals of the squares of the natural series of numbers; the sum of this series of fractions will not only be limited, but it is remarkable that this sum will be precisely equal to the 6th part of the number which expresses the ratio of the square of the circumference of a circle to the square of its diameter. That is, if c denote 3·14159 &c, the ratio of the circumference to the diameter, then is $\frac{1}{6} c^2 = \frac{1}{1} + \frac{1}{4} + \frac{1}{9} + \frac{1}{16} + \frac{1}{25}$ &c. This property was first discovered by John Bernoulli; and his investigation may be seen in the Acta Petrop. vol. 7. And Maclaurin has since observed, that this may easily be deduced from his Fluxions, art. 822. Philos. Trans. numb. 469.

It would require a whole volume to enumerate the various kinds of series of fractions which may or may not be summed. Sometimes the sum cannot be assigned, either because it is infinite, as in the harmonic series $\frac{1}{1} + \frac{1}{2} + \frac{1}{3} + \frac{1}{4}$ &c, or, though its sum be finite (as in the series $\frac{1}{1} + \frac{1}{4} + \frac{1}{9}$ &c), yet its sum cannot be assigned in finite terms, or by the quadrature of the circle or hyperbola, which was the case of this series before Euler's discovery; but yet the sum of any given number of the terms of the series may be expeditiously found, and the whole sum may be assigned by approximation, independent of the circle. See Stirling's Method. Different. and De Moivre's Miscel. Analyt. Also the works of John Bernoulli, who first summed this series.

Besides the series of fractions, the sums of which converge to a certain quantity, there sometimes occur others, which converge by a continued multiplication. Of this kind is the series found by Wallis, for the quadrature of the circle, which he expresses thus,

$$\square = \frac{3 \times 3 \times 5 \times 5 \times 7 \times 7 \times 9 \times 9 \times \&c}{2 \times 4 \times 4 \times 6 \times 6 \times 8 \times 8 \times 10 \times \&c},$$

where the character $\square$ denotes the ratio of the square of the diameter to the area of the circle. Hence the denominator of this fraction, is to its numerator, both infinitely continued, as the circle is to the square of the diameter. It may further be observed that this series is equivalent to $\frac{9}{8} \times \frac{25}{24} \times \frac{49}{48} \times$ &c, or to $\frac{3^2}{3^2 - 1} \times \frac{5^2}{5^2 - 1} \times \frac{7^2}{7^2 - 1} \times$ &c, that is, the product of the squares of all the odd numbers 3, 5, 7, 9, &c, is to the produce of the same squares severally diminished by unity, as the square of the diameter is to the area of the circle. See Arithmet. Infinit. prop. 191. Oper. vol. 1, pa. 469. Id. Oper. vol. 2, pa. 819. And these products of fractions, and the like quantities arising from the continued multiplication of certain factors, have been particularly considered by Euler, in his Analysis Infinit. vol. 1, chap. 15, pa. 221.

For an easy and general method of summing all alternate series, such as $a - b + c - d$ &c, see my Tracts, vol. 1, pa. 176; and in the same vol. may be seen many other curious tracts on infinite series.

Summation of Infinite SERIES, is the finding the value of them, or the radix from which they may be raised. For which consult the authors upon this science, particularly Stirling, and Clark's translation of Lorgna.

To find an infinite series by extracting of roots; and to find an infinite series by a presupposed series; see QUADRATURE *of the Circle*.

To extract the roots of an infinite series, see EXTRACTION *of Roots*.

To raise an infinite series to any power, see INVOLUTION, and POWER.

Transcendental SERIES. See TRANSCENDENTAL.

There are many other important writings on the subject of Infinite series, besides those above quoted. A very good elementary tract on this science is that of James Bernoulli, intituled, Tractatus de Seriebus Infinitis, and annexed to his Ars Conjectandi, published in 4to, 1713.

SERPENS, in Astronomy, a constellation in the northern hemisphere, being one of the 48 old constellations mentioned by all the ancients, and is called more particularly Serpens Ophiuchi, being grasped in the hands of the constellation Ophiuchus. The Greeks, in their fables, have ascribed it sometimes to one of Triptolemus's dragons, killed by Carnabos; and sometimes to the serpent of the river Segaris, destroyed by Hercules. This is by some supposed to be the same as the author of the book of Job calls the Crooked Serpent; but this expression more probably meant the constellation Draco, near the north pole.—The stars in the constellation Serpens, in Ptolemy's catalogue are 18, in Tycho's 13, in Hevelius's 22, and in the Britannic catalogue 64.

SERPENTARIUS, a constellation of the northern hemisphere, being one of the 48 old constellations mentioned by all the ancients. It is called also Ophiuchus, and anciently Æsculapius. It is in the figure of a man grasping the serpent. The Greeks had different fables about this, and other constellations, because they were ignorant of the true meaning of them. Some of them say, it represents Carnabos, who killed one of the dragons of Triptolemus. Others say, it was Hercules, killing the serpent at the river Segaris. And others again say, it represents the celebrated physician Æsculapius, to denote his skill in medicine in curing the bite of the serpent.

The stars in the constellation Serpentarius, in Ptolemy's catalogue are 29, in Tycho's 15, in Hevelius's 40, and in the Britannic catalogue they are 74.

SERPENTINE *Line*, the same with spiral.

SESQUI, an expression of a certain ratio, viz, the second ratio of inequality, called also superparticular ratio; being that in which the greater term contains the less once, and some certain part over; as 3 to 2, where the first term contains the second once, and unity over, which is a quota part of 2. Now if this part remaining be just half the less term, the ratio is called sesquialtera; if the remaining part be a 3d part of the less term, as 4 to 3, the ratio is called sesquitertia, or sesquiterza; if a 4th part, as 5 to 4, the ratio is called sesquiquarta; and so on continually, still adding to sesqui the ordinal number of the smaller term. In English we sometimes say, sesquialteral, or sesquialterate, sesquithird, sesquifourth, &c. As to the kinds of triples expressed by the particle sesqui, they are these:

SESQUILATERATE, the greater perfect, which is a triple, where the breve is three measures, or semibreves.

Sesquialterate, greater imperfect, which is where the breve, when pointed, contains three measures, and without any point, two

Sesquialterate, less imperfect, a triple, where the semibreve with a point contains three measures, and two without.

Sesquialterate, in Arithmetic and Geometry, is a ratio between two numbers, or lines, &c, where the greater is equal to once and a half of the less. Thus 6 and 9 are in a sesquialterate ratio, as also 20 and 30.

SESQUIDITONE, in Music, a concord resulting from the sounds of two strings whose vibrations, in equal times, are to each other in the ratio of 5 to 6.

SESQUIDUPLICATE *Ratio*, is that in which the greater term contains the less, twice and a half; as the ratio of 15 to 6, or 50 to 20.

SESQUIQUADRATE, an aspect or position of the planets, when they are distant by 4 signs and a half, or 135 degrees.

SESQUIQUINTILE, is an aspect of the planets when they are distant $\frac{1}{5}$ of the circle and a half, or 108 degrees.

SESQUITERTIONAL *Proportion*, is that in which the greater term contains the less once and one third; as 4 to 3, or 12 to 9.

SETTING, in Astronomy, the sinking of a star or planet below the horizon. Astronomers and poets count three different kinds of setting of the stars, viz, Achronical, Cosmical, and Heliacal. See these terms respectively.

Setting, in Navigation, Surveying, &c, denotes the observing the bearing or situation of any distant object by the compass, &c, to discover the angle it makes with the nearest meridian, or with some other line. See Bearing. Thus, to *set the land*, or *the sun*, by the compass, is to observe how the land bears on any point of the compass, or on what point of the compass the sun is. Also, when two ships come in sight of each other, to mark on what point the chace bears, is termed Setting the chace by the compass.

Setting also denotes the direction of the wind, current, or sea, particularly of the two latter.

SEVEN Stars, a commou denomination given to the cluster of stars in the neck of the sign Taurus, the bull, properly called the pleiades. They are so called from their number seven which appear to the naked eye, though some persons can discover only 6 of them; but by the help of telescopes there appears to be a great multitude of them.

SEVENTH, *Septima*, an interval in Music, called by the Greeks heptachordon.

SEXAGENARY, something relating to the number 60.

Sexagenary *Arithmetic*. See Sexagesimal.

Sexagenary *Tables*, are tables of proportional parts, showing the product of two sexagenaries that are to be multiplied, or the quotient of two that are to be divided.

SEXAGESIMA, the eighth Sunday before Easter; being so called because near 60 days before it.

SEXAGESIMAL or Sexagenary *Arithmetic*, a method of computation proceeding by 60ths. Such is that used in the division of a degree into 60 minutes, of the minute into 60 seconds, of the second into 60 thirds, &c.

The Greeks performed many of their calculations by means of the sexagesimal division of quantities, particularly their divisions and extraction of roots. This method, though very laborious, was certainly preferable to what these rules would have been in their common notation, as they appear to have had no idea, nor indeed did their notation admit, of finding one figure at a time in the quotient as we do. The Greeks therefore were under the necessity of finding either by trials, or otherwise, the whole quotient for the first period, then the whole quotient again for the second period, and so on. See Notation.

SEXAGESIMALS, or Sexagesimal *Fractions*, are fractions whose denominators proceed in a sexagecuple ratio; that is, a prime, or the first minute $= \frac{1}{60}$, a second $= \frac{1}{3600}$, and third $= \frac{1}{216000}$. Anciently there were no other than sexagesimals used in astronomical operations, for which reason they are sometimes called astronomical fractions, and they are still retained in many cases, as in the divisions of time and of a circle; but decimal arithmetic is now much used in the calculations, and the French have entirely discarded the sexagesimal division, and employed only the decimal, an improvement in astronomy which may in time be adopted by other nations. See Degree.—Sexagesimals were probably first used for the divisions of a circle, 360, or 6 times 60 making up the whole circumference, on account that 360 days made up the year of the ancients, in which time the sun was supposed to complete his course in the circle of the ecliptic.—In these fractions, the denominator being always 60, or a multiple of it, it is usually omitted, and the numerator only set down: thus, 3° 45′ 24″ 40‴ &c, is to be read, 3 degrees, 45 minutes, 24 seconds, 40 thirds, &c.

SEXANGLE, in Geometry, a figure having 6 angles, and consequently 6 sides also.

SEXENARY or Sextuple *Scale* of Notation, is that in which the local value of the digits increase in a sixfold proportion. See Scale, and Notation.

SEXTANS, a sixth part of certain things. The Romans divided their *as*, which was a pound of brass, into 12 ounces, called uncia, from unum; and the quantity of 2 ounces was called sextans, as being the 6th part of the pound.

Sextans was also a measure, which contained 2 ounces of liquor, or 2 cyathi.

Sextans, the Sextant, in Astronomy, a new constellation, placed across the equator, but on the south side of the ecliptic, and by Hevelius made up of some unformed stars, or such as were not included in any of the 48 old constellations. In Hevelius's catalogue it contains 11 stars, but in the Britannic catalogue 41.

SEXTANT, denotes the 6th part of a circle, or an arch containing 60 degrees.

SEXTANT is more particularly used for an astronomical instrument. It is made like a quadrant, excepting that its limb only contains 60 degrees. Its use and application are the same with those of the QUADRANT; which see.

SEXTARIUS, an ancient Roman measure, containing 2 cotylæ, or 2 heminæ.

SEXTILE, the aspect or position of two planets, when they are distant the 6th part of the circle, viz, 2 signs or 60 degrees; and it is marked thus ✱.

SEXTUPLE, denotes 6 fold in general. But in music it denotes a mixed sort of triple time, which is beaten in double time.

SHADOW, *Shade*, in Optics, a certain space deprived of light, or where the light is weakened by the interposition of some opaque body before the luminary. The doctrine of shadows makes a considerable article in optics, astronomy, and geography; and is the general foundation of dialling. As nothing is seen but by light, a mere shadow is invisible; and therefore when we say we see a shadow, we mean, partly that we see bodies placed in the shadow, and illuminated by light reflected from collateral bodies, and partly that we see the confines of the light.

When the opaque body, that projects the shadow, is perpendicular to the horizon, and the plane it is projected on is horizontal, the shadow is called a right one: such as the shadows of men, trees, buildings, mountains, &c. But when the body is placed parallel to the horizon, it is called a versed shadow; as the arms of a man when stretched out, &c.

Laws of the Projection of Shadows.

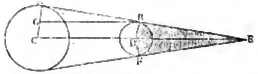
1. Every opaque body projects a shadow in the same direction with the rays of light; that is, towards the part opposite to the light. Hence, as either the luminary or the body changes place, the shadow likewise changes its place.

2. Every opaque body projects as many shadows as there are luminaries to enlighten it.

3. As the light of the luminary is more intense, the shadow is the deeper. Hence, the intensity of the shadow is measured by the degrees of light that space is deprived of. In reality, the shadow itself is not deeper; but it appears so, because the surrounding bodies are more vividly illuminated.

4. When the luminous body and opaque one are equal, the shadow is always of the same breadth with the opaque body. But when the luminous body is the larger, the shadow becomes always less and less, the farther it is from the body. And when the luminous body is the smaller of the two, the shadow increases always the wider, the farther from the body. Hence, the shadow of an opaque globe is, in the first case a cylinder, in the second case it is a cone verging to a point, and in the third case a truncated cone that enlarges still the more the farther it is from the body. Also, in all these cases, a transverse section of the shadow, by a plane, is a circle, respectively, in the three cases, equal, less, or greater than a great circle of the globe.

5. To find the length of the shadow, or the axis of the shady cone, projected by a sphere, when it is illuminated by a larger one; the diameters and distance of the two spheres being known. Let C and D be the centres of the two spheres, CA the semidiameter of the larger, and DB that of the smaller, both perpendicular to the side



of the conical shadow BEF, whose axis is DE, continued to C; and draw BG parallel to the same axis. Then, the two triangles AGB and BDE being similar, it will be AG : GB or CD : : BD : DE, that is, as the difference of the semidiameters is to the distance of the centres, so is the semidiameter of the opaque sphere to the axis of the shadow, or the distance of its vertex from the said opaque sphere.

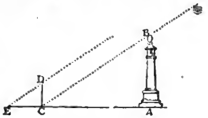
Ex. gr. If BD = 1 be the semidiameter of the earth, and AC = 101 the mean semidiameter of the sun, also their distance CD or GB = 24000; then as 100 : 24000 : : 1 : 240 = DE, which is the mean height of the earth's shadow, in semidiameters of the base.

6. To find the length of the shadow AC projected by an opaque body AB; having given the altitude of the luminary, for ex. of the sun, above the horizon, viz, the angle C, and the height of the object AB. Here the proportion is, as tang. ∠C : radius : : AB : AC.

Or, if the length of the shadow AC be given, to find the height AB, it will be,

as radius : tang. ∠C : : AC : AB.

Or, if the length of the shadow AC, and of the object AB, be given, to find the sun's altitude above the horizon, or the angle at C. It will be,



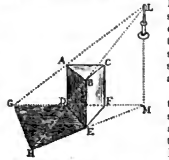
as AC : AB : : radius : tang. ∠C sought.

7. To measure the height of any object, ex. gr. a column AB, by means of its shadow projected on an horizontal plane.—At the extremity of the shadow, at C, erect a stick or pole CD, and measure the length of its shadow CE; also measure the length of the shadow AC of the tower. Then, by similar triangles, it will be, as EC : CD : : CA : AB. So if EC = 10 feet, CD = 6 feet, and CA = 95 feet; then as 10 : 6 : : 95 : 57 feet = AB, the height of the tower sought.

SHADOW, in Geography. The inhabitants of the earth are divided, with respect to their shadows, into ASCII, AMPHISCII, HETEROSCII, and PERISCII. See these several terms.

SHADOW, in Perspective, is of great use in this art.—Having given the appearance of an opaque body, and a luminous one, whose rays diverge, as a candle, or lamp, &c; to find the exact appearance of the shadow, according to the laws of perspective. The method is this: From the luminous body, which is here considered as a point, let fall a perpendicular to the perspective plane or table; and from the several angles, or raised points of the body, let fall perpendiculars to the same plane; then connect the points on which these latter perpendiculars fall, by right lines, with the point on which the first falls; continuing these lines beyond the side opposite to the luminary, till they meet with asmany other lines drawn from the centre of the luminary through the said angles or raised points; so shall the points of intersection of these lines be the extremes or bounds of the shadow.

For example, to project the appearance of the shadow of a prism ABCDEF, scenographically delimated. Here M is the place of the perpendicular of the light L, and D, E, F those of the raised points A, B, C, of the prism; therefore, draw MEH, MDG, &c, and LBH, LAG, &c, which will give DEGH &c for the appearance of the shadow.



As for those shadows that are intercepted by other objects, it may be observed, that when the shadow of a line falls upon any object, it must necessarily take the form of that object. If it fall upon another plane, it will be a right line; if upon a globe, it will be circular; and if upon a cylinder or cone, it will be circular, or oval, &c. If the body intercepting it be a plane, whatever be the situation of it, the shadow falling upon it might be found by producing that plane till it intercepted the perpendicular let fall upon it from the luminous body; for then a line drawn from that point would determine the shadow, just as if no other plane had been concerned. But the appearance of all these shadows may be drawn with less trouble, by first drawing it through these intercepted objects, as if they had not been in the way, and then making the shadow to ascend perpendicularly up every perpendicular plane, and obliquely on those that are situated obliquely, in the manner described by Dr. Priestley, in his Perspective, pa. 73 &c.

Here we may observe in general, that since the shadows of all objects which are cast upon the ground, will vanish into the horizontal line; so, for the same reason, the vanishing points of all shadows, which are cast upon any inclined or other plane, will be somewhere in the vanishing line of that plane.

When objects are not supposed to be viewed by the light of the sun, or of a candle &c, but only in the light of a cloudy day, or in a room into which the sun does not shine, there is no sensible shadow of the upper part of the object, and the lower part only makes the adjacent objects, or plane of the ground or floor on which it stands, a little darker than the rest. This imperfect obscure kind of shadow is easily made, being nothing more than a shade on the ground, opposite to the side on which the light comes; and it may be continued to a greater or less distance, according to the supposed brightness of the light by which it is made. It is in this manner (in order to save trouble, and sometimes to prevent confusion) that the shadows in most drawings are made. On this subject, see Priestley's Perspect. above quoted; also Kirby's Persp. book 2, ch. 4.

SHAFT *of a Column*, in Building, is the body of it; thus called from its straightness: but by architects more commonly the Fust.

SHAFT is also used for the spire of a church steeple; and for the shank or tunnel of a chimney.

SHARP (ABRAHAM), an ingenious mathematician, mechanist, and astronomer, was descended from an ancient family at Little-Horton, near Bradford, in the West Riding of Yorkshire, where he was born about the year 1651. At a proper age he was put apprentice to a merchant at Manchester; but his genius led him so strongly to the study of mathematics, both theoretical and practical, that he soon became uneasy in that situation of life. By the mutual consent therefore of his master and himself, though not altogether with that of his father, he quitted the business of a merchant. On this he removed to Liverpool, where he gave himself up wholly to the study of mathematics, astronomy, &c; and where, for a subsistance, he opened a school, and taught writing and accounts, &c.

He had not been long at Liverpool when he accidentally fell in company with a merchant or tradesman visiting that town from London, in whose house it seems the astronomer Mr. Flamsteed then lodged. With the view therefore of becoming acquainted with this eminent man, Mr. Sharp engaged himself with the merchant as a book-keeper. In consequence he soon contracted an intimate acquaintance and friendship with Mr. Flamsteed, by whose interest and recommendation he obtained a more profitable employment in the dock-yard at Chatham; where he continued till his friend and patron, knowing his great merit in astronomy and mechanics, called him to his assistance, in contriving, adapting, and fitting up the astronomical apparatus in the Royal Observatory at Greenwich, which had been lately built, namely about the year 1676; Mr. Flamsteed being then 30 years of age, and Mr. Sharp 25.

In this situation he continued to assist Mr. Flamsteed in making observations (with the mural arch, of 80 inches radius, and 140 degrees on the limb, contrived and graduated by Mr. Sharp) on the meridional zenith distances of the fixed stars, sun, moon, and planets, with the times of their transits over the meridian; also the diameters of the sun and moon, and their eclipses, with those of Jupiter's satellites, the variation of the compass, &c. He assisted him also in making a catalogue of near 3000 fixed stars, as to their longitudes and magnitudes, their right ascensions and polar distances, with the variations of the same while they change their longitude by one degree.

But from the fatigue of continually observing the stars at night, in a cold thin air, joined to a weakly constitution, he was reduced to a bad state of health; for the recovery of which he desired leave to retire to his house at Horton; where, as soon as he found himself on the recovery, he began to fit up an observatory of his own; having first made an elegant and curious engine for turning all kinds of work in wood or brass, with a maondril for turning irregular figures, as ovals, roses, wreathed pillars, &c. Besides these, he made himself most of the tools used by joiners, clockmakers, opticians, mathematical instrument-makers, &c. The limbs or arcs of his large equatorial instrument, sextant, quadrant, &c, he graduated with the nicest accuracy, by diagonal divisions into degrees and minutes. The telescopes he used were all of his own making, and the lenses ground, figured, and adjusted with his own hands.

It was at this time that he assisted Mr. Flamsteed in calculating most of the tables in the second volume of his Historia Cœlestis, as appears by their letters, to be seen in the hands of Mr. Sharp's friends at Horton. Likewise the curious drawings of the charts of all the constellations visible in our hemisphere, with the still more excellent drawings of the planispheres both of the northern and southern constellations. And though these drawings of the constellations were sent to be engraved at Amsterdam by a masterly hand, yet the originals far exceeded the engravings in point of beauty and elegance: these were published by Mr. Flamsteed, and both copies may be seen at Horton.

The mathematician meets with something extraordinary in Sharp's elaborate treatise of Geometry Improved (in 4to 1717, signed A. S. Philomath.), 1st, by a large and accurate table of segments of circles, its construction and various uses in the solution of several difficult problems, with compendious tables for finding a true proportional part; and their use in these or any other tables exemplified in making logarithms, or their natural numbers, to 60 places of figures; there being a table of them for all primes to 1100, true to 61 figures. 2d, His concise treatise of Polyedra, or solid bodies of many bases, both the regular ones and others: to which are added twelve new ones, with various methods of forming them, and their exact dimensions in surds, or species, and in numbers: illustrated with a variety of copper-plates, neatly engraved by his own hands. Also the models of these polyedra he cut out in boxwood with amazing neatness and accuracy. Indeed few or none of the mathematical instrument-makers could exceed him in exactly graduating or neatly engraving any mathematical or astronomical instrument, as may be seen in the equatorial instrument above-mentioned, or in his sextant, quadrants and dials of various kinds; also in a curious armillary sphere, which, besides the common properties, has moveable circles &c, for exhibiting and resolving all spherical triangles; also his double sector, with many other instruments, all contrived, graduated and finished, in a most elegant manner, by himself. In short, he possessed at once a remarkably clear head for contriving, and an extraordinary hand for executing any thing, not only in mechanics, but also in drawing, writing, and making the most exact and beautiful schemes or figures in all his calculations and geometrical constructions.

The quadrature of the circle was undertaken by him for his own private amusement in the year 1699, deduced from two different series, by which the truth of it was proved to 72 places of figures; that is, if the diameter of a circle be 1, the circumference will be found equal to 3·141592653589793238462643383279502884197169399375105820974944592307816405&c. He gave also ingenious improvements on the making of logarithms, and the constructing of the natural sines, tangents, and secants.

He also calculated the natural and logarithmic sines, tangents, and secants, to every second in the first minute of the quadrant: the laborious investigation of which may probably be seen in the archives of the Royal Society, as they were presented to Mr. Patrick Murdoch for that purpose; exhibiting his very neat and accurate manner of writing and arranging his figures, not to be equalled perhaps by the best penman now living.

The late ingenious Mr. Smeaton says (Philos. Trans. an. 1786, pa. 5, &c):—"In the year 1689, Mr. Flamsteed completed his mural arc at Greenwich; and, in the Prolegomena to his Historia Cœlestis, he makes an ample acknowledgment of the particular assistance, care, and industry of Mr. Abraham Sharp; whom, in the mouth of August 1688, he brought into the observatory, as his amanuensis; and being, as Mr. Flamsteed tells us, not only a very skilful mathematician, but exceedingly expert in mechanical operations, he was principally employed in the construction of the mural arc; which in the compass of 14 months he finished, so greatly to the satisfaction of Mr. Flamsteed, that he speaks of him in the highest terms of praise.

"This celebrated instrument, of which he also gives the figure at the end of the Prolegomena, was of the radius of 6 feet 7½ inches; and, in like manner as the sextant, it was furnished both with screw and diagonal divisions, all performed by the accurate hand of Mr. Sharp. Yet, whoever compares the different parts of the table for conversion of the revolutions and parts of the screw belonging to the mural arc into degrees, minutes, and seconds, with each other, at the same distance from the zenith on different sides; and with their halves, quarters, &c, will find as notable a disagreement of the screw-work from the hand divisions, as had appeared before in the work of Mr. Tompion: and hence we may conclude, that the method of Dr. Hooke, being executed by two such masterly hands as Tompion and Sharp, and found defective, is in reality not to be depended upon in nice matters.

"From the account of Mr. Flamsteed it appears also, that Mr. Sharp obtained the zenith point of the instrument, or line of collimation, by observation of the zenith stars, with the face of the instrument on the east and on the west side of the wall: and that having made the index stronger (to prevent flexure) than that of the sextant, and thereby heavier, he contrived, by means of pulleys and balancing weights, to relieve the hand that was to move it from a great part of its gravity. Mr. Sharp continued in strict correspondence with Mr. Flamsteed as long as he lived, as appeared by letters of Mr. Flamsteed's found after Mr. Sharp's death; many of which I have seen.

"I have been the more particular relating to Mr. Sharp, in the business of constructing this mural arc; not only because we may suppose it the first good and valid instrument of the kind, but because I look upon Mr. Sharp to have been the first person that cut accurate and delicate divisions upon astronomical instruments; of which, independent of Mr. Flamsteed's testimony, there still remain considerable proofs: for, after leaving Mr. Flamsteed, and quitting the department above-mentioned, he retired into Yorkshire, to the village of Little Horton, near Bradford, where he ended his days about the year 1742; and where I have seen not only a large and very fine collection of mechanical tools, the principal ones being made with his own hands, but also a great variety of scales and instruments made with them, both in wood and brass, the divisions of which were so exquisite, as would not discredit the first artists of the present times: and I believe there is now remaining a quadrant, of 4 or 5 feet radius, framed of wood, but the limb covered with a brass plate; the subdivisions being done by diagonals, the lines of which are as finely cut as those upon the quadrants at Greenwich. The delicacy of Mr. Sharp's hand will indeed permanently appear from the copper-plates in a quarto book, published in the year 1718, intituled Geometry Improved by A. Sharp, Philomath." (or rather 1717, by A. S. Philomath.) "whereof not only the geometrical lines upon the plates, but the whole of the engraving of letters and figures, were done by himself, as I was told by a person in the mathematical line, who very frequently attended Mr. Sharp in the latter part of his life. I therefore look upon Mr. Sharp as the first person that brought the affair of hand division to any degree of perfection."

Mr. Sharp kept up a correspondence by letters with most of the eminent mathematicians and astronomers of his time, as Mr. Flamsteed, Sir Isaac Newton, Dr. Halley, Dr. Wallis, Mr. Hodgson, Mr. Sherwin, &c, the answers to which letters are all written upon the backs, or empty spaces, of the letters he received, in a short-hand of his own contrivance. From a great variety of letters (of which a large chest full remain with his friends) from these and many other celebrated mathematicians, it is evident that Mr. Sharp spared neither pains nor time to promote real science. Indeed, being one of the most accurate and indefatigable computers that ever existed, he was for many years the common resource for Mr. Flamsteed, Sir Jonas Moore, Dr. Halley, and others, in all sorts of troublesome and delicate calculations.

Mr. Sharp continued all his life a bachelor, and spent his time as recluse as a hermit. He was of a middle stature, but very thin, being of a weakly constitution; he was remarkably feeble the last three or four years before he died, which was on the 18th of July 1742, in the 91st year of his age.

In his retirement at Little Horton, he employed four or five rooms or apartments in his house for different purposes, into which none of his family could possibly enter at any time without his permission. He was seldom visited by any persons, except two gentlemen of Bradford, the one a mathematician, and the other an ingenious apothecary: these were admitted, when he chose to be seen by them, by the signal of rubbing a stone against a certain part of the outside wall of the house. He duly attended the dissenting chapel at Bradford, (of which he was a member,) every Sunday; at which time he took care to be provided with plenty of halfpence, which he very charitably suffered to be taken singly out of his hand, held behind him during his walk to the chapel, by a number of poor people who followed him, without his ever looking back, or asking a single question.

Mr. Sharp was very irregular as to his meals, and remarkably sparing in his diet, which he frequently took in the following manner. A little square hole, something like a window, made a communication between the room where he was usually employed in calculations, and another chamber or room in the house where a servant could enter; and before this hole he had contrived a sliding board: the servant always placed his victuals in this hole, without speaking or making any the least noise; and when he had a little leisure he visited his cupboard to see what it afforded to satisfy his hunger or thirst. But it often happened, that the breakfast, dinner, and supper have remained untouched by him, when the servant has gone to remove what was left—so deeply engaged had he been in calculations. Cavities might easily be perceived in an old English oak table where he sat to write, by the frequent rubbing and wearing of his elbows.—*Gutta cavat lapidem, &c.*

By Mr. Sharp's epitaph it appears that he was related to archbishop Sharp. And Mr. Sharp the eminent surgeon, who it seems has lately retired from business, is the nephew of our author. Another nephew was the father of Mr. Ramsden, the late celebrated instrument-maker, who says that his grand uncle Abraham, our author, was some time in his younger days an exciseman; which occupation he quitted on coming to a patrimonial estate of about 200l. a-year.

SHARP, in Music, a kind of artificial note, or character, thus formed ♯: this being prefixed to any note, shows that it is to be sung or played a semitone or half note higher than the natural note is. When a sharp is placed at the beginning of a stave or movement, it shows that all notes that are found on the same line, or space, throughout, are to be raised half a tone above their natural pitch, unless a natural intervene. When a sharp occurs accidentally, it only affects as many notes as follow it on the same line or space, without a natural, in the compass of a bar.

SHEAVE, in Mechanics, a solid cylindrical wheel, fixed in a channel, and moveable about an axis, as being used to raise or increase the mechanical powers applied to remove any body.

SHEERS, aboard a ship, an engine used to hoist or displace the lower masts of a ship.

SHEKEL, or SHEKLE, an ancient Hebrew coin and weight, equal to 4 Attic drachmas, or 4 Roman denarii, or 2s. 9½d. sterling. According to father Mersenne, the Hebrew shekel weighs 268 grains, and is composed of 20 oboli, each obolus weighing 16 grains of wheat.

SHERBURNE (EDWARD), an ingenious scholar, was born in London in 1616, and died in 1702. After completing his education, he travelled abroad; but returned in 1641, and succeeded, on his father's death, to the office of clerk of the ordnance. He was imprisoned for some time by the parliament, and on recovering his liberty joined the king, whom he served with great bravery, by which he suffered considerably in his estate. After the battle of Edgehill he went to Oxford, where he was created master of arts. At the restoration he recovered his place, was knighted, and made commissary-general of the artillery.

Sherburne published a volume of poems, and a translation of Seneca's tragedies. But his chief work was a translation of The Sphere of M Manilius, made an English poem, with annotations and an astronomical appendix: London 1675, in folio. Of the parts of this poem, their distribution and order, and of the interpreter's labours in explaining it, both in his learned notes and considerable appendix, he observes, that the poem begins with a succinct indication of the origin and progress of arts and sciences, particularly of astronomy; of which last, besides what the translator has noted in his marginal illustrations, he has added, for the satisfaction of the more curious, a compendious history, continued down to the age of Manilius; with a very instructive catalogue of the most eminent astronomers, from the first parent of all arts, and mankind itself, to the editor's time. A more particular and satisfactory account of this work may be seen in the Philos. Trans. vol. 9, pa. 228, or in my Abridg. vol. 2, pa. 185.

SHILLING, an English silver coin, equal to 12 pence, or the 20th part of a pound sterling. This was a Saxon coin, being the 48th part of their pound weight. Its value at first was 5 pence; but it was reduced to 4 pence about a century before the conquest. After the conquest, the French solidus of 12 pence, which was in use among the Normans, was called by the English name of shilling; and the Saxon shilling of 4 pence took a Norman name, and was called the groat, or great coin, because it was the largest English coin then known. From this time, the shilling underwent many alterations.

In the time of Edward the 1st, the pound troy was the same as the pound sterling of silver, consisting of 20 shillings; so that the shilling weighed the 20th part of a pound, or more than half an ounce troy. But some are of opinion, there were no coins of this denomination, till Henry the 7th, in the year 1504, first coined silver pieces of 12 pence value, which we call shillings. Since the reign of Elizabeth, a shilling weighs the 62nd part of a pound troy, or 3 dwts. $20\frac{8}{31}$ grs, the pound weight of silver making 62 shillings. And hence the ounce of silver is worth $5\frac{1}{6}$ shillings, or 5s. 2d.

Many other nations have also their shillings. The English shilling is worth about 23 French sols; those of Holland and Germany about half as much, or $11\frac{1}{2}$ sols; those of Flanders, about 9. The Dutch shillings are also called sols de gros, because equal to 12 gross. The Danes have copper shillings, worth about one fourth of a farthing sterling.

SHIVERS, in a ship, the seamen's term for those little round wheels, in which the rope of a pulley or block runs. They turn with the rope, and have pieces of brass in their centres, into which the pin of the block goes, and on which they turn.

SHORT (James), a very eminent optician and telescope-maker, was the son of a joiner at Edinburgh, where James was born in 1710. At ten years of age, his parents being both dead, he was placed as a poor boy, in Heriot's charity hospital at that place. Two years after however, having shown uncommon talents, he was sent to the high-school of that city, where he so much distinguished himself in classical learning, that his friends thought of qualifying him for a learned profession. After 4 years spent at the high-school, in 1726 he was entered a student in the university of Edinburgh; where he passed through a regular course of study; took his degree of master of arts; and, at the earnest entreaties of his relations, attended the divinity hall; after which, in 1731, he passed his trials to fit him for a preacher in the church of Scotland.

Soon after this, however, the mind of our young artist began to revolt against the idea of a profession so little suited to his talents; and having had occasion to attend a course of Mr. Maclaurin's mathematical class in the college, he there so much distinguished himself, that the professor took great notice of him, and invited him often to his house, where he had opportunities of knowing more fully the extent of the young man's capacity. In 1732, Mr. M. kindly permitted his pupil to make use of his rooms in the college, for his apparatus, where he began to work in his new profession of telescope-making, under the eye of his eminent master and patron; who, in a letter about two years after to Dr. Jurin, mentions the proficiency made by Mr. Short, in constructing reflecting telescopes, in these words: "Mr. Short, who had begun with making glass specula, is now employing himself to improve the metallic. By taking care of the figure, he is enabled to give them larger apertures than others have done; and, upon the whole, they surpass in perfection all that I have seen of other workmen." The figure which Mr. S. gave to his great specula, was parabolic: which he did however not by any rule or canon, but by practice and mechanical devices.

Mr. S. continued from this time to practise his art as a regular profession, with much success; so that when, in the year 1736, he was called up to London, at the desire of queen Caroline, to give mathematical instructions to Wm. duke of Cumberland, he had cleared the sum of 500l. by the profits of his business. Towards the end of the same year he returned to Edinburgh; and having made several useful improvements in his art, during his stay in England, he now prosecuted it with fresh vigour and success. In 1739, being then again at London, the earl of Morton took Mr. S. with him on a tour to the Orkney isles, and engaged him there to adjust the geography of that part of Scotland. He returned to London with the earl, and finally established himself there, in the line of his profession. In 1743, he was employed by lord Thos. Spencer, to make a reflector of 12 feet focus, being the largest that he ever constructed, except those for the king of Spain, and some others of the same focal distance, with great improvements and higher magnifiers. The telescope for the king of Spain was finished in the year 1752, which, with its whole apparatus, cost 1200*l*. But the instrument made for lord Thomas Spencer, having fewer accompaniments, was purchased for 600 guineas. Mr. Short died at Newington Butts, near London, in 1768, at 58 years of age; and, from the great profits and success of his trade, left at his death a fortune of 20 thousand pounds.

Mr. S. was a good general scholar, besides well skilled in optics and mathematical learning. He was a very useful member of the Royal Society, and wrote a great multitude of excellent papers in the Philos. Trans. from the year 1736 till the time of his death. Among them, his determination of the sun's parallax at about $8\frac{2}{3}''$, from his ingenious calculations on the transit of Venus, has been pretty generally adopted by astronomers.

SHORT-SIGHTEDNESS, *myopia*, a defect in the conformation of the eye, when the crystalline &c being too convex, the rays that enter the eye are refracted too much, and made to converge too fast, so as to unite before they reach the retina, by which means vision is rendered dim and confused.

It is commonly thought that short-sightedness wears off in old age, on account of the eye becoming flatter; but Dr. Smith questions whether this be matter of fact, or only hypothesis. It is remarkable that short-sighted persons commonly write a small hand, and affect a small print, because they can see more of it at one view: that it is customary with them not to look at the person they converse with, because they cannot well see the motion of his eyes and features, and are therefore attentive to his words only: that they see more distinctly, and somewhat further off, by a strong light, than by a weak one; because a strong light causes a contraction of the pupil, and consequently of the pencils, both here and at the retina, which lessens their mixture, and consequently the apparent confusion; and therefore, to see more distinctly, they almost close their eye-lids, for which reason they were anciently called myopes. Smith's Optics, vol. 2, Rem. pa. 10.

Dr. Jurin observes, that persons who are much and long accustomed to view objects at small distances, as students in general, watchmakers, engravers, painters in miniature, &c, see better at small distances, and worse at great distances, than other people. And he gives the reasons, from the mechanical effect of habit in the eye. Essay on Dist. and Indist. Vision.

The ordinary remedy for short-sightedness is a concave lens, held before the eye; for this causing the rays to diverge, or at least diminishing much of their convergency, it makes a compensation for the too great convexity of the crystalline. Dr. Hooke suggests another remedy; which is to employ a convex glass, in a position between the object and the eye, by means of which, the object may be made to appear at any distance from it, and so the eye be made to contemplate the picture in the same manner as if the object itself were in its place. But here unfortunately the image will appear inverted: for this however he has some whimsical expedients; viz, in reading to turn the book upside down, and to learn to write upside down. As to distant objects, the doctor asserts, from his own experience, that with a little practice in contemplating inverted objects, one gets as good an idea of them as if seen in their natural posture.

SHOT, in the Military Art, includes all kinds of balls or bullets for fire arms, from the cannon to the pistol. As to those for mortars, they are usually called shells. Shot are mostly of a round form, though there are other shapes. Those for cannon are of iron; but those for muskets and pistols are of lead. Cannon shot and shells are usually set up in piles, or heaps, tapering from the base towards the top; the base being either a triangle, a square, or a rectangle; from which the number in the pile is easily computed. See PILE.

The weight and dimensions of balls may be found, the one from the other, whether they are of iron or of lead. Thus, the weight of an iron ball of 4 inches diameter, is 9lb, and because the weight is as the cube of the diameter, therefore as $4^3 : 9 :: d^3 : \frac{9}{64} d^3 = w$, the weight of the iron ball whose diameter is d; that is, $\frac{9}{64}$ of the cube of its diameter. And, conversely, if the weight be given, to find the diameter, it will be $\sqrt[3]{\frac{64}{9} w} = d$; that is, take $\frac{64}{9}$ or $7\frac{1}{9}$ of the weight, and the cube root of that will be the diameter of the iron ball.

For leaden balls; one of $4\frac{1}{2}$ inches diameter weighs 17 pounds; therefore as the cube of $4\frac{1}{2}$ is to 17, or nearly as $9 : 2 :: d^3 : \frac{2}{9} d^3 = w$, the weight of the leaden ball whose diameter is d, that is, $\frac{2}{9}$ of the cube of the diameter. On the contrary, if the weight be given, to find the diameter, it will be $\sqrt[3]{\frac{9}{2} w} = d$; that is, $\frac{9}{2}$ or $4\frac{1}{2}$ of the weight, and the cube root of the product. See my Conic Sections and Select Exercises, pa. 141; or my Math. Course, vol. 2, p. 269

SHOULDER *of a Bastion*, in Fortification, is the angle where the face and the flank meet.

SHOULDERING, in Fortification. See EPAULEMENT

SHUCKBURGH-EVELYN (Sir GEORGE A. W. bart.) died at his seat in Warwickshire, Sept. 1804, in the 54th year of his age. He had represented that county in three successive parliaments; where his integrity, and independent conduct as a British senator, procured him the respect of all wise and good men. Sir G. was an elegant classical scholar, and had improved his knowledge of men and science by profitable travels through Europe. He was a considerable mathematician and philosopher, and well skilled in astronomy both theoretical and practical; in which sciences his deep and laborious researches gave him a distinguished rank in the Royal and Antiquarian Societies, whose publications are adorned with several of his learned and ingenious compositions, particularly his paper on the Barometrical Measurements of Altitudes. Sir Geo. carried his mathematical and logical habits into every purpose in life, in every circumstance of which, he was one of the most correct and methodical of men. Of men, and motives of action, Sir Geo. was a most accurate judge, and was always attentive to guard himself against the impositions of the designing. In matters of science too, no man was more wary of making hasty inferences, or of forming general conclusions from partial or inaccurate observations. Truth was his darling object; which he endeavoured to discover, and to detect error, by the most patient vigilance. Had Sir Geo. devoted more of his time to those pursuits, he would probably have had few superiors in philosophical celebrity. The pains he took to adjust a regular and uniform standard of weights and measures, the tardy cautiousness of his experiments, the accuracy of his calculations, and the practicability of his schemes, entitle him to the highest praise, among such as have laboured for the public benefit.

SHWAN-*pan*, a Chinese instrument, composed of a number of wires, with beads upon them, which they move backwards, and forwards, and which serves to assist them in their computations. See ABACUS.

SIDE, *latus*, in Geometry. The side of a figure is a line making part of the periphery of any superficial figure. In triangles, the sides are also called legs. In a right-angled triangle, the two sides that include the right angle, are called catheti, or sometimes the base and perpendicular; and the third side, the hypothenuse.

SIDE *of a Polygonal Number*, is the number of terms in the arithmetical progression that are summed up to form the number.

SIDE *of a Power*, is what is usually called the root.

SIDES of *Horn-works*, *Crown-works*, *Double-tenailles*, &c, are the ramparts and parapets which inclose them on the right and left, from the gorge to the head.

SIDEREAL, something relating to the stars. As sidereal year, day, &c, being those marked out by the stars.

SIDEREAL *Year*. See YEAR.

SIDEREAL *Day*, is the time in which any star appears to revolve from the meridian to the meridian again; or the time in which the earth makes one complete revolution on its axis, which is 23 hours 56′ 4″ 6‴ of mean solar time; there being 366 sidereal days in a year; that is, the earth makes 366 revolutions on its axis, though we only see the sun rise 365 times; so that 366 terrestrial revolutions would be exactly equal to 365 diurnal revolutions of the sun, if the equinoctial points were at rest in the heavens. But these points go backward, with respect to the stars, at the rate of 50″ of a degree in a Julian year; which causeth the stars to have an apparent progressive motion eastward 50″ in that time. And as the sun's mean motion in the ecliptic is only 11 signs 29° 45′ 40″ 15‴ in 365 days, it follows, that at the end of that time he will be 14′ 19″ 45‴ short of that point of the ecliptic from which he set out at the beginning; and the stars will be advanced 50″ of a degree with respect to that point.

Consequently, if the sun's centre be on the meridian with any star on any given day of the year, that star will be 14′ 19″ 45‴ + 50″ or 15′ 9″ 45‴ east of the sun's centre, on the 365th day afterward, when the sun's centre is on the meridian; and therefore that star will not come to the meridian on that day till the sun's centre has passed it by 1′ 0″ 38‴ 57⁗ of mean solar time; for the sun takes so much time to go through an arc of 15′ 9″ 45‴; and then, in 365d 0h 1′ 0″ 38‴ 57⁗ the star will have just completed its 366th revolution to the meridian.

In the following table, of sidereal revolutions, the first column contains the number of revolutions of the stars; the others exhibit the times in which these revolutions are made, as shown by a well regulated clock; those on the right hand show the daily accelerations of the stars, that is, how much any star gains upon the time shown by such a clock, in the corresponding revolutions.

Revol. of the stars.	Times in which the revolutions are made.						Accelerations of the stars.

This table will not differ the 279,936,000,000th part of a second of time from the truth in a whole year. It was calculated by Mr. Ferguson; and it is the only table of the kind in which the recession of the equinoctial points has been taken into the calculation.

SIGN, in Algebra, a symbol or character, employed to denote some particular operation. Those most commonly used are, + for addition, − for subtraction, × or · for multiplication, ÷ for division, $\surd$ for the square root, $\sqrt[3]{}$ for the cube root, and $\sqrt[n]{}$ for the *n*th root; also = for equality, &c.

SIGNS, *like, positive, negative, radical*, &c. See the adjectives.

SIGN, in Astronomy, a 12th part of the ecliptic, or zodiac; or a portion containing 30 degrees of the same.

The ancients divided the zodiac into 12 segments, called signs; commencing at the point where the ecliptic and equinoctial intersect, and so counting forward from west to east, according to the course of the sun; these signs they named from the 12 constellations which possessed those segments in the time of Hipparchus. But the constellations have since so changed their places, by the precession of the equinox, that Aries is now found in the sign called Taurus, and Taurus in that of Gemini, &c.

The names, and characters, of the 12 signs, and their order, are as follow: Aries ♈, Taurus ♉, Gemini ♊, Cancer ♋, Leo ♌, Virgo ♍, Libra ♎, Scorpio ♏, Sagittarius ♐, Capricornus ♑, Aquarius ♒, Pisces ♓; each of which, with the stars in them, see under its proper article, ARIES, TAURUS, &c.

The signs are distinguished, with regard to the season of the year when the sun is in them, into vernal, æstival, autumnal, and brumal.

Vernal or *Spring* SIGNS, are Aries, Taurus, Gemini.

Æstival or *Summer* SIGNS, are Cancer, Leo, Virgo.

Autumnal SIGNS, are Libra, Scorpio, Sagittary.

Brumal or *Winter* SIGNS, are Capricorn, Aquarius, Pisces. The vernal and summer signs are also called northern signs, because they are on the north side of the equinoctial; and the autumnal and winter signs are called southern ones, because they are on the south side of the same.

The signs are also distinguished into ascending and descending, according as they are ascending toward the north, or descending toward the south. Thus, the

Ascending SIGNS, are the winter and spring signs, or those six from the winter solstice to the summer solstice, viz, the signs Capricorn, Aquarius, Pisces, Aries, Taurus, Gemini. And the

Descending SIGNS are the summer and autumn signs, or the signs Cancer, Leo, Virgo, Libra, Scorpio, Sagittary.

SIGNS, *Fixed, Masculine*, &c; see the adjectives.

SILLON, in Fortification, an elevation of earth, made in the middle of the moat, to fortify it, when too broad. It is more usually called the Envelope.

SIMILAR, in Arithmetic and Geometry, the same with like. Similar things have the same disposition or conformation of parts, and differ in nothing but as to their quantity or magnitude; as two squares, or two circles, &c. In Mathematics, similar parts, as A, *a*, have the same ratio to their wholes B, *b*; and if the wholes have the same ratio to the parts, the parts are similar.

SIMILAR *angles*, are also equal angles.

SIMILAR *arcs*, of circles, are such as are like parts of their whole peripheries. And, in general, similar arcs of any like curves, are the like parts of the wholes.

SIMILAR *bodies*, in Natural Philosophy, are such as have their particles of the same kind and nature one with another.

SIMILAR *Curves*. Two segments of two curves are said to be similar when, any right-lined figure being inscribed within one of them, we can inscribe always a similar rectilineal figure in the other.

SIMILAR *Conic Sections*, are such as are of the same kind, and have their principal axes and parameters proportional. So, two ellipses are figures of the same kind, but they are not similar unless the axes of the one have the same ratio as the axes of the other. And the same of two hyperbolas, or two parabolas. And generally, those curves are similar, that are of the same kind, and have their corresponding dimensions in the same ratio.—All circles are similar figures.

SIMILAR *Diameters of Conic Sections*, are such as make equal angles with their ordinates.

SIMILAR *Figures*, or plane figures, are such as have all their angles equal respectively, each to each, and their sides about the equal angles proportional. And the same of similar polygons.—Similar plane figures have their areas or contents, in the duplicate ratio of their like sides, or as the squares of those sides.

SIMILAR *Plane Numbers*, are such as may be ranged into the form of similar rectangles; that is, into rectangles whose sides are proportional. Such are 12 and 48; for the sides of 12 are 6 and 2, and the sides of 48 are 12 and 4, which are in the same proportion, viz, 6 : 2 : : 12 : 4.

SIMILAR *Polygons*, are polygons of the same number of angles, and the angles in the one equal severally to the angles in the other, also the sides about those angles proportional.

SIMILAR *Rectangles*, are those that have their sides about the like angles proportional.—All squares are similar.

SIMILAR *Segments of circles*, are such as contain equal angles.

SIMILAR *Solids*, are such as are contained under the same number of similar planes, alike situated.—Similar solids are to each other as the cubes of their like linear dimensions.

SIMILAR *Solid Numbers*, are those whose little cubes may be so ranged, as to form similar parallelopipedons.

SIMILAR *Triangles*, are such as are equiangular ones, or have all their three angles respectively equal in each triangle. For it is sufficient for triangles to be similar, that they be equiangular; because, being equiangular, they necessarily have their sides proportional, which is a condition of similarity in all figures. As to other figures, having more sides than three, they may be equiangular, without having their sides proportional, and therefore without being similar.—Similar triangles are as the squares of their like sides.

SIMILITUDE, in Arithmetic and Geometry, denotes the relation of things that are similar to each other. Euclid and, after him, most other authors, demonstrate every thing in geometry from the principle of congruity. Wolfius, instead of it, substitutes that of similitude, which, he says, was communicated to him by Leibnitz, and which he finds of very considerable use in geometry, as serving to demonstrate many things directly, which are only demonstrable from the principle of congruity in a very tedious manner.

SIMPLE, something not mixed, or not compounded; in which sense it stands opposed to compound. The elements are simple bodies, from the composition of which there result all sorts of mixed bodies.

SIMPLE *Equation, Fraction*, and *Surd*. See the substantives.

SIMPLE *Quantities*, in Algebra, are those that consist of one term only; as a, or $-ab$, or $3abc$: in opposition to compound quantities, which consist of two or more terms; as $a + b$, or $a + 2b - 3ac$.

SIMPLE *Flank*, and *Tenaille*, in Fortification. See the substantives.

SIMPLE *Machine, Motion, Pendulum*, and *Wheel*, in Mechanics. See the substantives. The simplest machines are always the most esteemed. And in geometry, the most simple demonstrations are the best.

SIMPLE *Problem*, in Mathematics. See LINEAR *Problem*.

SIMPLE *Vision*, in Optics. See VISION.

SIMPSON (THOMAS), F. R. S. a very eminent mathematician, and professor of mathematics in the Royal Military Academy at Woolwich, was born at Market Bosworth, in the county of Leicester, the 20th of August 1710. His father was a stuff weaver in that town; and though in tolerable circumstances, yet, intending to bring up his son Thomas to his own business, he took so little care of his education, that he was only taught to read English. But nature had furnished him with talents and a genius for far other pursuits; which led him afterwards to the highest rank in the mathematical and philosophical sciences.

Young Simpson very soon gave indications of his turn for study in general, by eagerly reading all books he could meet with, teaching himself to write, and embracing every opportunity he could find of deriving knowledge from other persons. His father observing him thus to neglect his business, by spending his time in reading what he thought useless books, and following other similar pursuits, used all his endeavours to check such proceedings, and to induce him to follow his profession with steadiness and better effect. And after many struggles for this purpose, the differences thus produced between them at length rose to such a height, that our author quitted his father's house entirely.

On this occasion he repaired to Nuneaton, a town at a small distance from Bosworth, where he went to lodge at the house of a tailor's widow, of the name of Swinfield, who had been left with two children, a daughter and a son, by her husband, of whom the son, who was the younger, being but about two years older than Simpson, had become his intimate friend and companion. And here he continued some time, working at his trade, and improving his knowledge by reading such books as he could procure.

Among several other circumstances which, long before this, gave occasion to show our author's early thirst for knowledge, as well as proving a fresh incitement to acquire it, was that of a large solar eclipse, which took place on the 11th day of May, 1724. This phenomenon, so awful to many who are ignorant of the cause of it, struck the mind of young Simpson with a strong curiosity to discover the reason of it, and to be able to predict the like surprising events. It was however several years before he could obtain his desire, which at length was gratified by the following accident. After he had been some time at Mrs. Swinfield's, at Nuneaton, a travelling pedlar came that way, and took a lodging at the same house, according to his usual custom. This man, to his profession of an itinerant merchant, had joined the more profitable one of a fortune-teller, which he performed by means of judicial astrology. Every one knows with what regard persons of such a cast are treated by the inhabitants of country villages; it cannot be surprising therefore that an untutored lad of 19 should look upon this man as a prodigy, and, regarding him in this light, should endeavour to ingratiate himself into his favour; in which he succeeded so well, that the sage was no less taken with the quick natural parts and genius of his new acquaintance. The pedlar, intending a journey to Bristol fair, left in the hands of young Simpson an old edition of Cocker's Arithmetic, to which was subjoined a short Appendix on Algebra, and a book upon Genitures, by Partridge the almanac-maker. These books he had perused to so good purpose, during the absence of his friend, as to excite his amazement upon his return; in consequence of which he set himself about erecting a genethliacal figure, in order to a presage of Thomas's future fortune.

This position of the heavens having been maturely considered secundum artem, the wizard, with great confidence, pronounced, that, "within two years time Simpson would turn out a greater man than himself!"

In fact, our author profited so well by the encouragement and assistance of the pedlar, afforded him from time to time when he occasionally came to Nuneaton, that, by the advice of his friend, he at length made an open profession of casting nativities himself; from which, together with teaching an evening school, he derived a pretty pittance, so that he greatly neglected his weaving, to which indeed he had never manifested any great attachment, and soon became the oracle of Nuneaton, Bosworth, and the environs. Scarce a courtship advanced to a match, or a bargain to a sale, without previously consulting the infallible Simpson about the consequences. But as to helping people to stolen goods, he always declared that above his skill; and over life and death he declared he had no power: all those called lawful questions he readily resolved, provided the persons were certain as to the horary data of the horoscope: and, he has often declared, with such success, that if from very cogent reasons he had not been thoroughly convinced of the vain foundation and fallaciousness of his art, he never should have dropt it, as he afterwards found himself in conscience bound to do.

About this time he married the widow Swinfield, in whose house he lodged, though she was then almost old enough to be his grandmother, being upwards of fifty years of age. After this the family lived comfortably enough together for some short time, Simpson occasionally working at his business of a weaver in the day-time, and teaching an evening school or telling fortunes at night; the family being also further assisted by the labours of young Swinfield, who had been brought up in the profession of his father.

But this tranquillity was soon interrupted, and our author driven at once from his home and the profession of astrology, by the following accident. A young woman in the neighbourhood had long wished to hear or know something of her lover, who had been gone to sea; but Simpson had put her off from time to time, till the girl grew at last so importunate, that he could deny her no longer. He asked her if she would be afraid if he should raise the devil, thinking to deter her; but she declared she feared neither ghost nor devil: so he was obliged to comply. The scene of action pitched on was a barn, and young Swinfield was to act the devil or ghost; who being concealed under some straw in a corner of the barn, was, at a signal given, to rise slowly out from among the straw, with his face marked so that the girl might not know him. Every thing being in order, the girl came at the time appointed; when Simpson, after cautioning her not to be afraid, began muttering some mystical words, and chalking round about them, till, on the signal given, up rises the tailor slow and solemn, to the great terror of the poor girl, who, before she had seen half his shoulders, fell into violent fits, crying out, it was the very image of her lover; and the effect upon her was so dreadful, that it was thought either death or madness must be the consequence. So that poor Simpson was obliged immediately to abandon at once both his home and the profession of a conjuror.

On this occasion it would seem he fled to Derby, where he remained about two or three years, viz, from 1733 till 1735 or 1736; instructing pupils in an evening school, and working at his trade by day.

It would seem that Simpson had an early turn for versifying, both from the circumstance of a song written here in favour of the Cavendish family, on occasion of the parliamentary election at that place, in the year 1733; and from his first two mathematical questions that were published in the Ladies Diary, which were both in a set of verses, not ill written for the occasion. These were printed in the Diary for 1736, and therefore must at latest have been written in the year 1735. These two questions, being at that time pretty difficult ones, show the great progress he had even then made in the mathematics; and from an expression in the first of them, viz, where he mentions his residence as being in latitude 52°, it appears he was not then come up to London, though he must have done so very soon after.

Together with his astrology, he had soon furnished himself with arithmetic, algebra, and geometry sufficient to be qualified for looking into the Ladies Diary (of which he had afterwards for several years the direction), by which he came to understand that there was a still higher branch of the mathematical knowledge than any he had yet been acquainted with; and this was the method of Fluxions. But our young analyst was quite at a loss to discover any English author who had written on the subject, except Mr. Hayes; and his work being a folio, and then pretty scarce, exceeded his ability of purchasing: however an acquaintance lent him Mr. Stone's Fluxions, which is a translation of the Marquis de l'Hospital's Analyse des Infinimens Petits: by this one book, and his own penetrating talents, he was, as we shall see presently, enabled in a very few years to compose a much more accurate treatise on this subject than any that had before appeared in our language.

After he had quitted astrology and its emoluments, he was driven to hardships for the subsistence of his family, while at Derby, notwithstanding his other industrious endeavours in his own trade by day, and teaching pupils at evenings. This determined him to repair to London, which he did in 1735 or 1736.

On his first coming to London, Mr. Simpson wrought for some time at his business in Spitalfields, and taught mathematics at evenings, or any spare hours. His industry turned to so good account, that he returned down into the country, and brought up his wife and three children, she having produced her first child to him in his absence. The number of his scholars increasing, and his abilities becoming in some measure known to the public, he was encouraged to make proposals for publishing by subscription, "A new Treatise of Fluxions: wherein the Direct and Inverse Methods are demonstrated after a new, clear, and concise Manner, with their Application to Physics and Astronomy: also the Doctrine of Infinite Series and Reverting Series universally, are amply explained, Fluxionary and Exponential Equations solved: together with a variety of new and curious Problems."

The book was published in 4to, in the year 1737, though the author had been frequently interrupted from furnishing the press so fast as he could have wished, through his unavoidable attention to his pupils for his immediate support. The principles of fluxions treated of in this work, are demonstrated in a method accurately true and genuine, not different from that of their great inventor, being entirely expounded by finite quantities.

In 1740, Mr. Simpson published a Treatise on The Nature and Laws of Chance, in 4to. To which are annexed, Full and clear Investigations of two important Problems added in the 2d edition of Mr. Demoivre's Book on Chances, as also two New Methods for the Summation of Series.

Our author's next publication was a 4to volume of Essays on several curious and interesting Subjects in Speculative and Mixed Mathematics; printed in the same year 1740. Soon after the publication of this book, he was chosen a member of the Royal Academy at Stockholm.

Our author's next work was, The Doctrine of Annuities and Reversions, deduced from general and evident Principles: with useful Tables, showing the Values of Single and Joint Lives, &c, in 8vo, 1742. This was followed, in 1743, by an Appendix containing some Remarks on a late book on the same Subject (by Mr. Abr. Demoivre, F. R. S.) with Answers to some personal and malignant Representations in the Preface thereof. To this answer Mr. Demoivre never thought fit to reply. A new edition of this work has lately been published, augmented with the tract on the same subject that was printed in our author's Select Exercises.

In 1743 also was published his Mathematical Dissertations on a variety of Physical and Analytical Subjects, in 4to; containing, among other particulars,

A Demonstration of the true Figure which the Earth, or any Planet, must acquire from its Rotation about an Axis. A general Investigation of the Attraction at the Surfaces of Bodies nearly spherical. A Determination of the Meridional Parts, and the Lengths of the several Degrees of the Meridian, according to the true Figure of the Earth. An Investigation of the Height of the Tides in the Ocean. A new Theory of Astronomical Refractions, with exact Tables deduced from the same. A new and very exact Method for approximating the Roots of Equations in Numbers; which quintuples the Number of Places at each Operation. Several new Methods for the Summation of Series. Some new and very useful Improvements in the Inverse Method of Fluxions. The work being dedicated to Martin Folkes, esq. president of the Royal Society.

His next book was A Treatise of Algebra, wherein the fundamental Principles are demonstrated, and applied to the Solution of a Variety of Problems. To which he added, The Construction of a great Number of Geometrical Problems, with the Method of resolving them numerically.

This work, which was designed for the use of young beginners, was printed in 8vo, 1745. A new edition appeared in 1755, with additions and improvements; among which was a new and general method of resolving all biquadratic equations, that are complete, or having all their terms. The work has gone through several other editions since that time: the 6th, or last, was in 1790.

His next work was, "Elements of Geometry, with their Application to the Mensuration of Superficies and Solids, to the Determination of Maxima and Minima, and to the Construction of a great Variety of geometrical Problems:" first published in 1747, in 8vo. And a second edition of the same came out in 1760, with great alterations and additions, being in a manner a new work, designed for young beginners, particularly for the gentlemen educated at the Royal Military Academy at Woolwich, and other editions have appeared since.

Mr. Simpson met with some trouble and vexation in consequence of the first edition of his Geometry. First, from some reflexions made upon it, as to the accuracy of certain parts of it, by Dr. Robert Simson, the learned professor of mathematics in the university of Glasgow, in the notes subjoined to his edition of Euclid's Elements. This brought an answer to those remarks from Mr. Simpson, in the notes added to the 2d edition as above; to some parts of which Dr. Simson again replied in his notes on the next edition of the said Elements of Euclid.— The second was by an illiberal charge of having stolen his Elements from Mr. Muller, the professor of fortification and artillery at the same academy at Woolwich, where our author was professor of geometry and mathematics. This charge was made at the end of the preface to Mr. Muller's Elements of Mathematics, in two volumes, printed in 1748; which was fully refuted by Mr. Simpson in the preface to the 2d edition of his Geometry.

In 1748 came out Mr. Simpson's Trigonometry, Plane and Spherical, with the Construction and Application of Logarithms, 8vo. This little book contains several things new and useful.

In 1750 came out, in two volumes, 8vo. The Doctrine and Application of Fluxions, containing, besides what is common on the Subject, a Number of new Improvements in the Theory, and the Solution of a Variety of new and very interesting Problems in different Branches of the Mathematics.—In the preface the author offers this to the world as a new book, rather than a second edition of that which was published in 1737, in which he acknowledges, that, besides errors of the press, there are several obscurities and defects, for want of experience, and the many disadvantages he then laboured under, in his first sally.

The idea and explanation here given of the first principles of fluxions, are not essentially different from what they are in his former treatise, though expressed in other terms. The consideration of time introduced into the general definition, will, he says, perhaps be disliked by those who would have fluxions to be mere velocities: but the advantage of considering them otherwise, viz, not as the velocities themselves, but as magnitudes they would uniformly generate in a given time, appears to obviate any objection on that head. By taking fluxions as mere velocities, the imagination is confined as it were to a point, and without proper care insensibly involved in metaphysical difficulties. But according to this other mode of explaining the matter, less caution in the learner is necessary, and the higher orders of fluxions are rendered much more easy and intelligible. Besides, though sir Isaac Newton defines fluxions to be the velocities of motions, yet he has recourse to the increments or moments generated in equal particles of time, in order to determine those velocities; which he afterwards teaches to expound by finite magnitudes of other kinds. This work was dedicated to George earl of Macclesfield.

In 1752 appeared, in 8vo, the Select Exercises for young Proficients in the Mathematics. This neat volume contains, A great Variety of algebraical Problems, with their Solutions. A select Number of Geometrical Problems, with their Solutions, both algebraical and geometrical. The Theory of Gunnery, independent of the Conic Sections. A new and very comprehensive Method for finding the Roots of Equations in Numbers. A short Account of the first Principles of Fluxions. Also the Valuation of Annuities for single and joint Lives, with a Set of new Tables, far more extensive than any extant. This last part was designed as a supplement to his Doctrine of Annuities and Reversions; but being thought too small to be published alone, it was inserted here at the end of the Select Exercises; from which however it has been removed in the last editions, and referred to its proper place, the end of the annuities, as before mentioned. The examples that are given to each problem in this last piece, are according to the London bills of mortality; but the solutions are general, and may be applied with equal facility and advantage to any other table of observations.

Mr. Simpson's Miscellaneous Tracts, printed in 4to, 1757, were his last legacy to the public: a most valuable bequest, whether we consider the dignity and importance of the subjects, or his sublime and accurate manner of treating them. The first of these papers is concerned in determining the Precession of the Equinox, and the different Motions of the Earth's Axis, arising from the Attraction of the Sun and Moon. It was drawn up about the year 1752, in consequence of another on the same subject, by M. de Sylvabelle, a French mathematician. Though this gentleman had gone through one part of the subject with success and perspicuity, and his conclusions were perfectly conformable to Dr. Bradley's observations; it nevertheless appeared to Mr. Simpson, that he had greatly failed in a very material part, and that indeed the only very difficult one; that is, in the determination of the momentary alteration of the position of the earth's axis, caused by the forces of the sun and moon; of which forces, the quantities, but not the effects, are truly investigated. The second paper contains the Investigation of a very exact Method or Rule for finding the Place of a Planet in its Orbit, from a Correction of Bishop Ward's circular Hypnthesis, by Means of certain Equations applied to the Motion about the upper Focus of the Ellipse. By this Method the Result, even in the Orbit of Mercury, may be found within a Second of the Truth, and that without repeating the Operation. The third shows the Manner of transferring the Motion of a Comet from a parabolic Orbit, to an elliptic one; being of great Use, when the observed Places of a new Comet are found to differ sensibly from those computed on the Hypothesis of a parabolic Orbit. The fourth is an Attempt to show, from mathematical Principles, the Advantage arising from taking the Mean of a Number of Observations, in practical Astronomy; wherein the Odds that the Result in this Way, is more exact than from one single Observation, is evinced, and the Utility of the Method in Practice clearly made appear. The fifth contains the Determination of certain Fluents, and the Resolution of some very useful Equations, in the higher Orders of Fluxions, by Means of the Measures of Angles and Ratios, and the right and versed Sines of circular Arcs. The 6th treats of the Resolution of algebraical Equations, by the Method of Surd-divisors; in which the Grounds of that Method, as laid down by Sir Isaac Newton, are investigated and explained. The 7th exhibits the Investigation of a general Rule for the Resolution of Isoperimetrical Problems of all Orders, with some Examples of the Use and Application of the said Rule. The 8th, or last part, comprehends the Resolution of some general and very important Problems in Mechanics and Physical Astronomy; in which, among other Things, the principal Parts of the 3d and 9th Sections of the first Book of Newton's Principia are demonstrated in a new and concise Manner. But what may perhaps best recommend this excellent tract, is the application of the general equations, thus derived, to the determination of the Lunar Orbit.

According to what Mr. Simpson had intimated at the conclusion of his Doctrine of Fluxions, the greatest part of this arduous undertaking was drawn up in the year 1750. About that time M. Clairaut, a very eminent mathematician of the French Academy, had started an objection against Newton's general law of gravitation. This was a motive to induce Mr. Simpson, among some others, to endeavour to discover whether the motion of the moon's apogee, on which that objection had its whole weight and foundation, could not be truly accounted for, without supposing a change in the received law of gravitation, from the inverse ratio of the squares of the distances. The success answered his hopes, and induced him to look farther into other parts of the theory of the moon's motion, than he had at first intended: but before he had completed his design, M. Clairaut arrived in England, and paid Mr. Simpson a visit; from whom he learnt, that he had a little before printed a piece on that subject, a copy of which Mr. Simpson afterwards received as a present, and found in it the same things demonstrated, to which he himself had directed his enquiry, besides several others.

The facility of the method Mr. Simpson fell upon, and the extensiveness of it, will in some measure appear from this, that it not only determines the motion of the apogee, in the same manner, and with the same ease, as the other equations, but utterly excludes all that dangerous kind of terms that had embarrassed the greatest mathematicians, and would, after a great number of revolutions, entirely change the figure of the moon's orbit: whence this important consequence is derived, that the moon's mean motion, and the greatest quantities of the several equations, will remain unchanged, unless disturbed by the intervention of some foreign or accidental cause.

Besides the foregoing, which are the whole of the regular books or treatises that were published by Mr. Simpson, he wrote and composed several other papers and fugitive pieces, as follow:

Several papers of his were read at the meetings of the Royal Society, and printed in their Transactions; but as most, if not all of them, were afterwards inserted, with alterations or additions, in his printed volumes, it is needless to take any farther notice of them here.

He proposed, and resolved many questions in the Ladies Diaries, &c; sometimes under his own name, as in the years 1735 and 1736; and sometimes under feigned or fictitious names; such as, it is thought, Hurlothrumbo, Kubernetes, Patrick O'Cavenah, Marmaduke Hodgson, Anthony Shallow, Esq. and probably several others; see the Diaries for the years 1735, 1736, 42, 43, 53, 54, 55, 56, 57, 58, 59, and 60. Mr. Simpson was also the editor or compiler of the Diaries from the year 1754 till the year 1760, both inclusive, during which time he raised that work to the highest degree of respect. He was succeeded in the editorship by Mr. Edw. Rollinson, who continued till his death in the year 1773. See my Diarian Miscellany, vol. 3.

It has also been commonly supposed that he was the real editor of, or had a principal share in, two other periodical works of a miscellaneous mathematical nature; viz, the Mathematician, and Turner's Mathematical Exercises, two volumes, in 8vo, which came out in periodical numbers, in the years 1750 and 1751, &c. The latter of these seems especially to have been set on foot to afford a proper place for exposing the errors and absurdities of Mr. Robert Heath, the then conductor of the Ladies Diary and Palladium; and which controversy between them ended in the disgrace of Mr. Heath, and expulsion from his office of editor to the Ladies Diary, and the substitution of Mr. Simpson in his stead, in the year 1753.

In the year 1760, when the plans proposed for erecting a new bridge at Blackfriars were in agitation, Mr. Simpson, among other gentlemen, was consulted on the best form for the arches, by the New-bridge Committee. On this occasion he gave a preference to the semicircular form; and, besides his report to the Committee, some letters also appeared, by himself and others, on the same subject, in the public newspapers, particularly in the Daily Advertiser, and in Lloyd's Evening Post. The same were also collected in the Gentleman's Magazine for that year, page 143 and 144.

It is probable that this reference to him, gave occasion to the turning his thoughts more seriously to this subject, so as to form the design of composing a regular treatise upon it: for his family have often informed me, that he laboured hard upon this work for some time before his death, and was very anxious to have completed it, frequently remarking to them, that this work, when published, would procure him more credit than any of his former publications. But he lived not to put the finishing hand to it. Whatever he wrote upon this subject, probably fell, together with all his other remaining papers, into the hands of Major Henry Watson, of the engineers, in the service of the India Company, being in all a large chest full of papers. This gentleman had been a pupil of Mr. Simpson's, and had lodged in his house. After Mr. Simpson's death, Mr. Watson prevailed upon the widow to let him have the papers, promising either to give her a sum of money for them, or else to print and publish them for her benefit. But neither of these was ever done; this gentleman always declaring, when urged on this point by myself and others, that no use could be made of any of the papers, owing to the very imperfect state in which he said they were left. And yet he persisted in his refusal to give them up again.

From Mr. Simpson's writings, I now return to himself. Through the interest and solicitations of William Jones, Esq. he was, in 1743, appointed professor of mathematics, then vacant by the death of Mr. Derham, in the Royal Academy at Woolwich; his warrant bearing date August 25th. And in 1745 he was admitted a fellow of the Royal Society, having been proposed as a candidate by Martin Folkes, esq. president, William Jones, esq. Mr. George Graham, and Mr. John Machin, secretary; all very eminent mathematicians. The president and council, in consideration of his very moderate circumstances, were pleased to excuse his admission fees, and likewise his giving bond for the settled future payments.

At the academy he exerted his faculties to the utmost, in instructing the pupils who were the immediate objects of his duty, as well as others, whom the superior officers of the ordnance permitted to be boarded and lodged in his house. In his manner of teaching, he had a peculiar and happy address; a certain dignity and perspicuity, tempered with such a degree of mildness, as engaged both the attention, esteem, and friendship of his scholars; of which the good of the service, as well as of the community, was a necessary consequence.

In the latter of stage of his existence, when his life was in danger, exercise and a proper regimen were prescribed him, but to little purpose; for he sank gradually into such a lowness of spirits, as often in a manner deprived him of his mental faculties, and at last rendered him incapable of performing his duty, or even of reading the letters of his friends; and so trifling an accident as the dropping of a tea-cup would flurry him as much as if a house had tumbled down.

The physicians advised his native air for his recovery; and in February, 1761, he set out, with much reluctance (believing he should never return), for Bosworth, along with some relations. The journey fatigued him to such a degree, that on his arrival he betook himself to his chamber, where he grew continually worse and worse, to the day of his death, which happened the 14th of May, in the fifty-first year of his age.

SIMSON (Dr. Robert), professor of mathematics in the university of Glasgow, was the eldest son of Mr. John Simson, of Kirtonhall in Ayrshire, and was born on the 14th of Oct. 1687. Being designed by his father for the church, after having got the usual school education, he was sent to the university of Glasgow about the year 1701, where he was distinguished by his proficiency in classical learning, and in the sciences. At this time, from temporary circumstances, it happened, that no mathematical lectures were given in the college; but young Simson's inquisitive mind, from some fortunate incident, having been directed to geometry, he soon found the study of that science to be congenial to his taste and capacity. This taste however, from an apprehension that it might obstruct his application to subjects more connected with the study of theology, was anxiously discouraged by his father, though it would seem with little effect.

Having procured a copy of Euclid's Elements, with the aid only of a few preliminary explanations from some more advanced students, he entered on the study of that oldest and best introduction to mathematics. In a short time he read and understood the first six, with the 11th and 12th books, and afterwards proceeding still farther in his mathematical pursuits, by his progress in the more difficult branches he laid the foundation of his future eminence. He did not however neglect the other sciences then taught in the college; but in proceeding through the regular course of academical study, he acquired the principles of that variety of knowledge, which he retained through life, and which contributed much to the estimation of his conversation and manners in society. His chief attention, however, was directed to his favourite science; so that his reputation as a mathematician in a few years became so high, and his general character so much respected, that in 1710, when he was only 22 years of age, the members of the college voluntarily made him an offer of the mathematical chair, in which a vacancy in a short time was expected to take a place. From his natural modesty however, he felt much reluctance, at so early an age, to advance abruptly from the state of a student, to that of a professor in the same college; and therefore he solicited permission to spend one year at least in London, where, besides other obvious advantages, he might have opportunities of becoming acquainted with some of the eminent mathematicians of England, who were then the most distinguished in Europe. In this proper request he was readily indulged; and without delay he proceeded to London, where he remained about a year, diligently employed in the improvement of his mathematical knowledge.

This journey turned out very favourable to his views; and he had much satisfaction in the acquaintance of some respectable mathematicians, particularly of Mr. Jones, Mr. Caswell, Dr. Jurin, and Mr. Ditton. With the latter, indeed, who was then mathematical master of Christ's-

Hospital, and well esteemed for his learning &c, he was more particularly connected. It appears from Mr. S.'s own account, in his letter, dated London, Nov. 1710, that he expected to have had an assistant in his studies chosen by Mr. Caswell; but, from some mistake, it was omitted, and Mr. S. himself applied to Mr. Ditton. He went to him not as a scholar (his own words), but to have general information and advice, about his mathematical studies. Mr. Caswell afterwards mentioned to Mr. S. that he meant to have procured Mr. Jones's assistance, if he had not been engaged.

When the vacancy in the professorship of mathematics at Glasgow did occur, in the following year, by the resignation of Dr. Robert Sinclair, or Sinclar (a descendant or other relative probably of Mr. George Sinclar, who died in that office in 1696), the university, while Mr. Simson was still in London, appointed him to fill it; and the minute of election, which is dated March 11, 1711, concluded with this very proper condition, "That they will admit the said Mr. Robert Simson, providing always, that he give satisfactory proof of his skill in mathematics, previous to his admission." He returned to Glasgow before the ensuing session of the college, and having gone through the form of a trial, by resolving a geometrical problem proposed to him, and also by giving "a satisfactory specimen of his skill in mathematics, and dexterity in teaching geometry and algebra;" having produced also respectable certificates of his knowledge of the science, from Mr. Caswell and others, he was duly admitted professor of mathematics, on the 20th of November of that year.

Mr. Simson, immediately after his admission, entered on the duties of his office, and his first occupation necessarily was the arrangement of a proper course of instruction for the students who attended his lectures, in two distinct classes. Accordingly he prepared elementary sketches of some branches on which there were not suitable treatises in general use. Both from a sense of duty and from inclination, he now directed the whole of his attention to the study of mathematics; and though he had a decided preference for geometry, which continued through life, yet he did not devote himself to it to the exclusion of the other branches of mathematical science, in most of which there is sufficient evidence of his being well skilled. From 1711, he continued near 50 years to teach mathematics to two separate classes, at different hours, five days in the week, during a continued session of seven months. His manner of teaching was uncommonly clear and successful; and among his scholars, several rose to distinction as mathematicians; among which may be mentioned the celebrated names of Dr. Matthew Stewart, professor of mathematics at Edinburgh; the two rev. Dr. Williamsons, one of whom succeeded Dr. Simson at Glasgow; the rev. Dr. Trail, formerly professor of mathematics at Aberdeen; Dr. James Moor, Greek professor at Glasgow: and professor Robison, of Edinburgh, with many others of distinguished merit. In the year 1758, Dr. S. being then 71 years of age, found it necessary to employ an assistant in teaching; and in 1761, on his recommendation, the rev. Dr. Williamson was appointed his assistant and successor.

During the remaining ten years of his life, he enjoyed a pretty equal share of good health; and continued to occupy himself in correcting and arranging some of his mathematical papers, and occasionally for amusement, in the solution of problems, and demonstration of theorems, which occurred from his own studies, or from the suggestions of others. His conversation on mathematical and other subjects continued to be clear and accurate; yet he had some strong impressions of the decline of his memory, of which he frequently complained; and this probably protracted, and finally prevented his undertaking the publication of some of his works, which were in so advanced a state, that with little trouble they might have been completed for the press. So that his only publication, after resigning his office, was a new and improved edition of Euclid's Data, which in 1762 was annexed to the 2d edition of the Elements. But from that period, though much solicited to bring forward some of his other works on the ancient geometry, though he knew well how much it was desired, and though he was fully apprised of the universal curiosity excited respecting his discovery of Euclid's Porisms, he resisted every importunity on the subject.

A life like Dr. Simson's, purely academical and perfectly uniform, seldom contains occurrences, the recording of which could be either interesting or useful. But his mathematical labours and inventions form the important part of his character; and with respect to them, there are abundant materials of information in his printed works; and some circumstances also may be gathered from a number of MS. papers which he left; and which, by the direction of his executor, are deposited in the library of the college of Glasgow. It is to be regretted, that, of the extensive correspondence which he carried on through life, with many distinguished mathematicians, a small portion only is preserved. Through Dr. Jurin, then secretary of the Royal Society, he had some intercourse with Dr. Halley, and other distinguished members of that Society. And both about the same time, and afterwards, he had frequent correspondence with Mr. Maclaurin, with Mr. James Stirling, Dr. James Moor, Dr. Matthew Stewart, Dr. Wm. Trail, and Mr. Williamson of Lisbon. In the latter part of his life, his mathematical correspondence was chiefly with that eminent geometer the late earl Stanhope, and with George Lewis Scott, esq.

As to his character, Dr. S. was originally possessed of great intellectual powers, an accurate and distinguishing understanding, an inventive genius, and a retentive memory: and these powers, being excited by an ardent curiosity, produced a singular capacity for investigating the truths of mathematical science. By such talents, with a correct taste, formed by the study of the Greek geometers, he was also peculiarly qualified for communicating his knowledge, both in his lectures and in his writings, with perspicuity and elegance. He was at the same time modest and unassuming; and, though not indifferent to literary fame, he was cautious, and even reserved, in bringing forward his own discoveries, but always ready to do justice to the merits and inventions of others. Though his powers of investigation, in the early part of life, were admirable, yet before any decline of his health appeared, he felt strong impressions of the decay both of his memory and other faculties; occasioned probably by the continued exertion of his mind, in those severe studies, which for a number of years he pursued with unremitting ardour.

Besides his mathematical attainments, from his liberal education he acquired a considerable knowledge of other sciences, which he preserved through life, by occasional reading, and, in some degree, by his constant intercourse with many learned men in his college. He was esteemed a good classical scholar; and, though the simplicity of geometrical demonstration does not admit of much variety of style, yet in his works a good taste in that respect may be distinguished. In his Latin prefaces also, in which there is some history and discussion, the purity of language has been generally approved. It is to be regretted, indeed, that he had not had an opportunity of employing, in early life, his Greek and mathematical learning, in giving an edition of Pappus in the original language.

Dr. Simson never was married; and the uniform regularity of a long life, spent within the walls of his college, naturally produced fixed and peculiar habits, which however, with the sincerity of his manners, were unoffending, and became even interesting to those with whom he lived. The strictness of these habits, which indeed pervaded all his occupations, probably had an influence also on the direction and success of some of his scientific pursuits. His hours of study, of amusement, and of exercise, were all regulated with uniform precision. The walks even in the squares or garden of the college were all measured by his steps, and he took his exercises by the hundreds of paces, according to his time or inclination.

It has been mentioned, that an ardent curiosity was an eminent feature in his character. It contributed essentially to his success in the mathematical investigations, and it displayed itself in the small and even trifling occurrences of common life. Almost every object and event excited it, and suggested some problem which he was impatient to resolve. This disposition, when opposed, as it often necessarily was, to his natural modesty, and to the formal civility of his manners, occasionally produced an embarrassment, which was amusing to his friends, and sometimes a little distressing to himself.

In his disposition, Dr. S. was both chearful and sociable; and his conversation, when he was at ease among his friends, was animated and various, enriched with much anecdote, especially of the literary kind, but always unaffected. It was enlivened also by a certain degree of natural humour; and even the slight fits of absence, to which in company he was occasionally liable, contributed to the entertainment of his friends, without diminishing their affection and respect, which his excellent qualities were calculated to inspire. One evening (Friday) in the week he devoted to a club, chiefly of his own selection, which met in a tavern near the college. The first part of the evening was employed in playing the game of whist, of which he was particularly fond; but, though he took no small trouble in estimating chances, it was remarked that he was often unsuccessful. The rest of the evening was spent in chearful conversation; and, as he had some taste for music, he did not scruple to amuse his party with a song; and it is said that he was rather fond of singing some Greek odes, to which modern music had been adapted. On Saturdays he usually dined in the village of Anderston, then about a mile distant from Glasgow, with some of the members of his regular club, and with a variety of other respectable visitors, who wished to cultivate the acquaintance, and enjoy the society of so eminent a person. In the progress of time, from his age and character, it became the wish of his company that every thing in these meetings should be directed by him; and though his authority, growing with his years, was somewhat absolute, yet the good humour with which it was administered, rendered it pleasing to every body. He had his own chair and place at table; he gave instructions about the entertainment, regulated the time of breaking up, and adjusted the expense. These parties, in the years of his severe study, were a desirable and useful relaxation to his mind, and they continued to amuse him till within a few months of his death.

Strict integrity and private worth, with corresponding purity of morals, gave the highest value to a character, which, from other qualities and attainments, was much respected and esteemed. On all occasions, even in the gayest hours of social intercourse, the Doctor maintained a constant attention to propriety. He had serious and just impressions of religion; but he was uniformly reserved in expressing particular opinions about it; and, from his sentiments of decorum, he never introduced religion as a subject of conversation in mixed society, and all attempts to do so in his clubs were checked with gravity and decision.

In his person, Dr. S. was tall and erect; and his countenance, which was handsome, conveyed a pleasing expression of the superior character of his mind. His manner had always somewhat of the fashion which prevailed in the early part of his life, but was uncommonly graceful. He was seriously indisposed only for a few weeks before his death, and through a very long life had enjoyed a uniform state of good health. He died on the first of October 1768, when his 81st year was almost completed; having bequeathed his small paternal estate in Ayrshire to the eldest son of his next brother, probably of his brother Thomas, who was professor of medicine in the university of St. Andrews, and who is known by some works of reputation, particularly a Dissertation on the Nervous System, occasioned by the Dissection of a Brain completely Ossified.

The preceding account of Dr. S. has been abridged and extracted from some other accounts of him; as, the Account of his Life and Writings by the rev. Dr. William Trail, lately published (1812); and from the account of Dr. S. and his works, by the late professor Robison, in the Encyclopædia Britannica; and partly from an ingenious MS. account of his life and writings, written and communicated by Mr. James Miller, the present mathematical professor of Glasgow; but more closely from Dr. Trail's work, where a very learned and critical account of Dr. Simson's writings is to be seen.

The writings and publications of Dr. S. were almost exclusively of the pure geometrical kind, after the genuine manner of the ancients. He has only two pieces printed in the volumes of the Philosophical Transactions: viz,

1. Two General Propositions of Pappus, in which many of Euclid's Porisms are included, vol. 32, ann. 1723.—These two propositions were afterwards incorporated into the author's large posthumous Works, published in 1776, by Philip, earl Stanhope.

2. On the Extraction of the Approximate Roots of Numbers by Infinite Series: vol. 48, ann. 1753.

The separate publications in his life-time, were:

3. Conic Sections, in 1735, 4to.

4. The Loci Plani of Apollonius, restored; in 1749, 4to.

4. Euclid's Elements; in 1756, 4to, and since that time, many editions in 8vo, with the addition of Euclid's Data.

5. After his death, earl Stanhope was at the expense of a publication, in 1776, of several of Dr. S.'s posthumous pieces; which were (1) Apollonius's Determinate Section: (2) A Treatise on Porisms: (3) A Tract on Logarithms: (4) On the Limits of Quantities and Ratios: (5) Some Select Geometrical Problems.

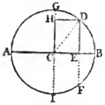
Besides the tracts published in these posthumous works, Dr. S.'s manuscripts contained a great variety of geometrical propositions, and other interesting observations on different parts of the mathematics; though not in a state fit for publication. Among other things, was an edition of the works of Pappus, in a state of considerable advancement, and which, had he lived, he perhaps might have published. The copy of Pappus, with all Dr. S.'s notes and explanations, it seems were, soon after his death, sent by his executor to the University of Oxford, with a view to publication; but which however it does not appear has yet been accomplished. It is true indeed, Dr. S.'s copy contains a large collection of materials, from which to make a proper selection would probably require considerable labour, as well as judgment.

SINCLAR (George), was professor of philosophy in the university of Glasgow, and author of several works on mathematical and physical subjects. He was dismissed from his professorship soon after the restoration, on account of his political principles; but was recalled to it on the change of government at the revolution in 1688; he died in 1696. Mr. Sinclar's publications were, 1. Tyrocinia Mathematica, 12mo. Glasc. 1661; 2. Ars Nova et Magna, &c, 4to. Roterod. 1669; 3. Hydrostatics, 4to, Edinb. 1672; 4. Hydrostatical Experiments, with a Discourse on Coal, 8vo. Edinb. 1680; 5. Principles of Astronomy and Navigation, 12mo. Edinb. 1688. Besides which, a very extravagant production, called, "Satan's Invisible World discovered" has been ascribed to him; it bears the initials, G. S. of his name.

Mr. Sinclar's writings are not destitute of ingenuity and research; though they may contain some erroneous and excentric views. His work on Hydrostatics, and his Ars Nova et Magna Gravitatis et Levitatis, and perhaps also his political principles, provoked the indignation of some persons; on which occasion Mr. James Gregory, author of the Optica Promota, &c, and then professor of mathematics at Saint Andrews, animadverted on him rather severely in a treatise entitled, "The Great and New Art of weighing Vanity, &c. under the name of Patrick Mathers, Archbedal of St. Andrews."

Considerable attention seems to have been paid by Mr. Sinclar to such branches of hydrostatics as were of a practical nature; and it has been said he was the first person who suggested the proper method of draining the water from the numerous coal mines in the south-west of Scotland. During the period he was deprived of his office, he resided about the southern and border counties, collecting and affording useful information on the subjects of mining, engineering, &c: particularly he was employed by the magistrates of Edinburgh on the then new plan for supplying the city with water, &c.

SINE, of an arc, in Trigonometry, a right line drawn from one extremity of the arc, perpendicular to the radius drawn to the other extremity of it: Or, it is half the chord of double the arc. Thus the line DE is the sine of the arc BD; being drawn from one end D of that arc, perpendicular to CB the radius drawn to the other extremity B. For the same reason also DE is the sine of the arc AD, which is the supplement of BD to a semicircle or 180 degrees; so that every sine is common to two arcs, which are supplements to each other, or whose sum is equal to 180 degrees.



Hence the sines increase always from nothing at B, till they become the radius CG, which is the greatest, being the sine of the quadrant BG. From hence they decrease throughout the second quadrant from G to A, till they quite vanish at the point A; thereby showing that the sine of the semicircle BGA, or 180 degrees, is nothing. After this they are negative in the next semicircle, or 3d and 4th quadrants AFB, being drawn on the opposite side, or downwards from the diameter AB.

Whole SINE, or *Sinus Totus*, is the sine of the quadrant BG, or of 90 degrees; that is, the whole sine is the same with the radius CG.

SINE-*Complement*, or *Cosine*, is the sine of an arc DG, which is the complement of another arc BD, to a quadrant. That is, the line DH is the cosine of the arc BD; because it is the sine of DG which is the complement of BD. And for the same reason DE is the cosine of DG. Hence the sine and cosine and radius, of any arc, form a right-angled triangle CDE or CDH, of which the radius CD is the hypothenuse; and therefore the square of the radius is equal to the sum of the squares of the sine and cosine of any arc, that is, $CD^2 = CE^2 + ED^2$ or $= CH^2 + DH^2$. It is evident that the cosine of 0 or nothing, is the whole radius CB. From B, where this cosine is greatest, the cosine decreases as the arc increases from B along the quadrant BDG, till it become 0 for the complete quadrant BG. After this, the cosines, decreasing, become negative from hence to the complete semicircle at A. Then the cosines increase again all the way from A through I to B; at I the negation is destroyed, and the cosine is equal to 0 or nothing; from I to B it is positive, and at B it is again become equal to the radius. So that, in general, the cosines in the 1st and 4th quadrants are positive, but in the 2d and 3d negative.

Versed-SINE, is the part of the diameter between the sine and the arc. So BE is the versed sine of the arc BD, and AE the versed sine of AD, also GH the versed sine of DG, &c. All versed sines are affirmative. The sum of the versed sine and cosine, of any arc or angle, is equal to the radius, that is, $BE + EC = AC$.

The sines &c, of every degree and minute in a quadrant, are calculated to the radius 1, and ranged in tables for use. But because operations with these natural sines require much labour in multiplying and dividing by them, the logarithms of them are taken, and ranged in tables also; and these logarithmic sines are commonly used in practice, instead of the natural ones, as they require only additions and subtractions, instead of multiplications and divisions. For the method of constructing the scales of sines &c, see the article SCALE.

The sines were introduced into trigonometry by the Arabians. And for the etymology of the word *Sine*, see Introduction to my Logarithms, pa. 17 &c. Also the various ways of calculating tables of the sines, may be seen in the same place, pa. 13 &c.

The relation which subsists between the sines and cosines of any arcs of a circle, and those of their sums, differences, and multiples, constitute what is sometimes termed the arithmetic of sines. This branch of calculation has its origin in the application of algebra to geometry, and is of great importance in the more difficult parts of the mathematics, as well as in their application to physics. The following theorems are those of the greatest utility, and of the most extensive application; the investigation of which may be seen in my Course of Mathematics, and other works on trigonometry.

Previous however to exhibiting those formulæ, we may make the following connected observations, which are immediately deduced from what has been before said in the definition of the sine of an arc: namely, in the

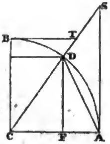
	1st quad.	2d quad.	3d quad.	4th quad.	
Sin is	+	+	−	−	
Cos	+	−	−	+	
Of	0°	90°	180°	270°	360°
Sin is	0	rad.	0	− rad.	0
Cos is	rad.	0	− rad.	0	r.

Again, if p be made to represent the semicircumference of a circle, the radius of which is r, and n be o, or any whole number, then we shall have the following general results,

$\text{Sin}\ np = 0$	$\text{Cos}\ 2np = r$
$\text{Sin}\ \frac{4n+1}{2}p = r$	$\text{Cos}\ \frac{4n+1}{2}p = 0$
$\text{Sin}\ \frac{4n+2}{2}p = 0$	$\text{Cos}\ \frac{4n+2}{2}p = -r$
$\text{Sin}\ \frac{4n+3}{2}p = -r$	$\text{Cos}\ \frac{4n+3}{2}p = 0$
$\text{Sin}\ \frac{4n+4}{2}p = 0$	$\text{Cos}\ \frac{4n+4}{2}p = r$
$\text{Sin}\ \frac{4n-1}{2}p = -r$	$\text{Cos}\ \frac{4n-1}{2}p = 0.$

Also, $\sin a = \sin(p - a) = \sin(2p - a) = \sin(3p - a)$ &c.

Now, from the annexed figure, and what has been already observed of the similar triangles, we easily deduce the following formulæ, expressing the sine and cosine of any arc a, in terms of the tangent, secant, radius, &c.



$$\text{Sin}\,a = \sqrt{(r^2 - \cos^2 a)} = \frac{r \,.\, \cos a}{\cot a} = \frac{\cos a \,.\, \tan a}{r} = \frac{r \,.\, \tan a}{\sqrt{(r^2 + \tan^2 a)}}$$

$$= \frac{r^2}{\sqrt{(r^2 + \cot^2 a)}} = \frac{r^2}{\text{cosec}\, a} = \frac{r \,.\, \tan a}{\sec a} = \frac{\cos a \,.\, \sec a}{\text{cosec}\, a}$$

$$= \frac{\tan a \,.\, \cot a}{\text{cosec}\, a} = \frac{r\sqrt{(\sec^2 a - r^2)}}{\sec a}.$$

$$\text{Cos}\,a = \sqrt{(r^2 - \sin^2 a)} = \frac{r \sin a}{\tan a} = \frac{\sin a \,.\, \cot a}{r} = \frac{r \,.\, \cot a}{\sqrt{(r^2 + \cot^2 a)}} = \frac{r^2}{\sqrt{(r^2 + \tan^2 a)}} = \frac{r^2}{\sec a} = \frac{r \,.\, \cot a}{\text{cosec}\, a}$$

$$= \frac{\sin a \,.\, \text{cosec}\, a}{\sec a} = \frac{\tan a \,.\, \cot a}{\sec a} = \frac{r\sqrt{(\text{cosec}^2 a - r^2)}}{\text{cosec}\, a}.$$

Vers $a = r - \cos a$; covers $a = r - \sin a$; supvers $a = r + \cos a$.

Also, for the sine of the sum and difference of any two arcs to radius 1, we have the following theorems:

1. $\text{Sin}\,(a + b) = \sin a \,.\, \cos b + \cos a \,.\, \sin b$
2. $\text{Sin}\,(a - b) = \sin a \,.\, \cos b - \cos a \,.\, \sin b$
3. $\text{Cos}\,(a + b) = \cos a \,.\, \cos b - \sin a \,.\, \sin b$
4. $\text{Cos}\,(a - b) = \cos a \,.\, \cos b + \sin a \,.\, \sin b.$

Hence again,

5. $\text{Sin}\,(a + b) + \sin\,(a - b) = 2 \sin a \,.\, \cos b$
6. $\text{Sin}\,(a + b) - \sin\,(a - b) = 2 \cos a \,.\, \sin b$
7. $\text{Cos}\,(a - b) + \cos\,(a + b) = 2 \cos a \,.\, \cos b$
8. $\text{Cos}\,(a - b) - \cos\,(a + b) = 2 \sin a \,.\, \sin b.$

And if in these last four formulæ, we substitute na for a, and a for b, we obtain,

9. $2\ \text{Cos}\, a \,.\, \sin na = \sin\ (n + 1)a + \sin\,(n - 1)\,a$
10. $2\ \text{Sin}\ a \,.\, \cos na = \sin\ (n + 1)a - \sin\,(n - 1)\,a$
11. $2\ \text{Cos}\ a \,.\, \cos na = \cos\ (n + 1)a + \cos\,(n -)\,a$
12. $2\ \text{Sin}\ a \,.\, \sin na = -\cos(n + 1)a + \cos\,(n - 1)\,a$

And from these we may deduce the powers of the sines and cosines of arcs, in terms of the sum and difference of certain multiples of those arcs, thus:

$\text{Sin}\ a = \sin\ a$
$2\ \text{Sin}^2 a = -\cos 2a + 1$
$4\ \text{Sin}^3 a = -\sin 3a + 3 \sin a$
$8\ \text{Sin}^4 a = \cos 4a - 4 \cos 2a + 3$
$16\ \text{Sin}^5 a = \sin 5a - 5 \sin 3a + 10 \sin a$
$32\ \text{Sin}^6 a = -\cos 6a + 6 \cos 4a - 15 \cos 2a + 10$
$64\ \text{Sin}^7 a = -\sin 7a + 7 \sin 5a - 21 \sin 3a + 35 \sin a.$

And generally

$2^{n-1} \sin^n a = \pm \sin na \pm n \sin\,(n - 2)\,a \pm \frac{n \,.\, (n - 1)}{2} \sin\,(n - 4)\,a$ &c; Or

$2^{n-1} \sin^n a = \pm \cos\ na \mp n \cos\ (n - 2)a \pm \frac{n \,.\, n\,(n - 1)}{2} \cos\,(n - 4)\,a$ &c.

In the first of which series, the upper sign must be used when n is an odd number of the form $4m + 1$, and the lower sign, when n is of the form $4m - 1$.

In the second series, the upper sign must be used when n is of the form $4m$, and the lower sign when n is of the form $2(2m + 1)$.

Similar formulæ may also be found for the successive powers of the cosines of any simple arc, which are as follows:

$\text{Cos}\ a = \cos\ a$
$2\ \text{Cos}^2 a = \cos 2a + 1$
$4\ \text{Cos}^3 a = \cos 3a + 3 \cos a$
$8\ \text{Cos}^4 a = \cos 4a + 4 \cos 2a + 3$
$16\ \text{Cos}^5 a = \cos 5a + 5 \cos 3a + 10 \cos a$
$32\ \text{Cos}^6 a = \cos 6a + 6 \cos 4a + 15 \cos 2a + 10$
$64\ \text{Cos}^7 a = \cos 7a + 7 \cos 5a + 21 \cos 3a + 35 \cos a.$

And generally

$2^{n-1}\ \text{Cos}^n a = \cos na + n \cos\,(n - 2)\,a + \frac{n \,.\, n - 1}{2} \cos\,(n - 4)a$ &c.

Again, the sines and cosines of the multiple arcs, may be expressed in terms of the sines and cosines of the inferior arcs, as below.

$\text{Sin}\ a = \sin\ a$
$\text{Sin}\ 2a = 2 \cos a \,.\, \sin a$
$\text{Sin}\ 3a = 2 \cos a \,.\, \sin 2a - \sin a$
$\text{Sin}\ 4a = 2 \cos a \,.\, \sin 3a - \sin 2a$
$\text{Sin}\ 5a = 2 \cos a \,.\, \sin 4a - \sin 3a$ &c
$\text{Sin}\ na = 2 \cos a \,.\, \sin\,(n - 1)\,a - \sin\,(n - 2)\,a$
$\text{Cos}\ a = \cos\ a$
$\text{Cos}\ 2a = 2 \cos a \,.\, \cos\ a - 1$
$\text{Cos}\ 3a = 2 \cos a \,.\, \cos 2a - \cos a$
$\text{Cos}\ 4a = 2 \cos a \,.\, \cos 3a - \cos 2a$
$\text{Cos}\ 5a = 2 \cos a \,.\, \cos 4a - \cos 3a$ &c
$\text{Cos}\ na = 2 \cos a \,.\, \cos\,(n - 1)\,a - \cos\,(n - 2)\,a$

And if now, in order to abbreviate, we make cos $a = c$, and sine $a = s$, and observing at the same time that $c^2 = 1 - s^2$, we derive

$$\text{Sin } a = s$$
$$\text{Sin } 2a = 2cs$$
$$\text{Sin } 3a = 4c^2s - s = -4s^3 + 3s$$
$$\text{Sin } 4a = 8c^3s - 4sc = c(-8s^3 + 4s)$$
$$\text{Sin } 5a = 16c^4s - 12c^2s + s = 16s^5 - 20s^3 + 5s$$
$$\text{Sin } na = nsc^{n-1} - \frac{n.n-1.n-2}{1.2.3}s^3c^{n-3} + \frac{n.n-1.n-2.n-3.n-4}{1.2.3.4.5}s^5c^{n-5} \text{ \&c}$$
$$\text{Cos } a = c$$
$$\text{Cos } 2a = 2c^2 - 1$$
$$\text{Cos } 3a = 4c^3 - 3c$$
$$\text{Cos } 4a = 8c^4 - 8c^2 + 1$$
$$\text{Cos } 5a = 16c^5 - 20c^3 + 5c$$
$$\text{Cos } na = 2^{n-1}c^n - \frac{n.2^{n-1}}{1.2}c^{n-2} + \frac{n.n-3.2^{n-1}}{1.2.2^4}c^{n-4} - \frac{n.n-4.n-5.2^{n-1}}{1.2.3.2^6}c^{n-6} \text{ \&c.}$$

Or if, instead of the above substitution, we make 2 cos $a = y + \frac{1}{y}$, we readily deduce the following elegant formulæ for the cosines of the multiple arcs.

$$2 \text{ Cos } \quad y + \frac{1}{y}$$
$$2 \text{ Cos } 2a = y^2 + \frac{1}{y^2}$$
$$2 \text{ Cos } 3a = y^3 + \frac{1}{y^3}$$
$$2 \text{ Cos } 4a = y^4 + \frac{1}{y^4}$$
$$2 \text{ Cos } 5a = y^5 + \frac{1}{y^5}$$
$$2 \text{ Cos } na = y^n + \frac{1}{y^n}.$$

We might pursue this subject to a much greater length, but the above are the principal formulæ which occur in the doctrine of sines &c. We shall conclude this article with the following formulæ, expressing the log. of the sine of an arc, the arc in terms of the sine, the sine in terms of the arc, &c; where it is to be observed, that s is the sine, c the cosine, a the arc, and r the radius:

$$s = a - \frac{a^3}{2.3r^2} + \frac{a^5}{2.3.4.5r^4} - \frac{a^7}{2.3.4.5.6.7r^6} \text{ \&c.}$$
$$a = s + \frac{s^3}{2.3r^2} + \frac{1.3s^5}{2.4.5r^4} + \frac{1.3.5s^7}{2.4.6.7r^6} \text{ \&c.}$$
$$\text{Log. } s = \text{log. } a - M\left(\frac{a^2}{6} + \frac{a^4}{180} + \frac{a^6}{2835} + \frac{a^8}{37800} \text{ \&c}\right)$$
$$\text{or Log. } s = -\tfrac{1}{2}M\left(c^2 + \tfrac{1}{2}c^4 + \tfrac{1}{3}c^6 + \tfrac{1}{4}c^8 \text{ \&c}\right)$$
$$\text{or Log. } s = -2M\left(z + \tfrac{1}{3}z^3 + \tfrac{1}{5}z^5 + \tfrac{1}{7}z^7 \text{ \&c.}\right)$$

where $z = \frac{1-s}{1+s}$, radius 1, and $M = \cdot43429448$ &c.

If $h = 2\cdot718281828$ &c, the number whose hyp. log. is 1; then

$$\text{Sin } a = s = \frac{h^{a\sqrt{-1}} - h^{-a\sqrt{-1}}}{2\sqrt{-1}}$$
$$\text{Cos } a = c = \frac{h^{a\sqrt{-1}} + h^{-a\sqrt{-1}}}{2}.$$

See many other curious expressions of this kind in Bougainville's Calcul Integral, and in Bertrand's mathematics.

From theorems 1, 2, &c, the sines of a great variety of angles, or number of degrees, may be computed. Ex. gr. as below.

Angles.	*Sines.*
90°	r
75	$\frac{1}{2}r\sqrt{2+\sqrt{3}} = r \times \frac{\sqrt{6}+\sqrt{2}}{4}$
72	$\frac{1}{2}r\sqrt{\frac{5+\sqrt{5}}{2}}$
67½	$\frac{1}{2}r\sqrt{2+\sqrt{2}}$
60	$\frac{1}{2}r\sqrt{3}$
54	$\frac{1}{2}r\sqrt{\frac{3+\sqrt{5}}{2}} = r \times \frac{\sqrt{5}+1}{4}$
45	$\frac{1}{2}r\sqrt{2}$
36	$\frac{1}{2}r\sqrt{\frac{5-\sqrt{5}}{2}}$
30	$\frac{1}{2}r$
22½	$\frac{1}{2}r\sqrt{2-\sqrt{2}}$
18	$\frac{1}{2}r\sqrt{\frac{3-\sqrt{5}}{2}} = r \times \frac{\sqrt{5}-1}{4}$
15	$\frac{1}{2}r\sqrt{2-\sqrt{3}} = r \times \frac{\sqrt{6}-\sqrt{2}}{4}$

Of the Tables of Sines, &c.

In estimating the quantity of the sines &c, we assume radius for unity; and then compute the quantity of the sines, tangents, and secants, in fractions of it. From Ptolemy's Almagest we learn, that the ancients divided the radius into 60 parts, which they called degrees, and thence determined the chords in minutes, seconds, and thirds; that is, in sexagesimal fractions of the radius, which they likewise used in the resolution of triangles. As to the sines, tangents and secants, they are modern inventions; the sines being introduced by the Moors or Saracens, and the tangents and secants afterwards by the Europeans. See Introd. to my Logs. pa. 1 to 19.

Regiomontanus, at first, with the ancients, divided the radius into 60 degrees; and determined the sines of the several degrees in decimal fractions of it. But he afterwards found it would be more convenient to assume 1 for radius, or 1 with any number of ciphers, and take the sines in decimal parts of it; and thus he introduced the present method in trigonometry. In this way, different authors have divided the radius into more or fewer decimal parts; but in the common tables of sines and tangents, the radius is conceived to be divided into 10000000 parts; by which all the sines are estimated.

An idea of some of the modes of constructing the tables of sines, may be conceived from what follows: First, by common geometry the sides of some of the regular polygons inscribed in the circle are computed, from the given radius, which will be the chords of certain portions of the circumference, denoted by the number of the sides; viz, the side of the triangle the chord of the 3d part, or 120 degrees; the side of the pentagon the chord of the 5th part, or 72 degrees; the side of the hexagon the chord of the 6th part, or 60 degrees; the side of the octagon the chord of the 8th part, or 45 degrees; and so on. By this means there are obtained the chords of several of such arcs; and the halves of these chords will be the sines of the halves of the same arcs. Then the theorem $c = \sqrt{(1 - s^2)}$ will give the cosines of the same half arcs. Next, by bisecting these arcs continually, there will be found the sines and cosines of a continued series as far as we please by these two theorems,

$\text{Sin } \frac{1}{2}a = \sqrt{\frac{1-c}{2}}$; and $\cos. \frac{1}{2}a = \sqrt{\frac{1+c}{2}}$.

Then, by the formulæ for the sums and differences of arcs, from the foregoing series will be derived the sines and cosines of various other arcs, till we arrive at length at the arc of 1′, or 1″, &c, whose sine and cosine thus become known. Or, rather, the sine of 1 minute will be much more easily found from the series $s = a - \frac{1}{6}a^3 + \frac{1}{120}a^5$ &c, because the arc may be considered as equal to its sine in small arcs; whence $s = a$ only in such small arcs. But the length of the arc of 180° or 10800′ is known to be 3·14159265 &c; therefore, by proportion, as 10800′ : 1′ : : 3·14159265 : 0·0002908882 $= a$ the arc or s the sine of 1′, which number is true to the last place of decimals. Then, for the cosine of 1′, it is $c = \sqrt{(1 - s^2)} =$ 0·9999999577 the cosine of the same 1′.

Hence we shall readily obtain the sines and cosines of all the multiples of 1′, as of 2′, 3′, 4′, 5′, &c, by the application of these two theorems,

$$\sin (n + 1)a = 2c \times \sin na - \sin (n - 1)a,$$
$$\cos (n + 1)a = 2c \times \cos na - \cos (n - 1)a;$$

for supposing $a =$ the arc of 1, then $c = 0·9999999577$, and taking n successively equal to 1, 2, 3, 4, &c, the theorems for the sines and cosines give severally the sines and cosines of 1′, 2′, 3′, 4′, &c; viz, the sines thus:

$\sin 1' = s$ - - - - - - - $=$ ·0002908882
$\sin 2' = 2c \times \sin 1' - \sin 0' =$ ·0005817764
$\sin 3' = 2c \times \sin 2' - \sin 1' =$ ·0008726645
$\sin 4' = 2c \times \sin 3' - \sin 2' =$ ·0011635526
$\sin 5' = 2c \times \sin 4' - \sin 3' =$ ·0014544406
&c.

And the cosines thus,

$\cos 1' = c$ - - - - - - - $=$ ·9999999577
$\cos 2' = 2c \times \cos 1' - \cos 0' =$ ·9999998308
$\cos 3' = 2c \times \cos 2' - \cos 1' =$ ·9999996192
$\cos 4' = 2c \times \cos 3' - \cos 2' =$ ·9999993231
$\cos 5' = 2c \times \cos 4' - \cos 3' =$ ·9999989423
&c.

In this manner then all the sines and cosines are made, by only one constant multiplication and a subtraction, up to 30 degrees, forming thus the sines of the first and last 30 degrees of the quadrant, or from 0 to 30° and from 60° to 90°; or, which will be much the same thing, the sines only may be thus computed all the way up to 60°.

Then the sines of the remaining 30°, from 60 to 90, will be found by one addition only for each of them, by means of this theorem, viz, $\sin. (60 + a) = \sin. (60 - a) + \sin. a$; that is, to the sine of any arc below 60°, add the sine of its defect below 60, and the sum will be the sine of another arc which is just as much above 60.

The sines of all arcs being thus found, they give also very easily the versed sines, the tangents, and the secants. The versed sines are only the arithmetical complements to 1, that is, each cosine taken from the radius 1.

The tangents are found by these three theorems:

1. As cosine to sine, so is radius to tangent.

2. Radius is a mean proportional between the tangent and cotangent.

3. Half the difference between the tangent and cotangent, is equal to the tangent of the difference between the arc and its complement. Or, the sum arising from the addition of double the tangent of an arc with the tangent of half its complement, is equal to the tangent of the sum of that arc and the said half complement.

By the 1st and 2d of these theorems, the tangents are to be found for one half of the quadrant: then the other half of them will be found by one single addition, or subtraction, for each, by the 3d theorem.

This done, the secants will be all found by addition or subtraction only, by these two theorems: 1st. The secant of an arc, is equal to the sum of its tangent and the tangent of half its complement, 2nd. The secant of an arc, is equal to the difference between the tangent of that arc and the tangent of the arc added to half its compliment.

Sines, &c, *by a new Division of the Quadrant.* In the 2d vol. of my Tracts, pa. 122, &c, is described a new mode of dividing the quadrantal arc, for which to construct new tables of sines, tangents, and secants, which would be very useful, and is different from all other methods of dividing it, and of constructing the tables. In this method the arcs of the quadrant are divided into, and expressed by the equal parts of the radius, the same as the sines and tangents themselves; being divisions in the common decimal scale of numbers. In this project I have made many thousands of calculations for the sines; and a specimen of the tables may be seen inserted in the volume above mentioned.

The French have also made and printed very extensive tables of sines &c, on a plan of divisions differing both from the old sexagesimal way, and from mine, above mentioned: those being to decimal divisions of arcs, the quadrant being divided into 10000 equal parts, each part being nearly equal 30″ in the sexagesimal division.

Artificial Sines, are the logarithmic sines, or the logarithms of the sines.

Arithmetic of Sines. See chap. iii, p. 53, vol. 3, of my Course of Mathematics; also the foregoing article in this dictionary.

Curve or *Figure of the* Sines. See Figure *of the Sines, &c.* To what is there said of the figure of the sines, may be here added as follows, from a property just given above, viz, if x denote the absciss of this curve, or the corresponding circular arc, and y its ordinate, or the sine of that arc; then the equation of the curve will be this,

$$y = \sin x = \frac{h^{x\sqrt{-1}} - h^{-x\sqrt{-1}}}{2\sqrt{-1}};$$

where $h = 2·718281828$ &c, the number whose hyp. log. is 1.

Line of Sines, is a line on the sector, or Gunter's scale, &c, divided according to the sines, or expressing the sines. See those articles.

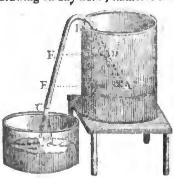
Sine *of Incidence*, or *of Reflection*, or *of Refraction*, is used for the sine of the *angle* of incidence, &c.

SINICAL *Quadrant*, is a quadrant, made of wood or metal, with lines drawn from each side intersecting one another, with an index, divided by sines, also with 90 degrees on the limb, and two sights at the edge. Its use is to take the altitude of the sun. Instead of the sines, it is sometimes divided all into equal parts; and then it is used by seamen to resolve, by inspection, any problem of plane sailing.

SIPHON, or Syphon, in Hydraulics, a crooked pipe or tube used in the raising of fluids, emptying of vessels, and in various hydrostatical experiments. It is otherwise called a crane. Wolfius describes two vessels under the name of Siphons; the one cylindrical in the middle and conical at the two extremes; the other globular in the middle, with two narrow tubes fitted to it axis-wise; both serving to take up a quantity of liquid, and to retain it when up.

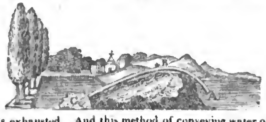
But the most usual syphon is that which is here represented; where ABC is any crooked tube, having two legs of unequal lengths; but such however that, in any position, the perpendicular altitude BD, of B above A, when AB is filled with any fluid, the weight of that fluid may not be more than about 15lb. upon every square inch of the base, or equal to the pressure of the atmosphere, because the pressure of the atmosphere will raise or suspend the fluid so high, when the tube is exhausted of air. This height is about 30 inches when the fluid is quicksilver, and about 34 feet when it is water; and so on for other fluids, according to the rarity of them.

To use the siphon, in drawing off any fluid; immerse the shorter end A into the fluid, then suck or draw the air out by the other or lower end C, and the fluid will presently follow, and run out by the siphon, from the vessel at A to the vessel at C; till such time as the surface of the fluid sink as low as the orifice at A, when the decanting will cease, and the siphon will empty itself of the fluid, the whole of that which is in it running out at C. The principle upon which the siphon acts, is this: when the tube is exhausted of air, the pressure of the atmosphere upon the surface of the fluid at D, forces it into the tube by the orifice at A, as in the barometer tube, and down the leg BC, if B is not above the surface at D more than 34 feet for water, or 30 inches for quicksilver, &c. Here, if the external leg of the siphon terminate at E, on a horizontal level with the immersed end at A, or rather on a level with the water at D, the perpendicular pressures of the fluid in each leg, and of the external air, against each orifice, being alike in both, the fluid will be at rest in the siphon, completely filling it, but without running or preponderating either way. But if the external end be the lower, terminating at C, then the fluid in this end being the heavier, or having more pressure, will preponderate and run out by the orifice at C; this would leave a vacuum at B but for the continual pressure of the atmosphere at D, which forces the fluid up by A to B, and so producing a continued motion of it through the tube, and a discharge or stream at C.



Instead of sucking out the air at C, another method is, first to fill the tube completely with the fluid, in an inverted position with the angle B downward; and, stopping the two orifices with the fingers, revert the tube again, and immerge the end A in the fluid; then take off the fingers, and immediately the stream commences from the end C.

Either of the two foregoing methods can be conveniently practised when the siphon is small, and easily managed by the hand; as in decanting off liquors from casks, &c. But when the siphon is very large, and many feet in height, as in exhausting water from a valley or a pit, the following method is then recommended: Stop the orifice C; and, by means of an opening made in the top at B, fill the tube completely with water; then stop the opening at B with a plug, and open that at C; upon which the water will presently flow out there, and so continue till that at A is exhausted. And this method of conveying water over a hill, from one valley to another, is described by Hero, the chief author of any consequence on this subject among the ancients. But in this experiment it must be noted, that the effect will not be produced when the hill at B is more than 33 or 34 feet above the surface of the water at A.

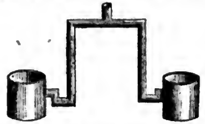


In an experiment of this kind, it is even said that the water in the legs, unless it be purged of its air, will not rest at a height of quite 30 feet above the water in the vessels; because air will extricate itself out of the water, and getting above the water in the legs, press it downward, so that its height will be less to balance the pressure of the atmosphere. But with very fine, or capillary tubes, the experiment will succeed to a height somewhat greater; because the attraction of the matter of the very fine tube will raise the fluid, and support it at some certain height, independent of the pressure of the atmosphere. For which reason also it is, that the experiment succeeds for small heights in the exhausted receiver; as has been tried both with water and mercury, by Desaguliers and many other philosophers. Exper. Philos. vol. 2, pa. 168.

The figure of the vessel may be varied at pleasure, provided the orifice C be but below the level of the surface of the water to be drawn off, but still the farther it is below it, the quicker will the fluid run off. And if, in the course of the efflux, the orifice A be drawn out of the fluid; all the liquor in the siphon will issue out at the lower orifice C; the fluid in the leg BC dragging, as it were, that in the shorter leg AB after it.

But if a filled siphon be so disposed, as that both orifices, A and C, be in the same horizontal line; the fluid will remain pendant in each leg, how unequal soever the length of the legs may be. So that fluids in siphons seem, as it were, to form one continued body; the heavier part descending like a chain, and drawing the lighter after it.

The *Wirtemberg* SIPHON, which is represented in the annexed figure, is a very extraordinary machine, perform-



ing several things which the common siphon will not reach. This siphon was projected by Jordan Pelletier, and executed at the expence of prince Frederic Charles, administrator of Wirtemberg, by his mathematician Shabarkard, who made each branch 20 feet long, and set them 18 feet apart; and the description of it was published by Reiselius, the duke's physician. This gave occasion to Papin to invent another, which performed the same things, and is described in the Philos. Trans. vol. 14. Reselius, in another paper in the same volume, ingenuously owns that this is the same with the Wirtemberg siphon.

In this engine, though the legs be on the same level, yet the water rises up the one, and descends through the other. The water rises even through the aperture if the less leg be only half immerged in water. The siphon has its effect after continuing dry a long time. Either of the apertures being opened, the other remaining shut for a whole day, and then opened, the water flows out as usual. Lastly, the water rises and falls indifferently through either leg.

Musschenbroek, in accounting for the operation of this siphon, observes that no discharge could be made by it, if the water applied to either leg did not cause the one to be shorter, and the other longer by its own weight. Introd. ad Phil. Nat. tom. 2, pa. 853, ed. 4to. 1762.

SIRIUS, the *Dog-star*; a very bright star of the first magnitude, in the mouth of the constellation *Canis Major*, or the Great Dog. This is the brightest of all the stars in our firmament, and therefore probably, says Dr. Maskelyne, the nearest to us of them all, in a paper recommending the discovery of its parallax, Philos. Trans. vol. 51, pa. 889. Some however suppose Arcturus to be the nearest. The Arabs call it Aschere, Elschecre, Scera; the Greeks, Sirius; and the Latins, Canicula, or Canis candens. See CANICULA.

This is one of the earliest named stars in the heavens. Hesiod and Homer mention only four or five constellations, or stars, and this is one of them. Sirius and Orion, the Hyades, Pleiades, and Arcturus are almost the whole of the old poetical astronomy. The three last the Greeks formed of their own observation, as appears by the names; the two others were Egyptian. Sirius was so called from the Nile, one of the names of that river being Siris; and the Egyptians, seeing that river begin to swell at the time of a particular rising of this star, paid divine honours to the star, and called it by a name derived from that of the river, expressing the star of the Nile.

SITUS, in Algebra and Geometry, denotes the situation of lines, surfaces, &c. Wolfius delivers some things in geometry, which are not deduced from the common analysis, particularly matters depending on the situs of lines and figures. Leibnitz has even founded a particular kind of analysis upon it, called Calculus Situs.

SKY, the blue expanse of the air or atmosphere. The azure colour of the sky is attributed, by Newton, to vapours beginning to condense, having attained consistence enough to reflect the most reflexible rays, viz, the violet ones; but not enough to reflect any of the less reflexible ones.

Labire attributes it to our viewing a black object, viz, the dark space beyond the regions of the atmosphere, through a white or lucid one, viz, the air illuminated by the sun; a mixture of black and white always appearing blue. But this hypothesis is not originally his; being as old as Leonardo da Vinci.

SLIDING, in Mechanics, is when the same point of a body, moving along a surface, describes a line on that surface. Such is the motion of a parallelopipedon moved along a plane.—From sliding arises friction.

SLIDING *Rule*, a mathematical instrument serving to perform computations in gauging, measuring, &c, without the use of compasses; merely by the sliding of the parts of the instrument one by another, the lines and divisions of which give the answer or amount by inspection. This instrument is variously contrived and applied by different authors, particularly Gunter, Partridge, Hunt, Everard, and Coggeshall; but the most usual and useful ones are those of the two latter.

Everard's SLIDING *Rule* is chiefly used in cask gauging. It is commonly made of box, 12 inches long, 1 inch broad, and $\frac{6}{10}$ of an inch thick. It consists of three parts; viz, the stock just mentioned, and two thin slips, of the same length, sliding in small grooves in two opposite sides of the stock: consequently, when both these pieces are drawn out to their full extent, the instrument is 3 feet long.

On the first broad face of the instrument are four logarithmic lines of numbers; for the properties &c, of which, see GUNTER's *Line*. The first, marked A, consisting of two radii numbered 1, 2, 3, 4, 5, 6, 7, 8, 9, 1; and then, 2, 3, 4, 5, &c, to 10. On this line are four brass centre-pins, two in each radius; one in each of them being marked MB, for malt-bushel, is set at 2150·42 the number of cubic inches in a malt-bushel; the other two are marked with A, for ale-gallon, at 282, the number of cubic inches in an ale gallon. The 2d and 3d lines of numbers are on the sliding pieces, and are exactly the same with the first; but they are distinguished by the letter B. In the first radius is a dot, marked *Si*, at ·707, the side of a square inscribed in a circle whose diameter is 1. Another dot, marked *Se*, stands at ·886, the side of a square equal to the area of the same circle. A third dot, marked W, is at 231, the cubic inches in a wine gallon. And a fourth, marked C, at 3·14, the circumference of the same circle whose diameter is 1. The fourth line of numbers, marked MD, to signify malt-depth, is a broken line of two radii, numbered 2, 10, 9, 8, 7, 6, 5, 4, 3, 2, 1, 9, 8, 7, &c; the number 1 being set directly against MB on the first radius.

On the second broad face, marked *cd*, are several lines: as 1st, a line marked D, and numbered 1, 2, 3, &c, to 10. On this line are four centre pins: the first, marked WG, for wine-gauge, is at 17·15, the gauge-point for wine gallons, being the diameter of a cylinder whose height is one inch, and content 231 cubic inches, or a wine gallon: the second centre-pin, marked AG, for ale-gauge, is at 18·95, the like diameter for an ale gallon: the 3d, marked MS, for malt-square, is at 46·3, the square root of 2150·42, or the side of a square whose content is equal to the number of inches in a solid bushel: and the fourth, marked MR, for malt-round, is at 52·32, the diameter of a cylinder, or bushel, the area of whose base is the same 2150·42, the inches in a bushel. 2dly, Two lines of numbers on the sliding piece, on the other side, marked C. On these are two dots; the one, marked *c*, at ·0795, the area of a circle whose circumference is 1; and the other, marked *d*, at ·785, the area of the circle whose diameter is 1. 3dly, Two lines of segments, each numbered 1, 2, 3, to 100; the first for finding the ullage of a cask, taken as the middle frustum of a spheroid, lying with its axis parallel to the horizon; and the other for finding the ullage of a cask standing.

Again, on one of the narrow sides, noted *c*, are, 1st, a line of inches, numbered 1, 2, 3, &c to 12, each subdivided into 10 equal parts. 2dly, A line by which, with that of inches, is found a mean diameter for a cask, in the figure of the middle frustum of a spheroid: it is marked Spheroid, and numbered 1, 2, 3, &c to 7. 3dly, A line for finding the mean diameter of a cask, in the form of the middle frustum of a parabolic spindle, which gaugers call the second variety of casks; it is therefore marked Second Variety, and is numbered 1, 2, 3, &c. 4thly, A line by which is found the mean diameter of a cask of the third variety, consisting of the frustums of two parabolic conoids, abutting on a common base; it is therefore marked Third Variety, and is numbered 1, 2, 3, &c.

On the other narrow face, marked *f*, are, 1st, a line of a foot divided into 100 equal parts, marked FM. 2dly, A line of inches, like that before mentioned, marked IN. 3dly, A line for finding the mean diameter of the fourth variety of casks, which is formed of the frustums of two cones, abutting on a common base. It is numbered 1, 2, 3, &c; and marked FC, for frustum of a cone.

On the back side of the two sliding pieces is a line of inches, from 12 to 36, for the whole extent of the 3 feet, when the pieces are put endwise; and against that, the correspondent gallons, and 100th parts, that any small tub, or the like open vessel, will contain at 1 inch deep. For the various uses of this instrument, see the authors mentioned above, and most other writers on gauging.

Coggeshall's SLIDING *Rule* is chiefly used in measuring the superficies and solidity of timber, masonry, brickwork, &c. This consists of two rulers, each a foot long, which are united together in various ways. Sometimes they are made to slide by one another, like glaziers' rules: sometimes a groove is made in the side of a common two-foot joint rule, and a thin sliding piece in one side, and Coggeshall's lines added on that side; thus forming the common or carpenter's rule: and sometimes one of the two rulers is made to slide in a groove made in the side of the other.

On the sliding side of the rule are four lines of numbers, three of which are double, that is, are lines to two radii, and the fourth is a single broken line of numbers. The first three, marked A, B, C, are figured 1, 2, 3, &c to 9; then 1, 2, 3, &c to 10; the construction and use of them being the same as those on Everard's Sliding rule. The single line, called the girt line, and marked D, whose radius is equal to the two radii of any of the other lines, is broken for the easier measuring of timber, and figured 4, 5, 6, 7, 8, 9, 10, 20, 30, &c. From 4 to 5 it is divided into 10 parts, and each 10th subdivided into 2; and so on from 5 to 10, &c.

On the back side of the rule are, 1st, a line of inch measures, from 1 to 12; each inch being divided and subdivided. 2dly, A line of foot measure, consisting of one foot divided into 100 equal parts, and figured 10, 20, 30, &c. The backside of the sliding piece is divided into inches, halves, &c, and figured from 12 to 24; so that when the slide is out, there may be a measure of 2 feet.

In the carpenter's rule, the inch measure is on one side, continued all the way from 1 to 24, when the rule is unfolded, and subdivided into 8ths or half-quarters: on this side are also some diagonal scales of equal parts. And upon the edge, the whole length of 2 feet is divided into 200 equal parts, or 100ths of a foot.

SLING, a string instrument, serving for the casting of stones &c with the greater violence. Pliny, lib. 76, chap. 5, attributes the invention of the sling to the Phœnicians; but Vegetius ascribes it to the inhabitants of the Balearic islands, who were celebrated in antiquity for the dextrous management of it. Florus and Strabo say, those people bore three kinds of slings; some longer, others shorter, which they used according as their enemies were more remote or nearer hand. Diodorus adds, that the first served them for a headband, the 2d for a girdle, and that the third they constantly carried with them in the hand. But it must be impossible to tell who were the first inventors of the sling, as the instrument is so simple, and has been in general use by almost all nations. The instrument is much spoken of in the wars and history of the Israelites. David was so expert a slinger, that he ventured to go out, with one in his hand, against the giant and champion Goliah, and at a distance struck him on the forehead with the stone. And there were a number of left-handed men of one of the tribes of Israel, who, it is said, could sling a stone at an hair's breadth. Judges, ch. 20, v. 16.

The motion of a stone discharged from a sling arises from its centrifugal force, when whirled round in a circle. The velocity with which it is discharged, is the same as that which it had in the circle, being much greater than what can be given to it by the hand alone. And the direction in which it is discharged, is that of the tangent to the circle at the point of discharge. Whence its motion and effect may be computed as a projectile.

SLUICE, a watergate, a floodgate, a vent for water.

SLUSE, or SLUSIUS (*René Francis Walter*), of Vise, a small town in the county of Liege, where he enjoyed honours and preferment. He became abbé of Amas, canon, counsellor and chancellor of Liege, and made his name famous for his knowledge in theology, physics, and mathematics. The Royal Society of London elected him one of their members, and inserted several of his compositions in their Transactions. This very ingenious and learned man died at Liege in 1685, at 63 years of age.—Of Slusius's works there have been published, some learned letters, and a work intitled, Mesolabium et Problemata solida; besides the following pieces in the Philosophical Transactions, viz,

1. Short and Easy Method of drawing Tangents to all Geometrical Curves; vol. 7, pa. 5143.
2. Demonstration of the same; vol. 8, pa. 6059.
3. On the Optic Angle of Alhazen; vol. 8, pa. 6139.

SMEATON (JOHN), F. R. S. and a very celebrated civil engineer, was born 1724, at Austhorpe, near Leeds, in a house built by his grandfather, where the family have resided ever since, and where our author died the 28th of October 1792, in the 69th year of his age.

Mr. Smeaton seems to have been born an engineer. The originality of his genius and the strength of his understanding appeared at a very early age. His playthings were not those of children, but the tools men work with; and he had always more amusement in observing artificers work, and asking them questions, than in any thing else. Thus had Mr. Smeaton, by the strength of his genius, and indefatigable industry, acquired, at 18 years of age, an extensive set of tools, and the art of working in most of the mechanical trades; which he continued to work with occasionally to the end of his life, part of every day when at the place where his tools were: and few men could work better.

Mr. Smeaton's father was an attorney, and was desirous of bringing his son up to the same profession. He was therefore sent up to London in 1742, where for some time he attended the courts in Westminster Hall. But, finding that the profession of the law did not suit the bent of his genius, as his usual expression was, he wrote a strong memorial to his father on the subject, whose good sense from that moment left Mr. Smeaton to pursue the bent of his genius in his own way.

Mr. Smeaton after this continued to reside in London, and about the year 1750 he commenced philosophical instrument maker, which he continued for some time, and became acquainted with most of the ingenious men of that time. This same year he made his first communication to the Royal Society, being an account of Dr. Knight's improvements of the mariner's compass. Continuing his very useful labours, and making experiments, he communicated to that learned body, the two following years, a number of other ingenious improvements, in the arts and sciences.

In 1753 he was elected a member of the Royal Society; and in 1759 he was honoured with their gold medal, for his paper concerning the natural powers of water and wind to turn mills, and other machines depending on a circular motion. This paper, he says, was the result of experiments made on working models in the years 1752 and 1753, but not communicated to the Society till 1759, having in the interval found opportunities of putting the result of these experiments into real practice, in a variety of cases, and for various purposes, so as to assure the Society he had found them to answer.—In 1754 his great thirst after experimental knowledge led him to undertake a voyage to Holland and the Low Countries, where he made himself acquainted with most of the curious works of art, so frequent in those places.

In December 1755, the Edystone lighthouse was burnt down, and the proprietors, being desirous of rebuilding it in the most substantial manner, inquired of the earl of Macclesfield, then president of the Royal Society, who he thought might be the fittest person to rebuild it, when he immediately recommended our author. Mr. Smeaton accordingly undertook the work, which he completed with stone in the summer of 1759. Of this work he gives an ample description in a folio volume, with plates, published in 1791; a work which contains, in a great measure, the history of four years of his life, in which the originality of his genius is fully displayed, as well as his activity, industry, and perseverance.

In 1764 Mr. S. was appointed one of the receivers of the forfeited Derwentwater estates, which were applied to the benefit of Greenwich Hospital; which office he held till 1777, when he was prevailed on to resign it, in favour of Sir John Turner, said to be a son of Earl Sandwich, who was then governor of that hospital, and first lord of the admiralty. After this, Mr. S. going into full employment as an engineer, it would be endless to attempt to particularize all the great works he so ably conducted; as mills, wheels, engines, levels, canals, bridges, harbours, &c, in all of which he was equally eminent. Particularly, he saved from destruction London Bridge, after the opening of its great arch. Indeed, as a civil engineer, Mr. S. was perhaps unrivalled, certainly not excelled by any one.

Astronomy was also, for amusement, a favourite pursuit of Mr. S., and he made several curious instruments of this kind for his friends, as well as for himself; with which, to the time of his death, he continued to make many observations. The chief of Mr. S.'s publications, was his History of Edystone lighthouse. Besides which, many of his reports and memorials, on the different works he was concerned in, were occasionally printed in his lifetime, which have since been collected and printed, in 3 vols. 4to, to which is prefixed a pretty full account of his life and labours. He had also inserted in the Philos. Trans. a considerable number of valuable papers, both mechanical and astronomical, in most of the volumes from the year 1750 to 1776.

In 1771, he became, jointly with his friend Mr. Holmes, proprietor of the works for supplying Deptford and Greenwich with water; which by their united endeavours they brought to be of general use to those they were made for, and moderately beneficial to themselves. About the year 1785, Mr. Smeaton's health began to decline; in consequence of which he took the resolution to avoid any new undertakings in business as much as he could, that he might thereby also have the more leisure to publish some account of his inventions and works. Of this plan however he got no more executed than the account of the Edystone lighthouse, and some preparations for his intended treatise on mills. It had for many years been the practice of Mr. Smeaton to spend part of the year in London, and the remainder in the country, at his house at Austhorpe; on one of these excursions in the country, while walking in his garden, on the 16th of September 1792, he was struck with the palsy, which put an end to his useful life the 28th of October following, to the great regret of a numerous set of friends and acquaintances.

In his person, Mr. Smeaton was of a middle stature, but broad and strong made, and possessed of an excellent constitution. He had a great simplicity and plainness in his manners: he had a warmth of expression that might appear, to those who did not know him well, to border on harshness; but such as were more closely acquainted with him, knew it arose from the intense application of his mind, which was always in the pursuit of truth, or engaged in the investigation of difficult subjects. He would sometimes break out hastily, when any thing was said that was contrary to his ideas of the subject; and he would not give up any thing he argued for, till his mind was convinced by sound reasoning. As a companion, he was always entertaining and instructive, and none could spend their time in his company without improvement.

As to the list of his writings; besides the large work above mentioned, being the History of Edystone Lighthouse, and numbers of reports and memorials, which have been printed in 3 vols. 4to, as before-mentioned, his communications to the Royal Society, and inserted in their Transactions, are as follow:

1. Account of Dr. Knight's Improvements of the Mariner's Compass; an. 1750, pa. 513.

2. Some Improvements in the Air-pump; an. 1752.

3. An Engine for raising Water by Fire; being an improvement on Savary's construction, to render it capable of working itself; an. 1752.

4. Description of a new Combination of Pulleys. Ib.

5. Experiments on a machine for measuring the Way of a Ship at Sea. An. 1754.

6. Description of a new Pyrometer. Ib.

7. Effects of Lightning on the Steeple and Church of Lestwithial in Cornwall. An. 1757.

8. Remarks on the different Temperature of the Air at Edystone Light-house, and at Plymouth. An. 1758.

9. Experimental inquiry concerning the natural powers of Water and Wind to turn mills and other machines depending on a circular motion. An. 1759.

10. On the Menstrual Parallax arising from the mutual gravitation of the earth and moon, its influence on the observation of the sun and planets, &c. An. 1768.

11. Description of a new method of observing the heavenly bodies out of the meridian. An. 1768.

12. Observations on a Solar Eclipse. An. 1769.

13. Description of a new Hygrometer. An. 1771.

14. An Experimental Examination of the quantity and proportion of Mechanical Power, necessary to be employed in giving different degrees of velocity to heavy bodies from a state of rest. An. 1776. pa. 450.

In two of those articles, viz, the experiments of 1759 and of 1776, it may be remarked that Mr. Smeaton has manifested several inconsistencies and inaccuracies, apparently from erroneous notions concerning the Newtonian doctrine of the force of bodies in motion. Hence, though the experiments are good in themselves, from reasoning wrongly upon them, he fallaciously infers that their results are contrary to the theory, which, rightly managed, they tend to confirm. He does not properly distinguish between what he calls Mechanical Power, and the Newtonian term Momentum, or quantity of motion. These two powers are, from their very definitions, as well as from their nature, of different kinds. The one being measured or estimated by its momentary or instantaneous action; the other by its action during some certain time. The one, by its definition, is in the compound ratio of the mass of a body and its velocity; or as the product of the body and its velocity, and therefore simply as the velocity in a given body: whereas the other, by its definition, is estimated by the mass or weight compounded with the space it has fallen, or described, in acquiring its velocity: and since, as is well known, the space fallen by a body, is as the square of the velocity acquired; it follows, that this force must needs be as the square of the velocity in a given body. The Newtonian momentum or force, therefore, and Mr. Smeaton's mechanical force or power, are two things that are quite different in their nature or measure, and in their mode of action; though both may produce true results when applied to their proper objects.

SMITH (Robert) D. D. and F. R. S. It seems not a little remarkable that I have not met with any account of the life, or death, or works of Dr. Smith, a man who, from his connections and situation and works, has so well deserved of the literary world. It barely appears, that he was the maternal cousin of the celebrated Roger Cotes, whom he succeeded, in the year 1716, as Plumian professor at Cambridge; that he became master of Trinity College there; that he published some of the works of his cousin Cotes; as, his Hydrostatical and Pneumatical Lectures, in 8vo, 1737; also a collection of Mr. Cotes's pieces from the Philosophical Transactions, and elsewhere, and his Harmonia Mensurarum, with a large commentary, &c, in one vol. 4to, 1722: that Dr. Smith published also two excellent works of his own, viz, his complete System of Optics, in 2 vols. 4to, 1728; and his Harmonics, or the Philosophy of Musical Sounds, &c.

SMOKE, or *Smoak*, a humid matter exhaled in form of vapour by the action of heat, either external or internal; or smoke consists of palpable particles, elevated by means of the rarefying heat, or by the force of the ascending current of air, from certain bodies exposed to heat; which particles vary much in their properties, according to the substances from which they are produced.

Sir Isaac Newton observes, that smoke ascends in the chimney by the impulse of the air it floats in: for that air, being rarefied by the heat of the fire underneath, has its specific gravity diminished; and thus, being disposed to ascend itself, it carries up the smoke along with it. The tail of a comet, the same author supposes, ascends from the nucleus after the same manner.—Smoke of fat unctuous woods, as fir, beech, &c, makes what is called lamp-black.

There are various inventions for preventing and curing smokey chimneys: as the æolipiles of Vitruvius, the ventiducts of Cardan, the windmills of Bernard, the capitals of Serlio, the little drums of Paduanus, and several artifices of De Lorme. See also the philosophical works of Dr. Franklin. Pans, resembling sugar pans, placed over the tops of chimneys, are useful to make them draw better; and the fire-grates called register-stoves, are always a sure remedy.

In the Philosophical Transactions is the description of an engine, invented by M. Dalesme, which consumes the smoke of all kinds of wood so effectually, that the eye cannot discover it in the room, nor the nose distinguish the smell of it, though the fire be made in the middle of the floor. It consists of several iron hoops, 4 or 5 inches in diameter, which shut into one another, and is placed on a trevet.

The late invention called Argand's lamp, also consumes the smoke, and gives a very strong light. Its principle is a thin broad cotton wick, rolled into the form of a hollow cylinder; the air passes up the hollow of it, and the smoke is almost all consumed.

Smoke *Jack*, is a jack for turning a spit, turned by the smoke of the kitchen fire, by means of thin iron sails set obliquely on an axis in the flue of the chimney. See Jack.

SNELL (Rodolph), a respectable Dutch philosopher, was born at Oudenwater in 1546. He was some time professor of Hebrew and mathematics at Leyden, where he died in 1613, at 67 years of age. He was author of several works on geometry, and on all parts of the philosophy of his time.

Snell (Willebrord), son of Rodolph above mentioned, an excellent mathematician, was born at Leyden in 1591, where he succeeded his father in the mathematical chair in 1613, and where he died in 1626, at only 35 years of age. Willebrord Snell was author of several ingenious works and discoveries. Thus, it was he who first discovered the true law of the refraction of the rays of light; a discovery which he made before it was announced by Descartes, as Huygens assures us. Though the work which Snell prepared on this subject, and on optics in general, was never published, yet the discovery was very well known to belong to him, by several authors about his time, who had seen it in his manuscripts.—He undertook also to measure the earth. This he effected by measuring a space between Alcmaer and Bergen-op-zoom, the difference of latitude between these places being 1° 11′ 30″. He also measured another distance between the parallels of Alcmaer and Leyden; and from the mean of both these measurements, he made a degree to consist of 55021 French toises or fathoms. These measures were afterwards repeated and corrected by Muschenbroek, who found the degree to contain 57033 toises.—He was author of a great many learned mathematical works, the principal of which are,

1. Apollonius Batavus; being the restoration of some lost pieces of Apollonius, concerning Determinate Section, with the Section of a Ratio and Space: in 4to, 1608, published in his 17th year.

2. A curious tract, De Re Nummariâ; in 12mo, 1613.

3. Eratosthenes Batavus; in 4to, 1617. Being the work in which he gives an account of his operations in measuring the earth.

4. A translation out of the Dutch language, into Latin, of Ludolph van Collen's book De Circulo & Adscriptis, &c; in 4to, 1619.

5. Cyclometricus, De Circuli Dimensione &c; 4to, 1621. In this work, the author gives several ingenious approximations to the measure of the circle, both arithmetical and geometrical.

6. Tiphis Batavus; being a treatise on Navigation and Naval Affairs; in 4to, 1624; a very well-written work.

7. A posthumous treatise, being four books Doctrinæ Triangulorum Canonicæ; in 8vo, 1627. In which are contained the canon of secants; and in which the construction of sines, tangents, and secants, with the dimension or calculation of triangles, both plane and spherical, are briefly and clearly treated.

8. Hessian and Bohemian Observations; with his own notes.

9. Libra Astronomica & Philosophica; in which he undertakes the examination of the principles of Galileo concerning comets.

10. Concerning the Comet which appeared in 1618, &c.

SNOW, a well known meteor, formed by the freezing of the vapours in the atmosphere. It differs from hail and hoar-frost in being as it were chrystallized, which they are not. This appears on examination of a flake of snow by a magnifying glass; when the whole of it appears to be composed of fine shining spicula diverging like rays from a centre. As the flakes descend through the atmosphere, they are continually joined by more of these radiated spicula, and thus increase in bulk like the drops of rain or hailstones; so that it seems as if the whole body of snow were an infinite mass of icicles irregularly figured. The lightness of snow, though it is firm ice, is owing to the excess of its surface, in comparison to the matter contained under it; as even gold itself may be extended in surface, till it will float upon the least breath of air.

According to Beccaria, clouds of snow differ in nothing from clouds of rain, but in the circumstance of cold that freezes them. Both the regular diffusion of the snow, and the regularity of the structure of its parts, show that clouds of snow are acted on by some uniform cause like electricity; and he endeavours to show how electricity is capable of forming these figures. He was confirmed in his conjectures by observing, that his apparatus for showing the electricity of the atmosphere, never failed to be electrified by snow as well as by rain. Professor Wintrop sometimes found his apparatus electrified by snow when driven about by the wind, though it had not been affected by it when the snow itself was falling. A more intense electricity, according to Beccaria, unites the particles of hail more closely than the more moderate electricity does those of snow, in the same manner as we see that the drops of rain which fall from the thunder-clouds, are larger than those which fall from others, though the former descend through a less space.

In the northern countries, the ground is covered with snow for several months; which proves excedingly favourable for vegetation, by preserving the plants from those intense frosts which are common in such countries, and which would certainly destroy them. Bartholin ascribes great virtues to snow-water, but experience does not seem to warrant his assertions. Snow-water, or ice-water, is always deprived of its fixed air: and those nations who live among the Alps, and use it for their constant drink, are subject to affections of the throat, which it is thought are occasioned by it.

From some late experiments on the quantity of water yielded by snow, it appears that the latter gives only about one-tenth of its bulk in water.

SOCIETY, an assemblage or union of several learned persons, for their mutual assistance, improvement, or information, and for the promotion of philosophical or other knowledge. There are various philosophical societies instituted in different parts of the world. See ROYAL *Society*.

Royal SOCIETY *of England*, is an academy or body of persons, supposed to be eminent for their learning, instituted by king Charles the 2d, for promoting natural knowledge. This society originated from an assembly of ingenious men, residing in London, who, being inquisitive into natural knowledge, and the new and experimental philosophy, agreed, about the year 1645, to meet weekly on a certain day, to discourse upon such subjects. These meetings, it is said, were suggested by Mr. Theodore Haak, a native of the Palatinate in Germany; and they were held sometimes at Dr. Goddard's lodgings in Wood-street, sometimes at a convenient place in Cheapside, and sometimes in or near Gresham College. This assembly seems to be that mentioned under the title of the Invisible, or Philosophical College, by Mr. Boyle, in some letters written in 1646 and 1647. About the years 1648 and 1649, the company which formed these meetings, began to be divided, some of the gentlemen removing to Oxford, as Dr. Wallis, and Dr. Goddard, where, in conjunction with other gentlemen, they held meetings also, and brought the study of natural and experimental philosophy into fashion there; meeting first in Dr. Petty's lodgings, afterwards at Dr. Wilkins's apartments in Wadham College, and, on his removal, in the lodgings of Mr. Robert Boyle; while those gentlemen who remained in London continued their meetings as before. The greater part of the Oxford Society coming to London about the year 1659, they met once or twice a week in term-time at Gresham College, till they were dispersed by the public distractions of that year, the place where they met being made a quarter for soldiers. On the restoration, in 1660, their meetings were revived, and attended by many gentlemen, eminent for their character and learning.

They were at length noticed by the government, and probably by the advice of Sir Jonas Moore, the king granted them a charter, first the 15th of July 1662, then a more ample one on the 22d of April 1663, and thirdly the 8th of April 1669; by which they were erected into a corporation, "consisting of a president, council, and fellows, for promoting natural knowledge," and endued with various privileges and authorties.

Their manner of electing members is by balloting; and two-thirds of the members present are necessary to carry the election in favour of the candidate. The council consists of 21 members, including the president, vice-president, treasurer, and two secretaries; ten of whom go out annually, and ten new members are elected instead of them, all chosen on St. Andrew's day. They had formerly also two curators, whose business it was to perform experiments before the society.

Each member, at his admission, subscribes an engagement, that he will endeavour to promote the good of the society; from which he may be freed at any time, by signifying to the president that he desires to withdraw.

The charges are five guineas paid to the treasurer at admission; and one shilling per week, or 52s. per year, as long as the person continues a member; or, in lieu of the annual subscription, a composition of 25 guineas in one payment.

The ordinary meetings of the society, are once a week, from November till the end of Trinity term the next summer. At first, the time of meeting was from 3 o'clock till 6 in the afternoon. Afterwards, it was from 6 till 7 in the evening, to allow more time for dinner, which continued for a long series of years, till the hour of meeting was removed, by the present president, to between 8 and 9 at night, that gentlemen of fashion, as was alleged, might have the opportunity of coming to attend the meetings after dinner; which has not been found to answer the purpose; besides that many members, especially elderly persons, find it inconvenient to be so late out as 9 or 10 o'clock at night.

Their design is to "make faithful records of all the works of nature or art, which come within their reach; so that the present, as well as after ages, may be enabled to put a mark on errors which have been strengthened by long prescription; to restore truths that have been long neglected; to push those already known to more various uses; to make the way more passable to what remains unrevealed, &c."

To this purpose they have made a great number of experiments and observations on most of the works of nature; as eclipses, comets, planets, meteors, mines, plants, earthquakes, inundations, springs, damps, fires, tides, currents, the magnet, &c: their motto being Nullius in Verba. They have registered experiments, histories, relations, observations, &c, and reduced them into one common stock. They have, from time to time, published some of the most useful of these, under the title of Philosophical Transactions, &c, usually one volume each year. Those papers that are not printed, are laid up in their registers.

They have a good library of books, which has been formed, and continually augmenting, by numerous donations. They had also a museum of curiosities in nature, kept in one of the rooms of their own house in Crane Court, Fleet-street, where they held their meetings, with the greatest reputation, for many years, keeping registers of the weather, and making other experiments; for all which purposes those apartments were well adapted. But, disposing of these apartments, in order to remove into those allotted them in Somerset Place, where having neither room nor convenience for such purposes, the museum was obliged to be disposed of, and their useful meteorological registers discontinued for many years.

Sir Godfrey Copley, bart. left 5 guineas to be given annually to the person who should write the best paper in the year, under the head of experimental philosophy: this reward, which is now changed to a gold medal, is the highest honour the society can bestow; and it is conferred on St. Andrew's day: but the communications of late years have been thought of so little importance, that the prize medal remains sometimes for years undisposed of.

Indeed, this society now consists of a great proportion of honorary members, who do not usually communicate papers; and many scientific members being discouraged from making their usual communications, by what is deemed the present arbitrary government of the society, the annual volumes have in consequence become of much less importance, both in respect of their bulk and the quality of their contents. The number of home members has increased to about 600; the foreign members are about 44 in number.

American Philosophical SOCIETY, was established at Philadelphia in the year 1769, for promoting useful knowledge, under the direction of a patron, a president, three vice-presidents, a treasurer, four secretaries, and three curators. The first volume of their Transactions comprehends a period of two years, viz, from Jan. 1, 1769, to Jan. 1, 1771. Their labours seem to have been interrupted during the troubles in America, which commenced soon after; but since their termination, other volumes have been published, containing a number of very ingenious and useful memoirs.

American Academy of Arts and Sciences, was established by a law of the Commonwealth of Massachusetts in North America, in the year 1780.

Boston Academy of Arts and Sciences. This is a society similar to the former, which has lately been established at Boston in New England, under the title of the Academy of Arts and Sciences &c.

Berlin SOCIETY. The Society of Natural Historians at Berlin, was founded by Dr. Martini. There is also a philosophical society in the same place.

Brussels SOCIETY. The Imperial and Royal Academy of Sciences and Belles Lettres of Brussels was founded in 1773. Several volumes of their Transactions have since been published.

Dublin SOCIETY. This is an experimental society, for promoting natural knowledge, which was instituted in 1777: the members meet once a week, and distribute three honarary gold medals annually for the most approved discovery, invention, or essay, on any mathematical or philosophical subject. The society is under the direction of a president, two vice-presidents, and a secretary.

Edinburgh Royal or *Philosophical* SOCIETY, succeeded the Medical Society, and was formed upon the plan of including all the different branches of natural knowledge and the antiquities of Scotland. The meetings of this society, interrupted in 1745, were revived in 1752; and in 1754 the first volume of their collection was published, under the title of Essays or Observations Physical and Literary, which has been succeeded by other volumes. This society has been lately incorporated by royal charter, under the name of the Royal Society of Scotland, instituted for the advancement of learning and useful knowledge. The members are divided into two classes, physical and literary; and those who are near enough to Edinburgh to attend the meetings, pay a guinea on admission, and the same sum annually. The first meeting was held on the first Monday of August 1783; when there were chosen, a president, two vice-presidents, a secretary, treasurer, and a council of 12 persons. Several of the volumes of their Transactions have been published, which are very respectable both for their magnitude and contents.

In *France* there have been several institutions of this kind for the improvement of science, besides those recounted under the word Academy: As, the Royal Academy at Soissons, founded in 1674; at Villefranche, Beaujolois, in 1679; at Nismes, in 1682; at Angers, in 1685; the Royal Society at Montpelier, in 1706, which is so intimately connected with the Royal Academy of Sciences of Paris, as to form with it, in some respects, one body: the literary productions of this society are published in the memoirs of the academy: the Royal Academy of Sciences and Belles Lettres at Lyons, in 1700; at Bourdeaux, in 1703; at Marseilles, in 1726; at Rochelle, in 1734; at Dijon, in 1740; at Pau in Bern, in 1721; at Beziers, in 1723; at Montauban, in 1744; at Rouen, in 1744; at Amiens, in 1750; at Toulouse, in 1750; at Besançon, in 1752; at Metz, in 1760; at Arras, in 1773; and at Chalons sur Maine, in 1775. And the National Institute, established at Paris in 1794. For other institutions of a similar nature, and their literary productions, see the articles ACADEMY, JOURNAL, and TRANSACTIONS.

Manchester Literary and Philosophical SOCIETY, is of considerable reputation, and has been lately established there, under the direction of two presidents, four vice-presidents, and two secretaries. The number of members is limited to 50; besides these there are several honorary members, all of whom are elected by ballot; and the officers are chosen annually in April. Several valuable essays have been already read at the meetings of this society.

Newcastle-upon-Tyne Literary and Philosophical SOCIETY. This society was instituted the 7th of February 1793, under the direction of a president, four vice-presidents, two secretaries, a treasurer, which together with four of the ordinary members form a committee, all annually elected at a general meeting. The subjects proposed for the consideration and improvement of this society, comprehend the mathematics, natural philosophy and history, chemistry, polite literature, antiquity, civil history, biography, questions of general law and policy, commerce, and the arts. From such ample scope in the objects of the society, with the known respectability, zeal, and talents of the members, the greatest improvements and discoveries may be expected to be made in those important branches of useful knowledge.

Several other similar societies have been since instituted at other places.

SOCRATES, the chief of the ancient philosophers, was born at Alopece, a small village of Attica, in the 4th year of the 77th olympiad, or about 467 years before Christ. Sophroniscus, his father, being a statuary or carver of images in stone, our author followed the same profession for some time, for a subsistence. But being naturally averse to this employment, he only followed it when necessity compelled him; and on getting a little before-hand, would for a while lay it aside. These intermissions of his trade were bestowed upon philosophy, to which he was naturally addicted; and this being observed by Crito, a rich philosopher of Athens, Socrates was at length taken from his shop, and put into a condition of philosophising at his ease and leisure.

He had various instructors in the sciences, as Anaxagoras, Archylaus, Damon, Prodicus, to whom may be added the two learned women Diotyma and Aspasia, of the last of whom he learned rhetoric: of Euenus he learned poetry; of Ichomachus, husbandry; and of Theodorus, geometry.

At length he began himself to teach; and was so eloquent, that he could lead the mind to approve or disapprove whatever he pleased; but never used this talent for any other purpose than to conduct his fellow-citizens into the path of virtue. The academy of the Lycæum, and a pleasant meadow without the city on the side of the river Ilyssos, were places where he chiefly delivered his instructions, though it seems he was never out of his way in that respect, as he made use of all times and places for that purpose.

He is represented by Xenophon as excellent in all kinds of learning, and particularly instances arithmetic, geometry, and astrology or astronomy: Plato mentions natural philosophy; Idomeneus, rhetoric; Laertius, medicine. Cicero affirms, that by the testimony of all the learned, and the judgment of all Greece, he was, as well in wisdom, acuteness, politeness, and subtlety, as in eloquence, variety, and richness, in whatever he applied himself to, without exception, the prince of all.

It has been observed by many, that Socrates little affected travel; his life being wholly spent at home, excepting when he went out upon military services. In the Peloponnesian war he was thrice personally engaged: on which occasions it is said he outwent all the soldiers in hardiness: and if at any time, saith Alcibiades, as it often happens in war, the provisions failed, there were none who could bear the want of meat and drink like Socrates: yet, on the other hand, in times of feasting, he alone seemed to enjoy them; and though of himself he would not drink, yet being invited, he far outdrank every one, though he was never seen intoxicated.

To this great philosopher Greece was principally indebted for her glory and splendor. He formed the manners of the most celebrated persons of Greece, as Alcibiades, Xenophon, Plato, &c. But his great services and the excellent qualities of his mind could not secure him from envy, persecution, and calumny. The thirty tyrants forbad his instructing youth; and as he derided the plurality of the Pagan deities, he was accused of impiety. The day of trial being come, Socrates made his own defence, without procuring an advocate, as the custom was, to plead for him. He did not defend himself with the tone and language of a suppliant or guilty person, but, as if he were master of the judges themselves, with freedom, firmness, and some degree of contumacy. Many of his friends also spoke in his behalf; and lastly, Plato went up into the chair, and began a speech in these words: "Though I, Athenians, am the youngest of those that come up into this place"—but they stopped him, crying out, "of those that go down," which he was thereupon constrained to do; and then proceeding to vote, they condemned Socrates to death, which was effected by means of poison, when he was 70 years of age. Plato gives an affecting account of his imprisonment and death, and concludes, "This was the end of the best, the wisest, and the justest of men." And that account of it by Plato, Tully professes, he could never read without tears.

As to the person of Socrates, he is represented as very homely; he was bald, had a dark complexion, a flat nose, eyes sticking out, and a severe downcast look. But the defects of his person were amply compensated by the virtues and accomplishments of his mind. Socrates was indeed a man of all virtues; and so remarkably frugal, that how little soever he had, it was always enough. When he was amidst a great variety of rich and expensive objects, he would often say to himself, "How many things are there which I do not want!"

Socrates had two wives, one of which was the noted Xantippe; whom Aulus Gellius describes as an accursed froward woman, always chiding and scolding, by day and by night, and whom it was said he made choice of as a trial and exercise of his temper. Several instances are recorded of her impatience and his forbearance. One day, before some of his friends, she fell into the usual extravagances of her passion; when he, without answering a word, went abroad with them: but on his going out of the door, she ran up into the chamber, and threw down water upon his head; upon which, turning to his friends, "Did not I tell you (says he), that after so much thunder we should have rain?" Another time she pulled his cloak from his shoulders in the open forum; and some of his friends advising him to beat her, "Yes (says he), that while we two fight, you may all stand by, and cry, Well done, Socrates; to him, Xantippe."

They who affirm that Socrates wrote nothing, mean only in respect to his philosophy; for it is attested and allowed, that he assisted Euripides in composing tragedies, and was the author of some pieces of poetry. Dialogues also and epistles are ascribed to him: but his philosophical disputations were committed to writing only by his scholars; and that chiefly by Plato and Xenophon. The latter set the example to the rest in doing it first, and also with the greatest punctuality; as Plato did it with the most liberty, intermixing so much of his own, that it is hardly possible to know what part belongs to each. Hence Socrates, hearing him recite his Lysis, cried out, "How many things doth this young man feign of me!" Accordingly, the greatest part of his philosophy is to be found in the writings of Plato. To Socrates is ascribed the first introduction of moral philosophy. Man having a twofold relation to things divine and human, his doctrines were with regard to the former metaphysical, to the latter moral. His metaphysical opinions were chiefly, that, There are three principles of all things, God, matter, and idea. God is the universal intellect; matter the subject of generation and corruption; idea, an incorporeal substance, the intellect of God; God the intellect of the world. God is one, perfect in himself, giving the being and well-being of every creature.—That God, not chance, made the world and all creatures, is demonstrable from the reasonable disposition of their parts, as well for use as defence; from their care to preserve themselves, and continue their species.—That he particularly regards man in his body, appears from his noble upright form, and from the gift of speech; in his soul, from the excellency of it above others.—That God takes care of all creatures, is demonstrable from the benefit he gives them of light, water, fire, and fruits of the earth in due season. That he hath a particular regard of man, from the destination of all plants and creatures for his service; from their subjection to man, though they may exceed him ever so much in strength; from the variety of man's sense, accommodated to the variety of objects, for necessity, use, and pleasure; from reason, by which he discourseth through reminiscence from sensible objects; from speech, by which he communicates all he knows, gives laws, and governs states. Finally, that God, though invisible himself, at once sees all, hears all, is every where, and orders all.

As to the other great object of metaphysical research, the soul, Socrates taught, that it is pre-existent to the body, endued with the knowledge of eternal ideas, which in its union to the body it loseth, as stupefied, until awakened by discourse from sensible objects; on which account, all its learning is only reminiscence, a recovery of its first knowledge. That the body, being compounded, is dissolved by death; but that the soul, being simple, passeth into another life, incapable of corruption. That the souls of men are divine. That the souls of the good after death are in a happy state, united to God in a blessed inaccessible place; that the bad in convenient places suffer condign punishment.

All the Grecian sects of philosophers refer their origin to the discipline of Socrates; particularly the Platonics, Peripatetics, Academics, Cyrenaics, Stoics, &c.

SOLAR, something relating to the sun. Thus, we say solar fire in contradistinction to culinary fire.

SOLAR *Civil Month*. See MONTH.

SOLAR *Cycle*. See CYCLE.

SOLAR *Comet*. See DISCUS.

SOLAR *Eclipse*, is a privation of the light of the sun, by the interposition of the opake body of the moon. See ECLIPSE.

SOLAR *Month*, *Rising*, *Spots*. See the substantives.

SOLAR *System*, the order and disposition of the several heavenly bodies, which revolve round the sun as the centre of their motion; viz, the planets, primary and secondary, and the comets. See SYSTEM.

SOLAR *Year*. See YEAR.

SOLID, in Physics, a body whose minute parts are connected together, so as not to give way, or slip from each other, on the smallest impression. The word is used in this sense, in contradistinction to fluid.

SOLID, in Geometry, is a magnitude extended in every possible direction. Though it is commonly said to be endued with three dimensions only, length, breadth, and depth or thickness. Hence, as all bodies have these three dimensions, and nothing but bodies, solid and body are often used indiscriminately. The extremes of solids are surfaces. That is, solids are terminated either by one surface, as a globe, or by several, either plane or curved. And from the circumstances of these, solids are distinguished into regular or irregular.

Regular SOLIDS, are those that are terminated by regular and equal planes. These are the tetraedron, hexaedron, or cube, octaedron, dodecaedron, and icosaedron; nor can there possibly be more than these five regular solids or bodies, unless perhaps the sphere or globe be considered as one of an infinite number of sides. See these articles severally, also the article *Regular* BODY.

Irregular SOLIDS, are all such as do not come under the definition of regular ones: such as cylinder, cone, prism, pyramid, &c. Similar solids are to one another in the triplicate ratio of their like sides, or as the cubes of the same. And all sorts of prisms, as also pyramids, are to one another in the compound ratio of their bases and altitudes.

SOLID *Angle*, is that formed by three or more plane angles meeting in a point; like an angle of a die, or the point of a diamond well cut. The sum of all the plane angles forming a solid angle, is always less than 360°;

otherwise they would constitute the plane of a circle, and not a solid. See a disquisition on the nature and measure of solid angles in my Course of Mathematics, vol. 3.

Atmosphere of SOLIDS. See ATMOSPHERE.

SOLID *Bastion*. See BASTION.

Cubature of SOLIDS. See CUBATURE and SOLIDITY.

Measure of a SOLID. See MEASURE.

SOLID *Foot*. See FOOT.

SOLID *Numbers*, are those which arise from the multiplication of a plane number, by any other number whatever. Thus, 18 is a solid number, produced from the plane number 6 and 3, or from 9 and 2.

SOLID *Place*. See LOCUS.

SOLID *Problem*, is one which cannot be constructed geometrically; but by the intersection of a circle and a conic section, or by the intersection of two conic sections. Thus, to describe an isosceles triangle on a given base, so that either angle at the base shall be triple of that at the vertex, is a solid problem, resolved by the intersection of a parabola and circle, and it serves to inscribe a regular heptagon in a given circle.

In like manner, to describe an isosceles triangle having its angles at the base each equal to 4 times that at the vertex, is a solid problem, effected by the intersection of an hyperbola and a parabola, and serves to inscribe a regular nonagon in a given circle. And such a problem as this has four solutions, and no more; because two conic sections can intersect in 4 points only.—How all such problems are constructed, is shown by Dr. Halley, in the Philos. Trans. num. 188.

SOLID *of Least Resistance*. See RESISTANCE.

Surfaces of SOLIDS. See AREA, and SUPERFICIES.

SOLID *Theorem*. See THEOREM.

SOLIDITY, in Physics, a property of matter or body, by which it excludes every other body from that place which is possessed by itself. Solidity in this sense is a property common to all bodies, whether solid or fluid. It is usually called impenetrability; but solidity expresses it better, as carrying with it somewhat more of positive than the other, which is a negative idea.

The idea of solidity, Mr. Locke observes, arises from the resistance we find one body makes to the entrance of another into its own place. Solidity, he adds, seems the most extensive property of body, as being that by which we conceive it to fill space; it is distinguished from mere space, by this latter not being capable of resistance or motion.—It is distinguished from hardness, which is only a firm cohesion of the solid parts.

The difficulty of changing situation gives no more solidity to the hardest body than to the softest; nor is the hardest diamond properly a jot more solid than water. By this we distinguish the idea of the extension of body, from that of the extension of space: that of body is the continuity or cohesion of solid, separable, moveable parts; that of space the continuity of unsolid, inseparable, immoveable parts.

The Cartesians however will, by all means, deduce solidity, or, as they call it, impenetrability, from the nature of extension; they contend, that the idea of the former is contained in that of the latter; and hence they argue against a vacuum. Thus, say they, one cubic foot of extension cannot be added to another without having two cubic feet of extension; for each has in itself all that is required to constitute that magnitude. And hence they conclude, that every part of space is solid, or impenetrable, as of its own nature it excludes all other. But the conclusion is false, and the instance they give follows from this, that the parts of space are immoveable, not from their being impenetrable or solid. See MATTER.

SOLIDITY is also used for hardness, or firmness; as opposed to fluidity; viz, when body is considered either as fluid or solid, or hard or firm.

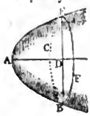
SOLIDITY, in Geometry, denotes the quantity of space contained in a solid body, or occupied by it; called also the solid content, or the cubical content; for all solids are measured by cubes, whose sides are inches, feet, or yards, &c; and hence the solidity of a body is said to be so many cubic inches, feet, yards, &c, as will fill its capacity or space, or another of an equal magnitude.

The solidity of a cube, parallelopipedon, cylinder, or any other prismatic body, i. e. one whose parallel sections are all equal and similar throughout, is found by multiplying the base by the height or perpendicular altitude. And of any cone or other pyramid, the solidity is equal to one-third part of the same prism, because any pyramid is equal to the 3d part of its circumscribing prism. Also, because a sphere or globe may be considered as made up of an infinite number of pyramids, whose bases form the surface of the globe, and their vertices all meet in the centre, or having their common altitude equal to the radius of the globe; therefore the solid content of it is equal to one-third part of the product of its radius and surface. For the solidity of other figures, see each figure separately.

The foregoing rules are such as are derived from common geometry. But there are in nature numberless other forms, which require the aid of other methods and principles, as follows.

Of the SOLIDITY *of Bodies formed by a Plane revolving about any Axis, either within or without the Body.*—Concerning such bodies, there is a remarkable property or relation between their solidity and the path or line described by the centre of gravity of the revolving plane; viz, the solidity of the body generated, whether by a whole revolution, or only a part of one, is always equal to the product arising from the generating plane drawn into the path or line described by its centre of gravity, during its motion in describing the body. And this rule holds true for figures generated by all kinds of motion whatever, whether rotatory, or direct or parallel, or irregularly zigzag, &c, provided the generating plane does not vary, but continue the same throughout. And the same law holds true also for all surfaces any how generated by the motion of a right line. This is called the Centrobaric method. See CENTROBARIC, and my Mensuration, sect. 3, part 4.

Of the SOLIDITY *of Bodies by the Method of Fluxions.*—This method applies very advantageously in all cases also in which a body is conceived to be generated by the revolution of a plane figure about an axis, or, which is much the same thing, by the parallel motion of a circle, gradually expanding and contracting itself, according to the nature of the generating plane. It is also particularly useful for the solids generated by any curvilineal plane figures. Thus, let the plane AED revolve about the axis AD; then it will generate the solid ABFEC. But as every ordinate DE, perpendicular to the axis AD, describes a circle BCEF in the revolution, therefore the same solid may be conceived as generated by a circle BCEF, gradually expanding itself larger and larger, and moving perpendicularly along the axis AD. Consequently the area of that circle being drawn into the fluxion of the axis, will produce the fluxion of the solid; and therefore the fluent, when taken, will give the solidity of that body. That is, AD × circle BCF, (whose radius is DE, or diameter BE) is the fluxion of the solidity.



Hence then, putting AD $= x$, DE $= y$, $c = 3{\cdot}1416$; because cy^2 is equal to the area of the circle BCF; therefore $cy^2\dot{x}$ is the fluxion of the solid. Consequently if the value of either y^2 or $\dot{x}$ be found in terms of each other, from the given equation expressing the nature of the curve, and that value be substituted for it in the fluxional expression $cy^2\dot{x}$, the fluent of the resulting quantity, being taken, will be the required solidity of the body.

For Ex. Suppose the figure to be a parabolic conoid, generated by the rotation of the common parabola ADE about its axis AD. In this case, the equation of the curve of the parabola is $px = y^2$, where p denotes the parameter of the axis. Substituting therefore px instead of y^2, in the fluxion $cy^2\dot{x}$, it becomes $cpx\dot{x}$; and the fluent of this is $\frac{1}{2}cpx^2 = \frac{1}{2}cxy^2$ for the solidity; that is, half the product of the base of the solid drawn into its altitude; for cy^2 is the area of the circular base BCF, and x is the altitude. And so on for other such figures. See the content of each solid under its proper article.

For the SOLIDITY *of Irregular Solids*, or such as cannot be considered as generated by any regular motion or description; they must either be considered as cut or divided into several parts of known forms, as prisms, or pyramids, or wedges, &c, and the contents of these parts found separately. Or, in the case of the smaller bodies, of forms so irregular as not to be easily divided in that way, put them into some hollow regular vessel, as a hollow cylinder or parallelopipedon, &c: then pour in water or sand so that it may fill the vessel exactly to the top of the inclosed irregular body, noting the height it rises to; then take out the body, and note the height the fluid again stands at; the difference of these two heights is to be considered as the altitude of a prism of the same base and form as the hollow vessel; and consequently the product of that altitude and base will be the accurate solidity of the immerged body, be it ever so irregular.

SOLSTICE, in Astronomy, is the time when the sun is in one of the solstitial points, that is, when he is at the greatest distance from the equator, which is now nearly 23° 28′ on either side of it. It is so called, because the sun then seems to stand still, and not to change his place, as to declination, either way. There are two solstices, in each year, when the sun is at the greatest distance on the north and south sides of the equator; viz, the estival or summer solstice, and the hyemal or winter solstice.

The summer solstice is when the sun is in the tropic of Cancer; which is about the 21st of June, when he makes the longest day. And the winter solstice is when he enters the first degree of Capricorn; which is about the 22d of December, when he makes the shortest day.—This is to be understood, as in our northern hemisphere; for in the southern, the sun's entrance into Capricorn makes their summer solstice, and that into Cancer the winter one. So that it is more precise and determinate, to say the northern and southern solstice.

SOLSTITIAL *Points*, are those points of the ecliptic the sun is in at the times of the two solstices, being the first points of Cancer and Capricorn, which are diametrically opposite to each other.

SOLSTITIAL *Colure*, is that which passes through the solstitial points.

SOLUTION, in Mathematics, is the answering or resolving of a question or problem that is proposed. See RESOLUTION, and REDUCTION *of Equations*.

SOLUTION, in Physics, is the reduction of a solid or firm body, into a fluid state, by means of some menstruum.—Solution is often confounded with what is called dissolution, though there is a difference.

SOSIGENES, was an Egyptian mathematician, whose principal studies were chronology and the mathematics in general, and who flourished in the time of Julius Cæsar. He is represented as well versed in the mathematics and the astronomy of the ancients; particularly of those celebrated mathematicians, Thales, Archimedes, Hipparchus, Calippus, and many others, who had undertaken to determine the quantity of the solar year; which they had ascertained much nearer the truth than one can well imagine they should, with instruments so very imperfect; as may appear by reference to Ptolemy's Almagest.

It seems that Sosigenes made great improvements, and gave proofs of his being able to demonstrate the certainty of his discoveries; by which means he became popular, and obtained repute with those who had a genius to understand and relish such inquiries. Hence he was sent for by Julius Cæsar, who being convinced of his capacity, employed him in reforming the calendar; and it was he who formed the Julian year which begins 45 years before the birth of Christ. His other works are lost since that period.

SOUND, in Geography, denotes a strait or inlet of the sea, between two capes or head-lands.

The SOUND is used, by way of eminence, for that celebrated strait which connects the German sea to the Baltic. It is situated between the island of Zealand and the coast of Schonen. It is about 16 leagues in length, and in general about 5 in breadth, except near the castle of Cronenberg, where it is but one; so that there is no passage for vessels but under the cannon of the fortress.

SOUND, in Physics, a perception of the mind, communicated by means of the ear; being an effect of the collision of bodies, and their consequent tremulous motion, communicated to the ambient fluid, and so propagated through it to the organs of hearing.

To illustrate the cause of sound, it is to be observed, 1st, That a motion is necessary in the sonorous body for the production of sound. 2dly, That this motion exists first in the small and insensible parts of the sonorous bodies, and is excited in them by their mutual collision against each other, which produces the tremulous motion so observable in bodies that have a clear sound, as bells, musical chords, &c. 3dly, That this motion is communicated to, or produces a like motion in the air, or such parts of it as are fit to receive and propagate it. Lastly, That this motion must be communicated to those parts that are the proper and immediate instruments of hearing.

Now that motion of a sonorous body, which is the immediate cause of sound, may be owing to two different causes; either the percussion between it and other hard bodies, as in drums, bells, chords, &c; or the beating and dashing of the sonorous body and the air immediately against each other, as in flutes, trumpets, &c.

But in both these cases, the motion, which is the consequence of the mutual action, as well as the immediate cause of the sonorous motion which the air conveys to the ear, is supposed to be an invisible, tremulous or undulating motion, in the small and insensible parts of the body. Perrault adds, that the visible motion of the grosser parts contributes no otherwise to sound, than as it causes the invisible motion of the smaller parts, which he calls particles, to distinguish them from the sensible ones, which he calls parts, and from the smallest of all, which are called corpuscles.

The sonorous body having made its impression on the contiguous air, that impression is propagated from one particle to another, according to the laws of pneumatics. A few particles, for instance, driven from the surface of the body, push or press their adjacent particles into a less space; and the medium, as it is thus rarefied in one place, becomes condensed in the other; but the air thus compressed in the second place, is, by its elasticity, returned back again, both to its former place and its former state; and the air contiguous to that is compressed; and the like obtains when the air less compressed, expanding itself, a new compression is generated. Therefore from each agitation of the air there arises a motion in it, analogous to the motion of a wave on the surface of the water; which is called a wave or undulation of air. In each wave, the particles go and return back again, through very short equal spaces; the motion of each particle being analogous to the motion of a vibrating pendulum while it performs two oscillations; most of the laws of the pendulum, with very little alteration, being applicable to the former.

Sounds are as various as are the means that concur in producing them. The chief varieties result from the figure, constitution, quantity, &c, of the sonorous body; the manner of percussion, with the velocity, &c, of the consequent vibrations; the state and constitution of the medium; the disposition, distance, &c, of the organ; the obstacles between the organ and the sonorous object and the adjacent bodies. The most notable distinction of sounds, arising from the various degrees and combinations of the conditions above mentioned, are into loud and low (or strong and weak); into grave and acute (or sharp and flat, or high and low); and into long and short. The management of which is the office of music.

Euler is of opinion, that no sound making fewer vibrations than 30 in a second, or more than 7520, is distinguishable by the human ear. According to this doctrine, the limit of our hearing, as to acute and grave, is an interval of 8 octaves. Tentam. Nov. Theor. Mus. cap. 1, sect. 13.

The velocity of sound is the same with that of the aerial waves, and does not vary much, whether it go with the wind or against it. By the wind indeed a certain quantity of air is carried from one place to another; and the sound is accelerated while its waves move through that part of the air, if their direction be the same as that of the wind. But as sound moves vastly swifter than the wind, the acceleration it will hereby receive is but inconsiderable; and the chief effect we can perceive from the wind is, that it increases and diminishes the space of the waves, so that by help of it the sound may be heard to a greater distance than otherwise it would.

That the air is the usual medium of sound, appears from various experiments in rarefied and condensed air. In an unexhausted receiver, a small bell may be heard to some distance; but when much exhausted, it can scarce be heard at the smallest distance, not at all in a perfect vacuum. When the air is condensed, the sound is louder in proportion to the condensation, or quantity of air crowded in; of which there are many instances in Hauksbee's experiments, in Dr. Priestley's, and others. Besides, sounding bodies communicate tremors to distant bodies; for example, the vibrating motions of a musical string put others in motion, whose tension and quantity of matter dispose their vibrations to keep time with the pulses of air, propagated from the string that was struck. Galileo explains this phenomenon by observing, that a heavy pendulum may be put in motion by the least breath of the mouth, provided the blasts be repeated, so as to keep time exactly with the vibrations of the pendulum; and also by attending to the same circumstances of vibration, the raising a large bell is easily effected.

It is not air alone that is capable of the impressions of sound, but water also; as is manifest by striking a bell under water, the sound of which may plainly enough be heard, only not so loud, and also a fourth deeper, according to good judges in musical notes. And Mersenne says, a sound made under water is of the same tone or note, as if made in air, and heard under the water.

The real vehicle of sound, or that by which it is transmitted from the sonorous body to the ear, is a subject that has much engaged the attention of philosophers. From the above-mentioned experiments in an exhausted receiver some have concluded, rather hastily, that air is this vehicle; but though air will convey sound, and even though it cannot be transmitted through a vacuum, yet it does not follow that air is the only medium of transmission: this indeed is proved by the experiment of striking a bell in water, which, as above observed, may be heard nearly as well as when sounded in the air. Again, solid bodies transmit sound much more readily than the air: it has been lately determined, by some experiments accurately made and frequently repeated in France by Mr. Biot, that sound is transmitted through a solid body in $0''{\cdot}29$, which in open air would require $2''{\cdot}79$ to be conveyed to the same distance, according to the experiments of the Academy of Sciences.

The velocity of sound, or the space through which it is propagated in a given time, has been very differently estimated by authors who have written on this subject. Roberval states it at the rate of 560 feet in a second; Gassendus at 1473; Mersenne at 1474; Duhamel, in the History of the Academy of Sciences at Paris, at 1338; Newton at 968; Derham, in whose measure Flamsteed and Halley acquiesce, at 1142.—The reason of this variety is ascribed by Derham, partly to some of those gentlemen using strings and plummets instead of regular pendulums; and partly to the too small distance between the sonorous body and the place of observation; and partly to no regard being had to the winds.

But by the accounts since published by M. Cassini de Thury, in the Memoirs of the Royal Acad. of Sciences at Paris, 1738, where cannon were fired at various great distances, under many varieties of weather, wind, and other circumstances, and where the measures of the different places had been settled with the utmost exactness, it was found that sound was propagated, on a medium, at the rate of 1038 French feet in a second of time. But the French foot is in proportion to the English as 15 to 16; and consequently 1038 French feet are equal to 1107 English feet. Therefore the difference of the measures of Derham and Cassini is 35 English feet, or 33 French feet, in a second. Whence the medium velocity of sound is nearly at the rate of a mile, or 5280 feet, in $4\frac{3}{4}$ seconds, or a league in 14 seconds, or 13 miles in a minute. But geographical miles are to English miles nearly as 7 to 6; and therefore sound moves over a geographical mile in $5\frac{1}{2}$ seconds nearly, or a sea league in 16 seconds.

Farther, it is a common observation, that persons in good health have about 75 pulsations, or beats of the artery at the wrist, in a minute: consequently in 75 pulsations, sound flies about 13 English miles, or $11\frac{1}{3}$ sea miles, which is about 1 English mile in 6 pulses, or a league in 20 pulses. And hence the distance of objects may be found, by knowing the time employed by sound in moving from those objects to an observer. For ex. On seeing the flash of a gun at sea, if 54 beats of the pulse at the wrist were counted before the report was heard; the distance of the gun will easily be found by dividing 54 by 20, which gives 2·7 leagues, or about 8 miles.

On the nature, production, &c, of sound, see the article PHONICS and ECHO; also the Memoirs of the Acad. and the Philos. Trans. in many places; Newton, Principia; Kircher, Mesurgia Universalis; Mersenne; Borelli, Del Suono; Bernoulli and Euler, &c, in the Petersburg Memoirs; Priestley, Exper. and Observ. vol. 5; Hales, Sonorum Doctrina rationalis et experimentalis, 4to, 1778; Dr. Matthew Young on Sounds and Musical Strings; see also an ingenious treatise published 1790, by Mr. Geo. Saunders, on Theatres; in which he relates many experiments made by himself, on the nature and propagation of sound. In this work, he shows the great effect of water, and some other bodies, in conducting of sound. Some of his conclusions and observations are as follow:

Earth may be supposed to have a twofold property with respect to sound. Being very porous, it absorbs sound, which is counteracted by its property of conducting sound, and occasions it to pass on a plane, in an equal proportion to its progress in air, unencumbered by any body. If a sound be sufficiently intense to impress the earth in its tremulous quality, it will be carried to a considerable distance, as when the earth is struck with any thing hard, as by the motion of a carriage, horses feet, &c. Plaster is proportionally better than loose earth for conducting sound, as it is more compact. Clothes of every kind, particularly woollen cloths, are very prejudicial to sound: their absorption of sound may be compared to that of water, which they greedily imbibe.

A number of people seated before others, as in the pit or gallery of a theatre, do considerably prevent the voice reaching those behind; and hence it is, that we hear so much better in the front of the galleries, or of any situation, than behind others, though we may be nearer to the speaker. Our seats, rising so little above each other, occasion this defect, which would be remedied, could we have the seats to rise their whole height above each other, as in the ancient theatres. Paint has generally been thought unfavourable to sound, from its being so to musical instruments, whose effects it quite destroys.

Musical instruments mostly depend on the vibrative or tremulous property of the material, which a body of colour hardened in oil must very much alter; but we should distinguish that this regards the formation of sound, which may not altogether be the case in the progress of it. Water has been little noticed, with respect to its conducting sound; but it will be found to be of the greatest consequence. I had often perceived in newly-finished houses, that while they were yet damp, they produced echoes; but that the echoing abated as they dried.

Exp. When I made the following experiment there was a gentle wind; consequently the water was proportionally agitated. I chose a quiet part of the river Thames, near Chelsea Hospital, and with two boats tried the distance the voice would reach. On the water we could distinctly hear a person read at the distance of 140 feet, on land at that of 76. It should be observed, that on land no noise intervened; but on the river some noise was occasioned by the flowing of the water against the boats; so that the difference on land and on water must be much more.

Watermen observe, that when the water is still, and the weather quite calm, if no noise intervene, a whisper may be heard across the river; and that with the current it will be carried to a much greater distance, and vice versa against the current.—Mariners well know the difference of sound on sea and land. When a canal of water was laid under the pit floor of the theatre of Argentino, at Rome, a surprising difference was observed; the voice has since been heard at the end very distinctly, where it was before scarce distinguishable. It is observable that, in this part, the canal is covered with a brick arch, over which there is a quantity of earth, and the timber floor over all.

The villa Simonetta near Milan, so remarkable for its echoes, is entirely over arcades of water. Another villa near Rouen, remarkable for its echo, is built over subterraneous cavities of water. A reservoir of water domed over, near Stanmore, has a strong echo. I do not remember ever being under the arches of a stone bridge that did not echo; which is not always the case with similar structures on land. A house in Lambeth Marsh, inhabited by Mr. Turtle, is very damp during winter, when it yields an echo which abates as the house becomes dry in summer. Kircher observes, that echoes repeat more by night than during the day: he makes the difference to be double. Dr. Plott says, the echo in Woodstock park, repeated 17 times by day, and 20 by night. And Addison's experiment at the Villa Simonetta was in a fog, when it produced 56 repetitions.

After all these instances, I think little doubt can remain of the influence water has on sound; and I conclude that it conducts sound more than any other body whatever. After water, stone may be reckoned the best conductor of sound. To what cause it may be attributed, I leave to future enquiries: I have confined myself to speak of facts only as they appear. Stone is sonorous, but gives a harsh disagreeable tone, unfavourable to music. Brick, in respect to sound, has nearly the same properties as stone. Part of the garden wall of the late

W. Pitt, esq. of Kingston in Dorsetshire, conveys a whisper to the distance of near 200 feet. Wood is sonorous, conductive, and vibrative; of all materials it produces a tone the most agreeable and melodious; and it is therefore the fittest for musical instruments, and for lining of rooms and theatres.

The common notion that whispering at one end of a long piece of timber would be heard at the other end, I found by experiment to be erroneous. A stick of timber 65 feet long being slightly struck at one end, a sound was heard at the other, and the tremor very perceptible: which is easily accounted for, when we consider the number or length of the fibres that compose it, each of which may be compared to a string of catgut.

For the Reflection, Refraction, &c, of SOUND; see ECHO, and PHONICS.

Articulate SOUND. See ARTICULATE.

SOUND, in Music, denotes a quality of the several agitations of the air, so as to make music or harmony.—Sound is the object of music; which is nothing but the art of applying sounds, under such circumstances of tone and time, as to raise agreeable sensations. The principal affection of sound, by which it becomes fitted to have this end, is that by which it is distinguished into acute and grave. This difference depends on the nature of the sonorous body; the particular figure and quantity of it; and even in some cases, on the part of the body where it is struck: and it is this that constitutes what are called different tones.

The cause of this difference appears to be no other than the different velocities of the vibrations of the sounding body. Indeed the tone of a sound is found, by numerous experiments, to depend on the nature of those vibrations, whose differences we can conceive no otherwise than as having different velocities: and since it is proved that the small vibrations of the same chord are all performed in equal times, and that the tone of a sound, which continues for some time after the stroke, is the same from first to last, it follows, that the tone is necessarily connected with a certain quantity of time in making each vibration, or each wave; or that a certain number of vibrations or waves, made in a given time, constitute a certain and determinate tone. From this principle are all the phenomena of tune deduced.

If the vibrations be isochronous, or performed in the same time, the sound is called musical, and is said to continue at the same pitch; and it is also accounted acuter, sharper, or higher than any other sound, whose vibrations are slower, and therefore graver, flatter, or lower, than any other whose vibrations are quicker. See UNISON.

From the same principle arise what are called concords, &c; which result from the frequent unions and coincidences of the vibrations of two sonorous bodies, and consequently of the pulses or the waves of the air occasioned by them. On the contrary, the result of less frequent coincidences of those vibrations, is what is called discord.

Another considerable distinction of musical sounds, is that by which they are called long and short, owing to the continuation of the impulse of the efficient cause on the sonorous body for a longer or shorter time, as in the notes of a violin &c, which are made longer or shorter by strokes of different length or quickness. This continuity is properly a succession of several sounds, or the effect of several distinct strokes, or repeated impulses, on the sonorous body, so quick, that we judge it one continued sound, especially where it is continued in the same degree of strength; and hence arises the doctrine of measure and time.

Musical sounds are also divided into simple and compound; and that in two different ways. In the first, a sound is said to be compound, when a number of successive vibrations of the sonorous body, and the air, come so fast upon the ear, that we judge them the same continued sound; like as in the phenomenon of the circle of fire, caused by putting the lighted end of a stick in a quick circular motion; where supposing the end of the stick in any point of the circle, the idea we receive of it there continues till the impression is renewed by a sudden return.

A *Simple* SOUND then, with regard to this composition, should be the effect of a single vibration, or of as many vibrations as are necessary to raise in us the idea of sound. In the second sense of composition, a simple sound is the product of one voice, or one instrument, &c.

A *Compound* SOUND consists of the sounds of several distinct voices or instruments all united in the same individual time, and measure of duration, that is, all striking the air together, whatever their other differences may be. But in this sense again, there is a twofold composition; a natural and an artificial one. The natural composition is that proceeding from the manifold reflections of the first sound from adjacent bodies, where the reflections are not so sudden as to occasion echoes, but are all in the same tune with the first note.

The artificial composition, which alone comes under the musician's province, is that mixture of several sounds, which being made by art, the ingredient sounds are separable, and distinguishable from one another. In this sense the distinct sounds of several voices or instruments, or several notes of the same instrument, are called simple sounds, in contradistinction from the compound ones, which, in order to answer the end of music, the simples must have such an agreement in all relations, chiefly as to acuteness and gravity, as that the ear may receive the mixture with pleasure.

Another distinction of sounds, with regard to music, is that by which they are said to be smooth or even, and rough or harsh, also clear and hoarse: the cause of which difference depends on the disposition and state of the sonorous body, or the circumstances of the place; but the ideas of the differences must be sought from observation.

Smooth and rough sounds depend chiefly on the sounding body; of which we have a remarkable instance in strings that are uneven, and not of the same dimension and constitution throughout.

As to clear and hoarse sounds, they depend on circumstances that are accidental to the sonorous body. Thus, a voice or instrument will be hollow and hoarse if sounded within an empty hogshead, that yet is clear and bright out of it: the effect is owing to the mixture of different sounds, raised by reflections, which corrupt and change the species of the primitive sound.

For sounds to be fit to obtain the end of music, they ought to be smooth and clear, especially the first; since, without this, they cannot have one certain and discernible tone, capable of being compared to others, in a certain relation of acuteness, which the ear may judge of. So that, with Malcolm, we call that an harmonic or musical sound which, being clear and even, is agreeable to the ear, and gives a certain and discernible tune (hence called tunable sound), which is the subject of the whole theory of harmony.—Wood has a particular vibrating quality, owing to its elasticity; and all musical instruments made of this matter, are of a thickness proportioned to the superficies of the wood, and the tone they are to produce.—Metals are sonorous and vibrative, producing a harsh tone, very serviceable to some parts of music. Most wind instruments are made of metal, which is acted on in its elastic and tremulous quality, being capable of being reduced very thin for that purpose. Instruments of this kind are such as horns, trumpets, &c. Some instruments however depend more on the form than the material; as flutes, for instance, which, if their lengths and bore be the same, have very little difference in their sounds, whatever the matter of them may be. See HARMONICAL.

SOUND-BOARD, the principal part of an organ, and that which makes the whole machine play. This sound-board, or summer, is a reservoir into which the air, drawn in by the bellows, is conducted by a port-vent, and thence distributed into the pipes placed over the holes of its upper part. This wind enters them by valves, which open by pressing upon the stops or keys, after drawing the registers, which prevent the air from going into any of the other pipes besides those it is required in.

SOUND-*board* denotes also a thin broad board placed over the head of a public speaker, to enlarge and extend or strengthen his voice. Sound-boards, in theatres, are found by experience to be of no service; their distance from the speaker being too great, to be impressed with sufficient force. But sound-boards immediately over a pulpit have often a good effect, when the case is made of a just thickness, and according to certain principles.

SOUND-*Post*, is a post placed withinside of a violin, &c, as a prop between the back and the belly of the instrument, and nearly under the bridge.

SOUNDING, in Navigation, the act of trying the depth of the water, and the quality of the bottom, by a line and plummet, or other artifice. At sea, there are two plummets used for this purpose, both shaped like the frustum of a cone or pyramid. One of these is called the hand-lead, weighing about 8 or 9lb; and the other the deep-sea-lead, weighing from 25 to 30lb. The former is used in shallow waters, and the latter at great distances from the shore. The line of the hand-lead, is about 25 fathoms in length, and marked at every two or three fathoms, in this manner, viz, at 2 and 3 fathoms from the lead there are marks of black leather; at 5 fathoms a white rag, at 7 a red rag, at 10 and at 13 black leather, at 15 a white rag, and at 17 a red one.

Sounding with the hand-lead, which the seaman call heaving the lead, is generally performed by a man who stands in the main-chains to windward. Having the line all ready to run out, without interruption, he holds it nearly at the distance of a fathom from the plummet, and having swung the latter backwards and forwards three or four times, in order to acquire the greater velocity, he swings it round his head, and thence as far forward as is necessary; so that, by the lead's sinking whilst the ship advances, the line may be almost perpendicular when it reaches the bottom. The person sounding then proclaims the depth of the water in a kind of song resembling the cries of hawkers in a city; thus, if the mark of 5 be close to the surface of the water, he calls, 'by the mark 5,' and as there is no mark at 4. 6, 8, &c, he estimates those numbers, and calls, 'by the dip four, &c.' If he judges it to be a quarter or a half more than any particular number, he calls, 'and a quarter 5,' 'and a half 4' &c. If he conceives the depth to be three quarters more than a particular number, he calls it a quarter less than the next: thus, at 4 fathom ¾, he calls, 'a quarter less 5,' and so on.

The deep-sea-lead line is marked with 2 knots at 20 fathom, 3 at 30, 4 at 40, &c, to the end. It is also marked with a single knot at the middle of each interval, as at 25, 35, 45 fathoms, &c. To use this lead more effectually at sea, or in deep water on the sea-coast, it is usual previously to bring-to the ship, in order to retard her course: the lead is then thrown as far as possible from the ship on the line of her drift, so that, as it sinks, the ship drives more perpendicularly over it. The pilot feeling the lead strike the bottom, readily discovers the depth of the water by the mark on the line nearest its surface. The bottom of the lead, which is a little hollowed there for the purpose, being also well rubbed over with tallow, retains the distinguishing marks of the bottom, as shells, ooze, gravel, &c, which naturally adhere to it.

The depth of the water, and the nature of the ground, which are called the soundings, are carefully marked in the log-book, as well to determine the distance of the place from the shore, as to correct the observations of former pilots. Falconer. For a machine to measure unfathomable depths of the sea, see ALTITUDE.

SOUNDING *the pump*, at sea, is done by letting fall a small line, with some weight at the end, down into the pump, to know what depth of water there is in it.

SOUTH, one of the four cardinal points of the wind, or compass, being that which is directly opposite to the north.

SOUTH *Direct Dials*. See PRIME *Verticals*.

SOUTHERN *Hemisphere, Signs, &c*, those in the south side of the equator.

SOUTHING, in Navigation, the difference of latitude made by a ship in sailing to the southward.

SPACE, denotes room, place, distance, capacity, extension, duration, &c. When space is considered barely in length between any two bodies, it gives the same idea as that of distance. When it is considered in length, breadth, and thickness, it is properly called capacity. And when considered between the extremities of matter, which fills the capacity of space with something solid, tangible, and moveable, it is then called extension. So that extension is an idea belonging to body only; but space may be considered without it. Therefore space, in the general signification, is the same thing with distance considered every way, whether there be any matter in it or not.

Space is usually divided into absolute and relative.

Absolute SPACE is that which is considered in its own nature, without regard to any thing external, which always remains the same, and is infinite and immoveable.

Relative SPACE is that moveable dimension, or measure of the former, which our senses define by its positions to bodies within it; and this is the vulgar use for immoveable space. Relative space, in magnitude and figure, is always the same with absolute; but it is not necessary it should be so numerically. Thus, when a ship is perfectly at rest, then the places of all things within her are the same both absolutely and relatively, and nothing changes its place: but, or the contrary, when the ship is under sail, or in motion, she continually passes through new parts of absolute space; though all things on board, considered relatively, in respect to the ship, may yet be in the same places, or have the same situation and position, in regard to one another.'

The Cartesians, who make extension the essence of matter, assert, that the space any body takes up, is the same thing with the body itself; and that there is no such thing in the universe as mere space, void of all matter; thus making space or extension a substance. See this disproved under VACUUM. Among those too who admit a vacuum, and consequently an essential difference between space and matter, there are some who assert that space is a substance. Among these we find Gravesande, Introd. ad Philos. sect. 19.

Others again put space in the same class of beings as time and number; thus making it to be no more than a notion of the mind. So that according to these authors, absolute space, of which the Newtonians speak, is a mere chimera. See the writings of the late bishop Berkeley. Space and time, according to Dr. Clarke, are attributes of the Deity; and the impossibility of annihilating these, even in idea, is the same with that of the necessary existence of the Deity.

SPACE, in Geometry, denotes the area of any figure; or that which fills the interval or distance between the lines that terminate or bound it. Thus, the parabolic space is that included in the whole parabola. The conchoidal space, or the cissoidal space, is what is included within the cavity of the conchoid or cissoid. And the asymptotic space, is what is included between an hyperbolic curve and its asymptote. By the application of algebra to geometry, it is demonstrated that the conchoidal and cissoidal spaces, though infinitely extended in length, are yet only finite magnitudes or spaces.

SPACE, in Mechanics, is the line a moveable body, considered as a point, is conceived to describe by its motion.

SPANDREL, or SPANDRIL, with builders, is the space included between the curve of an arch and the straight or right lines which inclose it; as the space *a*, or *b*.

SPEAKING *Trumpet*. See *Speaking* TRUMPET.

SPECIES, in Algebra, are the letters, symbols, marks, or characters, which represent the quantities in any operation or equation. This short and advantageous way of notation was chiefly introduced by Vieta, about the year 1590; and by means of which he made many discoveries in algebra, and the theory of numbers. The reason why Vieta gave this name of species to the letters of the alphabet used in algebra, and hence called Arithmetica Speciosa, seems to have been in imitation of the civilians, who call cases in law that are put abstractedly, between John a Nokes and Tom a Stiles, between A and B; supposing those letters to stand for any persons indefinitely. Such cases they call species: whence, as the letters of the alphabet will also as well represent quantities, as persons, and that also indefinitely, one quantity as well as another, they are properly enough called species; that is, general symbols, marks, or characters. Whence the literal algebra has since been often called Specious Arithmetic, or Algebra in Species.

SPECIES, in Optics, the image painted on the retina by the rays of light reflected from the several points of the surface of an object, received in by the pupil, and collected in their passage through the crystalline, &c. Philosophers have been in great doubt, whether the species of objects, which give the soul an occasion of seeing, are an effusion of the substance of the body; or a mere impression which they make on all ambient bodies, and which these all reflect, when in a proper disposition and distance; or lastly, whether they are not some other more subtile body, as light, which receives all these impressions from bodies, and is continually sent and returning from one to another, with the different impressions and figures it has taken. But the moderns have decided this point by their invention of artificial eyes, in which the species of objects are received on a paper, in the same manner as they are received in the natural eye.

SPECIFIC, in Philosophy, that which is proper and peculiar to any thing; or that characterises it, and distinguishes it from every other thing. Thus, the attracting of iron is specific to the loadstone, or is a specific property of it. A just definition should contain the specific notion of the thing defined, or that which specifies and distinguishes it from every thing else.

SPECIFIC *Gravity*, in Hydrostatics, is the relative proportion of the weight of bodies of the same bulk. See *Specific* GRAVITY.

SPECIFIC *Gravity of living men*. Mr. John Robertson, late librarian to the Royal Society, in order to determine the specific gravity of men, prepared a cistern 78 inches long, 30 inches wide, 30 inches deep; and having procured 10 men for his purpose, the height of each was taken and his weight; and afterwards they plunged successively into the cistern. A ruler or scale, graduated to inches and decimal parts, was fixed to one end of the cistern, and the height of the water shown by it was noted before each man went in, and to what height it rose when he immersed himself under its surface. The following table contains the several results of his experiments:

No. of Men.	Height. Ft.	Height. In.	Weight. lbs.	Water raised Inches.	Solidity. Feet.	Weight of water. lbs.	Specific gravity. (Wat. 1.)
1	6	2	161	1·90	2·573	160·8	1·001
2	5	$10\frac{3}{8}$	147	1·91	2·586	161·6	0·901
3	5	$9\frac{5}{8}$	156	1·85	2·505	156·6	0·991
4	5	$6\frac{3}{4}$	140	2·04	2·763	172·6	0·801
5	5	$5\frac{7}{8}$	158	2·08	2·817	176·0	0·900
6	5	$5\frac{1}{2}$	158	2·17	2·939	183·7	0·849
7	5	$4\frac{1}{8}$	140	2·01	2·722	170·1	0·823
8	5	$4\frac{6}{8}$	121	1·79	2·424	151·5	0·800
9	5	$3\frac{5}{8}$	146	1·73	2·343	146·4	0·997
10	5	$3\frac{1}{8}$	132	1·85	2·505	156·6	0·843
medium of all	5	$6\frac{2}{3}$	146	1·933	2·618	163·6	0·891

One of the reasons, Mr. Robertson says, that induced him to make these experiments, was a desire of knowing what quantity of timber would be sufficient to keep a man afloat in water, thinking that most men were specifically heavier than river or common fresh water; but the contrary appears from the trials above recited; for, except the first, every man was lighter than an equal bulk of fresh water, and much more so than that of sea-water. So that if persons who fall into water had presence of mind enough to avoid the fright usual on such occasions, they might be preserved from drowning; and a piece of wood not larger than an oar, would buoy a man partly above water as long as he had strength or spirits to keep his hold. Philos. Trans. vol. 50, art. 5.—From the last line of the table appears the medium of all the circumstances of height, weight, &c; particularly the mean specific gravity, 0·891, which is about $\frac{1}{9}$ less than common water.

SPECTACLES, an optical machine, consisting of two lenses set in a frame, and applied on the nose, to assist in correcting defects of the organ of sight.—Old people, and all presbytæ, use spectacles of convex lenses, to make amends for the flatness of the eye, which does not make the rays converge enough to have them meet in the retina. Short-sighted people, or myopes, use concave lenses, to prevent the rays from converging so fast, on account of the greater roundness of the eye, or smallness of the sphere, which is such as to make them meet before they reach the retina.—F. Cherubin, a capuchin, describes a kind of spectacle telescopes, for viewing remote objects with both eyes; and hence called binoculi. Though F. Rheita had mentioned the same before him, in his Oculus Enoch et Eliæ. See Binocle. The same author invented a kind of spectacles, with three or four glasses, which performed very well.

The invention of spectacles has been much disputed. They were certainly not known to the ancients. Francisco Redi, in a learned treatise on spectacles, contends that they were first invented between the years 1280 and 1311, probably about 1290; and adds, that Alexander de Spina, a monk of the order of Predicants of St. Catharine, at Pisa, first communicated the secret, which was of his own invention, on learning that another person had it as well as himself. The author tells us, that in an old manuscript still preserved in his library, composed in 1299, spectacles are mentioned as a thing invented about that time: and that a celebrated Jacobin, one Jourdon de Rivalto, in a treatise composed in 1305, says expressly, that it was not yet 20 years since the invention of spectacles. He likewise quotes Bernard Gordon in his Lilium Medicinæ, written the same year, where he speaks of a collyrium, proper to enable an old man to read without spectacles.

Musschenbroek observes, (Introd. vol. 2, pa. 786) that it is inscribed on the tomb of Salvinus Armatus, a nobleman of Florence, who died in 1317, that he was the inventor of spectacles. Du Cange, however, carries the invention of spectacles further back; assuring us, that there is a Greek poem in manuscript in the French king's library, which shows that spectacles were in use in the year 1150; however the dictionary of the Academy Della Crusca, under the word Occhiale, inclines to Redi's side; and quotes a passage from Jourdon's sermons, which says that spectacles had not been 20 years in use; and Salvati has observed that those sermons were composed between the years 1330 and 1336.

It is probable that the first hint of the construction and use of spectacles, was derived from the writings either of Alhazen, who lived in the 12th century, or of our own countryman Roger Bacon, who was born in 1214, and died in 1292, or 1294. The following remarkable passage occurs in Bacon's Opus Majus by Jebb, pa. 352. Si vero homo aspiciat literas et alias res minutas per medium crystalli, vel vitri, vel alterius perspicui suppositi literis, et sit portio minor sphæræ, cujus convexitas sit versus oculum et oculus sit in aëre, longe melius videbit literas, et apparebunt ei majores.—Et ideo hoc instrumentum est utile senibus et habentibus oculos debiles: nam literam quantumcunque parvam possunt videre in sufficienti magnitudine. Hence, and from other passages in his writings, much to the same purpose, Molyneux, Plott, and others, have attributed to him the invention of reading-glasses. Dr. Smith indeed, observing that there are some mistakes in his reasoning on this subject, has disputed his claim. See Molyneux's Dioptr. pa. 256. Smith's Optics, Rem. 86—89. Also the article Bacon, R. in this dictionary.

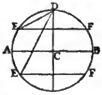
SPECULATIVE *Geometry*, *Mathematics*, *Music*, and *Philosophy*. See the Substantives.

SPECULUM, or *Mirror*, in Optics, any polished body, impervious to the rays of light: such as polished metals, and glasses lined with quicksilver, or any other opaque matter, popularly called Looking-glasses; or even the surface of mercury or of water, &c. For the several kinds and forms of specula, plane, concave, and convex, with their theory and phenomena, see Mirror. And for their laws and effects, see Reflection and Burning-*Glass*.

As for the specula of reflecting telescopes, it may here be observed, that the perfection of the metal of which they should be made, consists in its hardness, whiteness, and compactness; for upon these properties the reflective powers and durability of the specula depend. There are various compositions recommended for these specula, in Smith's Optics, book 3, ch. 2, sect. 787; also by Mr. Mudge in the Philos. Trans. vol. 67; and in various other places, as by Mr. Edwards, in the Naut. Alm. for 1787, whose metal is the whitest and best of any that I have seen.—For the method of grinding, see Grinding.

Mr. Hearne's method of cleaning a tarnished speculum was this: get a little of the strongest soap ley from the soap-makers, and having laid the speculum on a table with its face upwards, put on as much of the ley as it will hold, and let it remain about an hour: then rub it softly with a silk or muslin, till the ley is all gone; then put on some spirit of wine, and rub it dry with another part of the silk or muslin. If the speculum will not perform well after this, it must be new polished. A few faint spots of tarnish may be rubbed off with spirit of wine only, without the ley. Smith's Optics, Rem. p. 107.

SPHERE, in Geometry, a solid body contained under one single uniform surface, every point of which is equally distant from a certain point in the middle called its centre. The sphere may be supposed to be generated by the revolution of a semicircle ABD about its diameter AB, which is also called the axis of the sphere, and the extreme points of the axis, A and B, the poles of the sphere; also the middle of the axis C is the centre, and half the axis, AC, the radius.



Properties of the Sphere, are as follow.—1. A sphere may be considered as made up of an infinite number of pyramids, whose common altitude is equal to the radius of the sphere, their bases forming the surface of the sphere. Therefore the solid content of the sphere is equal to that of a pyramid whose altitude is the radius, and its base is equal to the surface of the sphere, that is, the solid content is equal to $\frac{1}{3}$ of the product of its radius and surface.

2. A sphere is equal to $\frac{2}{3}$ of its circumscribing cylinder, or of the cylinder of the same height and diameter, and therefore equal to the cube of the diameter multi-

plied by ·5236, or $\frac{2}{3}$ of ·7854; or equal to double a cone of the same base and height. Hence also different spheres are to one another as the cubes of their diameters. And their surfaces as the squares of the same diameters.

3. The surface or superficies of any sphere, is equal to 4 times the area of its great circle, or of a circle of the same diameter as the sphere. Or,

4. The surface of the whole sphere is equal to the area of a circle whose radius is equal to the diameter of the sphere. And, in like manner, the curve surface of any segment EDF, whether greater or less than a hemisphere, is equal to a circle whose radius is the chord line DE, drawn from the vertex D of the segment to the circumference of its base, or the chord of half its arc.

5. The curve surface of any segment or zone of a sphere, is also equal to the curve surface of a cylinder of the same height with that portion, and of the same diameter with the sphere. Also the surface of the whole sphere, or of a hemisphere, is equal to the curve surface of its circumscribing cylinder. And the curve surfaces of their corresponding parts are equal, that are contained between any two planes parallel to the base. And consequently the surface of any segment or zone of a sphere, is as its height or altitude.

Most of these properties are contained in Archimedes's treatise on the sphere and cylinder. And many other rules for the surfaces and solidities of spheres, their segments, zones, frustums, &c, may be seen in my Mensuration, part 3, sect. 1, prob. 10, &c. Hence, if d denote the diameter or axis of a sphere, s its curve surface, c its solid content, and a = ·7854 the area of a circle whose diameter is 1; then we shall, from the foregoing properties, have these following general values or equations, viz,

$$s = 4ad^2 = \frac{6c}{d} = 6\sqrt[3]{\tfrac{2}{3}ac^2}.$$

$$c = \tfrac{1}{6}ds = \tfrac{2}{3}ad^3 = \tfrac{1}{12}\sqrt{\frac{s^3}{a}}.$$

$$d = \frac{6c}{s} = \sqrt{\frac{s}{4a}} = \sqrt[3]{\frac{3c}{2a}}.$$

Doctrine of the SPHERE. See SPHERICS.

Projection of the SPHERE. See PROJECTION.

SPHERE *of Activity*, of any body, is that determinate space or extent all around it, to which, and no farther, the effluvia or the virtue of that body reaches, and in which it operates according to the nature of the body. See ACTIVITY.

SPHERE, in Astronomy, that concave orb or expanse which invests our globe, and in which the heavenly bodies, the sun, moon, stars, planets, and comets, appear to be fixed at an equal distance from the eye. This is also called the sphere of the world; and it is the subject of spherical astronomy.

This sphere, as it includes the fixed stars, whence it is sometimes called the sphere of the fixed stars, is immensely great. So much so, that the diameter of the earth's orbit is incomparably small in respect of it; and consequently the centre of the sphere is not sensibly changed by any alteration of the spectator's place in the several parts of the orbit: but still in all points of the earth's surface, and at all times, the inhabitants have the same appearance of the sphere; that is, the fixed stars seem to possess the same points in the surface of the sphere. For, our way of judging of the places &c of the stars, is to conceive right lines drawn from the eye, or from the centre of the earth, through the centres of the stars, and thence continued till they cut the sphere; and the points where these lines so meet, are the apparent places of those stars. The better to determine the places of the heavenly bodies in the sphere, several circles are conceived to be drawn in the surface of it, which are called circles of the sphere.

SPHERE, in Geography, &c, denotes a certain disposition of the circles on the surface of the earth, with regard to one another, which varies in the different parts of it. The circles originally conceived on the surface of the sphere of the world, are almost all transferred, by analogy, to the surface of the earth, where they are conceived to be drawn directly underneath those of the sphere, or in the same positions with them; so that, if the planes of those of the earth were continued to the sphere of the stars, they would coincide with the respective circles on it. Thus, we have an horizon, meridian, equator, &c, on the earth. And as the equinoctial, or equator, in the heavens, divides the sphere, into two equal parts, the one north and the other south, so does the equator on the surface of the earth divide its globe in the same manner. And as the meridians in the heavens pass through the poles of the equinoctial, so do those on the earth, &c. With regard then to the position of some of these circles in respect of others, we have a right, an oblique, and a parallel sphere.

A Right or Direct SPHERE, (fig. 4, plate 32), is that which has the poles of the world PS in its horizon, and the equator EQ in the zenith and nadir. The inhabitants of this sphere live exactly at the equator of the earth, or under the line. They have therefore no latitude, nor no elevation of the pole. They can see both poles of the world; all the stars rise, culminate, and set to them; and the sun always rises at right angles to their horizon, making their days and nights of equal length at all times of the year, because the horizon bisects the circle of the diurnal revolution.

An Oblique SPHERE, (fig. 5, plate 32), is that in which the equator EQ, as also the axis PS, cuts the horizon HO obliquely. In this sphere, one pole P is above the horizon, and the other below it; and therefore the inhabitants of it see always the former pole, but never the latter; the sun and stars &c all rise and set obliquely; and the days and nights are always varying, becoming alternately longer and shorter.

A Parallel SPHERE, (fig. 6, plate 32), is that which has the equator in or parallel to the horizon, as well as all the sun's parallels of declination. Hence, the poles are in the zenith and nadir; the sun and stars move always quite around parallel to the horizon, the inhabitants, if any, being just at the two poles, having 6 months continual day, and 6 months night, in each year; and the greatest height to which the sun rises to them, is 23° 28′, or equal to his greatest declination.

Armillary or Artificial SPHERE, is an astronomical instrument, representing the several circles of the sphere in their natural order; serving to give an idea of the office and position of each of them, and to resolve various problems relating to astronomy. It is thus called, as consisting of a number of rings of brass, or other matter, called by the Latins *armillæ*, from their resembling bracelets or rings for the arm. By this, it is distinguished from the globe, which, though it has all the circles of the sphere on its surface, yet is not cut into armillæ or rings, to represent the circles simply and alone; but exhibits also the intermediate spaces between the circles.

Armillary spheres are of different kinds, with regard to the position of the earth in them; whence they become distinguished into Ptolemaic and Copernican spheres: in the first of which, the earth is in the centre, and in the latter near the circumference, according to the position which that planet obtains in those systems.

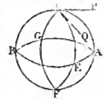
The Ptolemaic SPHERE, is that commonly in use, and is represented in fig. 6, plate 2, vol. 1, with the names of the several circles, lines, &c of the sphere inscribed upon it. In the middle, on the axis of the sphere, is a ball T, representing the earth, on the surface of which are the circles &c of the earth. The sphere is made to revolve about the said axis, which remains at rest; by which means the sun's diurnal and annual courses about the earth are represented according to the Ptolemaic hypothesis: and even by means of this, all problems relating to the phenomena of the sun and earth are resolved, as upon the celestial globe, and after the same manner; which see described under GLOBE.

Copernican SPHERE, fig. 7, plate 32, is very different from the Ptolemaic, both in its constitution and use; and is more intricate in both. Indeed the instrument is in the hands of so few people, and its use so inconsiderable, except what we have in the other more common instruments, particularly the globe and the Ptolemaic sphere, that any further account of it is unnecessary.

Dr. Long had an armillary sphere of glass, of a very large size, which is described and represented in his astronomy. And Mr. Ferguson constructed a similar one of brass, which is exhibited in his Lectures, p. 194 &c.

SPHERICAL, something relating to the sphere.

SPHERICAL *Angle*, is the angle formed on the surface of a sphere or globe by the circumferences of two great circles. This angle, formed by the circumferences, is equal to that formed by the planes of the same circles, or equal to the inclination of those two planes; or equal to the angle made by their tangents at the angular point. Thus, the inclination of the two planes CAF, CEF, forms the spherical angle ACE, equal to the tangential angle PCQ.



The measure of a spherical angle, ACE, is an arc of a great circle AE, described from the vertex C, as from a pole, and intercepted between the legs CA and CE. Hence, 1st, Since the inclination of the plane CEF to the plane CAF, is every where the same, the angles in the opposite intersections, C and F, are equal.—2d, Hence the measure of a spherical angle ACE, is an arc described at the interval of a quadrant CA or CE, from the vertex C between the legs CA, CE.—3d, If a circle of the sphere CEFG cut another AEBG, the adjacent angles AEC and BEC are together equal to two right angles; and the vertical angles AEC, BEF are equal to one another. Also all the angles formed at the same point, on the same side of a circle, are equal to 2 right angles, and all those quite around any point equal to 4 right angles.

SPHERICAL *Triangle*, is a triangle formed on the surface of a sphere, by the intersecting arcs of three great circles; as the triangle ACB.

Spherical triangles are either right-angled, oblique, equilateral, isosceles, or scalene, in the same manner as plane triangles. They are also said to be quadrantal, when they have one side a quadrant. Two sides or two angles are said to be of the same affection, when they are at the same time either both greater, or both less than a quadrant or a right angle or 90°; and of different affections, when one is greater and the other less than 90 degrees.

Properties of SPHERICAL *Triangles*.—1. Spherical triangles have many properties in common with plane ones: such as, That, in a triangle, equal sides subtend equal angles, and equal angles are subtended by equal sides: That the greater angles are subtended by the greater sides, and the less angles by the less sides.

2. In every spherical triangle, each side is less than a semicircle: any two sides taken together are greater than the third side: and all the three sides taken together are less than the whole circumference of a circle.

3. In every spherical triangle, any angle is less than 2 right angles; and the sum of all the three angles taken together, is greater than 2, but less than 6, right angles.

4. In an oblique spherical triangle, if the angles at the base be of the same affection, the perpendicular from the other angle falls within the triangle; but if they be of different affections, the perpendicular falls without the triangle.

Dr. Maskelyne's remarks on the properties of spherical triangles, are as follow: (See the Introd. to my Logs. pa. 171, 5th edition.)

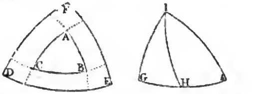
5. "A spherical triangle is equilateral, isosceles, or scalene, according as it has its three angles all equal, or two of them equal, or all three unequal; and vice versa.

6. The greatest side is always opposite the greatest angle, and the smallest side opposite the smallest angle.

7. The sum of any two sides is greater, and their difference less, than the third side.

8. If the three angles are all acute, or all right, or all obtuse; the three sides will be, accordingly, all less than 90°, or equal to 90°, or greater than 90°; and vice versa.

9. If from the three angles A, B, C, of a triangle ABC, as poles, there be described, on the surface of the sphere, three arches of a great circle DE, DF, FE, forming by their intersections a new spherical triangle DEF; each side of the new triangle will be the supplement of the angle at its pole; and each angle of the same triangle, will be the supplement of the side opposite to it in the triangle ABC.



10. In any triangle GHI, or GhI, right angled at G, 1st, The angles at the hypothenuse are always of the same kind as their opposite sides; 2dly, The hypothenuse is less or greater than a quadrant, according as the sides including the right angle, are of the same or different kinds; that is to say, according as these same sides are either both acute, or both obtuse, or as one is acute and the other obtuse. And, vice versa, 1st, The sides including the right angle, are always of the same kind as their opposite angles; 2dly, The sides including the right angle will be

of the same or different kinds, according as the hypothenuse is less or greater than 90°; but one at least of them will be of 90°, if the hypothenuse is so."

Of the Area of a SPHERICAL *Triangle.* The mensuration of spherical triangles and polygons was first found out by Albert Girard, about the year 1600, and is given at large in his Invention Nouvelle en l'Algebre, pa. 50, &c; 4to, Amst. 1629. In any spherical triangle, the area or surface inclosed by its three sides upon the surface of the globe, will be found by this proportion:

As 8 right angles or 720°,
Is to the whole surface of the sphere;
Or, as 2 right angles or 180°,
To one great circle of the sphere;
So is the excess of the 3 angles above 2 right angles,
To the area of the spherical triangle.

Hence, if a denote ·7854,
d = diam. of the globe, and
s = sum of the 3 angles of the triangle;

then $add \times \frac{s-180}{180}$ = area of the spherical triangle.

Hence also, if r denote the radius of the sphere, and c its circumference; then the area of the triangle will be thus variously expressed; viz, area =

$$ad^2 \times \frac{s-180}{150} = cd \times \frac{s-180}{720} = cr \times \frac{s-180}{360};$$

or barely $= r \times (s-180°)$, in square degrees, when the radius r is estimated in degrees; for then the circumference c is = 360°.

Further, because the radius r, of any circle, when estimated in degrees, is, $= \frac{180}{3\cdot14159 \text{ \&c.}} = 57\cdot2957795$, the last rule $r \times (s-180)$, for the area A of the spherical triangle, in square degrees, will be barely

$$A = 57\cdot2957795s - 10313\cdot24, \text{ or}$$
$$A = 57\tfrac{38}{129}s - 10313\tfrac{1}{4} \text{ very nearly.}$$

Hence may be found the sums of the three angles in any spherical triangle, having its area A known; for the last equation gives the sum

$$s = \frac{A}{r} + 180 = \frac{A}{57\cdot29 \text{ \&c.}} + 180 = \frac{169A}{9683} + 180.$$

So that, for a triangle on the surface of the earth, whose three sides are known; if it be but small, as of a few miles extent, its area may be found from the known lengths of its sides, considering it as a plane triangle, which gives the value of the quantity A; and then the last rule above will give the value of s, the sum of the three angles; which will serve to prove whether those angles are nearly exact, that have been taken with a very nice instrument, as in large and extensive measurements on the surface of the earth. Hence A ÷ 57·29 &c is the spherical excess.

Resolution of SPHERICAL *Triangles.* See TRIANGLE, and TRIGONOMETRY.

SPHERICAL *Polygon*, is a figure of more than three sides, formed on the surface of a globe by the intersecting arcs of great circles.

The area of any spherical polygon will be found by the following proportion; viz,

As 8 right angles or 720°,
To the whole surface of the sphere;
Or, as 2 right angles or 180°,
To a great circle of the sphere;
So is the excess of all the angles above the product of 180 and 2 less than the number of angles,
To the area of the spherical polygon.

That is, putting n = the number of angles,
s = sum of all the angles,
d = diam. of the sphere,
a = ·78539 &c;

Then $A = ad^2 \times \frac{s-(n-2)180}{180}$ = the area of the spherical polygon.—Hence other rules might be found, similar to those for the area of the spherical triangle. Hence also, the sum s of all the angles of any spherical polygon, is always less than $180n$, but greater than $180(n-2)$, that is less than n times 2 right angles, but greater than $n-2$ times 2 right angles.

SPHERICAL *Astronomy*, that part of astronomy which considers the universe such as it appears to the eye. See ASTRONOMY. Under spherical astronomy are included all the phenomena and appearances of the heavens and heavenly bodies, such as we perceive them, without any inquiry into the reason, the theory, or truth of them. By which it is distinguished from theorical astronomy, which considers the real structure of the universe, and the causes of those phenomena. In spherical astronomy, the world is conceived to be a concave spherical surface, in whose centre is the earth, or rather the eye, about which the visible frame revolves, with stars and planets fixed in its circumference. And on this supposition all the other phenomena are determined. Theorical astronomy teaches us, from the laws of optics, &c, to correct this scheme and reduce the whole to a juster system.

SPHERICAL *Compasses.* See COMPASSES.

SPHERICAL *Excess.* See EXCESS.

SPHERICAL *Geometry*, the doctrine of the sphere; particularly of the circles described on its surface, with the method of projecting the same on a plane; and measuring their arches and angles when projected.

SPHERICAL *Numbers.* See CIRCULAR *Numbers.*

SPHERICAL *Trigonometry.* See TRIGONOMETRY.

SPHERICITY, the quality of a sphere; or that by which a thing becomes spherical or round.

SPHERICS, the doctrine of the sphere, particularly of the several circles described on its surface; with the method of projecting the same on a plane. See PROJECTION *of the Sphere.*

A circle of the sphere is that which is made by a plane cutting it. If the plane pass through the centre, it is a great circle: if not, it is a small circle. The pole of a circle, is a point on the surface of the sphere equidistant from every point of the circumference of the circle. Hence every circle has two poles, which are diametrically opposite to each other; and all circles that are parallel to each other have the same poles.

Properties of the Circles of the Sphere.—1. If a sphere be cut in any manner by a plane, the section will be a circle; and a great circle when the section passes through the centre, otherwise it is a small circle. Hence, all great circles are equal to each other: and the line of section of two great circles of the sphere, is a diameter of the sphere: therefore two great circles intersect each other in points diametrically opposite; and make equal angles at those points; and divide each other into two equal parts; also any great circle divides the whole sphere into two equal parts.

2. If a great circle be perpendicular to any other circle, it passes through its poles. And if a great circle pass through the pole of any other circle, it cuts it at right angles, and into two equal parts.

3. The distance between the poles of two circles, is equal to the angle of their inclination.

4. Two great circles passing through the poles of another great circle, cut all the parallels to this latter into similar arcs. Hence, an angle made by two great circles of the sphere, is equal to the angle of inclination of the planes of these great circles. And hence also the lengths of those parallels are to one another as the sines of their distances from their common pole, or as the cosines of their distances from their parallel great circle. Consequently, as radius is to the cosine of the latitude of any point on the globe, so is the length of a degree at the equator, to the length of a degree in that latitude.

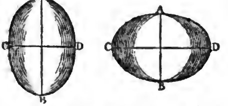
5. If a great circle pass through the poles of another; this latter also passes through the poles of the former; and the two circles cut each other perpendicularly.

6. If two or more great circles intersect each other in the poles of another great circle; this latter will pass through the poles of all the former.

7. All circles of the sphere that are equally distant from the centre, are equal; and the further they are distant from the centre, the less they are.

8. The shortest distance on the surface of a sphere, between any two points on that surface, is the arc of a great circle passing through those points. And the smaller the circle is that passes through the same points, the longer is the arc of distance between them. Hence the proper measure, or distance, of two places on the surface of the globe, is an arc of a great circle intercepted between the same. See Theodosius and other writers on spherics.

SPHEROID, a solid body approaching to the figure of a sphere, though not exactly round, but having one of its diameters longer than the other. This solid is usually considered as generated by the rotation of an oval plane figure about one of its axis. If that be the longer or transverse axis, the solid so generated is called an oblong spheroid, and sometimes prolate, which resembles an egg, or a lemon; but if the oval revolve about its shorter axis, the solid will be an oblate spheroid, which resembles an orange, which is the figure of the earth, and the other planets.



The axis about which the oval revolves, is called the fixed axis, as AB; and the other CD is the revolving axis: whichever of them happens to be the longer.

When the revolving oval is a perfect ellipse, the solid generated by the revolution is properly called an ellipsoid, as distinguished from the spheroid, which is generated from the revolution of any oval whatever, whether it be an ellipse or not. But generally speaking, in the common acceptation of the word, the term spheroid is used for an ellipsoid; and therefore, in what follows, they are considered as one and the same thing.

Any section of a spheroid, by a plane, is an ellipse (except the sections perpendicular to the fixed axe, which are circles); and all parallel sections are similar ellipses, or have their transverse and conjugate axes in the same constant ratio; and the sections parallel to the fixed axe are similar to the ellipse from which the solid was generated. See my Tracts, vol. 2, pa. 134.

For the Surface of a Spheroid, whether it be oblong or oblate. Let f denote the fixed axe, r the revolving axe; and $a = \cdot 7854$, and $q = \frac{f^2 \backsim r^2}{f^2}$; then will the surface s be expressed by the following series, using the upper signs for the oblong spheroid, and the under signs for the oblate one; viz,

$$s = 4arf \times \left(1 \mp \frac{1}{2.3}q - \frac{1}{2.4.5}q^2 \mp \frac{3}{2.4.6.7}q^3 \,\&c\right);$$

where the signs of the terms, after the first, are all negative for the oblong spheroid, but alternately positive and negative for the oblate one. Hence, because the factor $4arf$ is equal to 4 times the area of the generating ellipse, it appears that the surface of the oblong spheroid is less than 4 times the generating ellipse, but the surface of the oblate spheroid is greater than 4 times the same: while the surface of the sphere falls in between the two, being just equal to 4 times its generating circle.

Huygens, in his Horolog. Oscillat. prop. 9, has given two elegant constructions for describing a circle equal to the superficies of an oblong and an oblate spheroid, which he says he discovered towards the latter end of the year 1657. As he gave no demonstrations of these, I have demonstrated them, and also rendered them more general, by extending and adapting them to the surface of any segment or zone of the spheroid. See my Mensuration, pa. 226 &c, 4th ed. where also are several other rules and constructions for the surfaces of spheroids, besides those of their segments, and frustums.

Of the Solidity of a Spheroid. Every spheroid, whether oblong or oblate, is, like the sphere, exactly equal to two-thirds of its circumscribing cylinder. So that, if f denote the fixed axe, r the revolving axe, and $a = \cdot 7854$; then $\frac{2}{3}afr^2$ denotes the solid content of either spheroid. Or, which comes to the same thing, if t denote the transverse, and c the conjugate axe of the generating ellipse;

then $\frac{2}{3}ac^2t$ is the content of the oblong spheroid,

and $\frac{2}{3}act^2$ is the content of the oblate spheroid.

Consequently, the ratio of the former solid to the latter, is as c to t, or as the less axis to the greater.

Further, if about the two axes of an ellipse, there be generated two spheres and two spheroids, the four solids will be continued proportionals, and the common ratio will be that of the two axes of the ellipse; that is, as the greater sphere, or the sphere upon the greater axe, is to the oblate spheroid, so is the oblate spheroid to the oblong spheroid, and so is the oblong spheroid to the less sphere, and so is the transverse axis to the conjugate. See my Mensuration, pa. 248 &c, 4th ed. where may be seen many other rules for the solid contents of spheroids, and their various parts. See also Archimedes on spheroids and conoids.

Dr. Halley has demonstrated, that in a sphere, Mercator's nautical meridian line is a scale of logarithmic tangents of the half complements of the latitudes. But as it has been found that the shape of the earth is spheroidal, this figure will make some alteration in the numbers resulting from Dr. Halley's theorem. Maclaurin has therefore given a rule, by which the meridional parts to any spheroid may be found with the same exactness as in a sphere. There is also an ingenious tract by Mr. Murdoch on the same subject. See Philos. Trans. No. 219. Mr. Cotes has also demonstrated the same proposition, Harm. Mens. pa. 20, 21. See Meridional *Parts.*

Universal Spheroid, a name given to the solid generated by the rotation of an ellipse about some other diameter, which is neither the transverse nor conjugate axis. This produces a figure resembling a heart. See my Mensuration, pa. 266, 4th ed.

SPINDLE, in Geometry, a solid body generated by the revolution of some curve line about its base or double ordinate AB; in opposition to a conoid, which is generated by the rotation of the curve about its axis

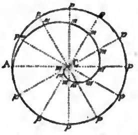
or absciss, perpendicular to its ordinate. The spindle is denominated circular, elliptic, hyperbolic, or parabolic, &c, according to the figure of its generating curve. See my Mensur. in several places.

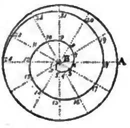
Spindle, in Mechanics, sometimes denotes the axis of a wheel, or roller, &c; and its ends are the pivots.

See also *Double* Cone.

SPIRAL, in Geometry, a curve line of the circular kind, which, in its progress, recedes always more and more from a point within, called its centre; or beginning its motion at a distance from the centre; it approaches nearer and nearer to that point. A spiral may be supposed to be thus generated.

Divide the circumference of a circle *App* &c into any number of equal parts, by a continual bisection at the points *pp* &c. Divide also the radius AC into the same number of equal parts, and make C*m*, C*m*, C*m*, &c, equal to 1, 2, 3, &c of these equal parts; then a line drawn, with a steady hand, through all the points *m*, *m*, *m*, &c, will trace out the spiral. This is more particularly called the first spiral, when it has made one complete revolution to the point A; and the space included between the spiral and the radius CA, is the spiral space. The first spiral may be continued to a second, by describing another circle with double the radius of the first; and the second may be continued to a third, by a third circle; and so on.





Hence it follows, that the parts of the circumference A*p*, are as the parts of the radii C*m*; or A*p* is to the whole circumference, as C*m* is to the whole radius. Consequently, if *c* denote the circumference, *r* the radius, $x =$ C*m*, and $y =$ A*p*; then there arises this proportion $r : c :: x : y$, which gives $ry = cx$ for the equation of this spiral; and which therefore it has in common with the quadratrix of Dinostrates, and that of Tschirnhausen: so that $r^n y^m = c^n x^m$ will serve for infinite spirals and quadratrices.

The first treatise on the spiral was by Archimedes, who thus gives the description of it, by a continued uniform motion. If a right line, as AB (*last fig. above*) having one end moveable about a fixed point at B, be uniformly turned round, so as the other end A may describe the circumference of a circle; and at the same time a point be conceived to move uniformly forward from B towards A, in the right line or radius AB, so that the point may describe that line, while the line generates the circle; then will the point, with the double motion, describe the curve B, 1, 2, 3, 4, 5, &c, of the same spiral as before.

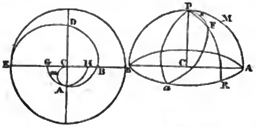
Again, if the point B be conceived to move only half as fast as the line AB revolves, so that it shall get but half way along BA, when that line shall have formed the circle; and if then you imagine a new revolution to be made of the line carrying the point, so that they shall end their motion at last together, there will be formed a double spiral line, as in the last figure. From the manner of this description may easily be drawn these corollaries:

1. That the lines B12, B11, B10, &c, making equal angles with the first and second spiral (as also B12, B10, B8), &c, are in arithmetical progression.

2. The lines B7, B10, &c, drawn any how to the first spiral, are to one another as the arcs of the circle intercepted between BA and those lines; because whatever parts of the circumference the point A describes, as suppose 7, the point B will also have run over 7 parts of the line AB.

3. Any lines drawn from B to the second spiral, as B18, B22, &c, are to each other as the aforesaid arcs, together with the whole circumference added on both sides: for at the same time that the point A runs over 12, or the whole circumference, or perhaps 7 parts more, shall the point B have run over 12, and 7 parts of the line AB, which is now supposed to be divided into 24 equal parts.

4. The first spiral space is equal to $\frac{1}{3}$ of the first or circumscribing circle. That is, the area CABDE of the spiral, is equal to $\frac{1}{3}$ part of the circle described with the radius CE. In like manner, the whole spiral area, generated by the ray drawn from the point C to the curve, when it makes two revolutions, is $\frac{7}{3}$ of the circle described with the radius 2CE.



And, generally, the whole area generated by the ray from the beginning of the motion, till after any number *n* of revolutions, is equal to $\frac{1}{3}$ of the circle whose radius is $n \times$ CE, that is equal to the 3d part of the space which is the same multiple of the circle described with the greatest ray, as the number of revolutions is of unity.

In like manner also, any sector or portion of the area of the spiral, terminated by the curve CMA and the right line CA, is equal to $\frac{1}{3}$ of the circular sector CAG terminated by the right lines CA and CG, this latter being the situation of the revolving ray when the point that describes the curve sets out from C. See Maclaurin's Flux. Introd. pa. 30, 31; also Quadrature of the Spiral of Archimedes; and Emerson's neat tract on spirals, added to his Conic Sections.

A brief synopsis of the first treatise on spirals, by Archimedes, is as follows:—Propositions 1 and 2 are of the nature of lemmas, and are employed to demonstrate the ratios of lines that are described by the equable motion of points.—Props. 3, 4, 5, 6, 7, 8, 9 demonstrate the possibility of taking, in a circle, chords, tangents, secants, &c, as well as certain parts of them, in a given ratio.—Prop. 10 shows that, in a series of quantities proceeding from 0, and equally exceeding one another, (viz, a continued arithmetical series,) the sum of the rectangles of the least term drawn into all the terms, together with as many times the square of the greatest term as is denoted by one more than the number of the terms, is equal to 3 times the sum of the squares of all the terms; that is,

$a(a + b + c + d + \&c, \text{ to } z) + (n + 1)z^2 = 3(a^2 + b^2 + c^2 + d^2 + \&c, \ldots . z^2)$;

where a, b, c, &c, are the terms of series whose common difference is a, the greatest term z, and number of terms n.—Prop. 11 is also employed about the squares of the terms of such a progression.

Having delivered these preparatory propositions, the author comes to the definitions of the helix or spiral, and of the several parts, lines, and circles attending it; in particular, his helix is the curve described by a point moving uniformly through a right line revolving equably about the end from which the point sets out.—The next 6 props. are employed about the proportions of the several parts and radii, &c, of the helix, till, in the 18th prop. it is shown that the circumference of the first circle, is equal to a line drawn from the centre perpendicular to the radius, and bounded by a tangent to the spiral at the extremity of the said radius.

Prop. 19 shows that such a perpendicular, as above, from the centre to the end of the 2d, 3d, 4th, &c spiral, and bounded by the tangent at the same point, is equal to double, triple, quadruple, &c, of the circumference of the circle described through the same tangent point.—Prop. 20, in like manner shows that such a perpendicular to a radius at any point, not at the end of the spiral, is as multiplex less by one of the circumference, together with as much more as is contained between that point and the beginning. So that here we have the rectification of the circular arc by means of the construction of the spiral.

Props. 21, 22, 23, are employed in showing that figures may be described in, and about spirals, that shall differ from them by less than any assignable quantity.—And then prop. 24 shows that the 1st spiral space is equal to $\frac{1}{3}$ of the 1st, or its circumscribing circle. And prop. 25 shows the ratio of the 2d, 3d, 4th, &c spiral space, to the 2d, 3d, 4th, &c circle.

Then the remaining three props. show the ratios of different parts of spirals to their corresponding sectors of the circles. After which is added a theorem showing the proportions of different sectors of a spiral, viz, that they are as the cubes of their respective radii. To which is subjoined a problem, to cut an angle, or a circular arc, in any ratio, by means of the spiral.

SPIRAL, *Logistic*, or *Logarithmic*. See LOGISTIC, and QUADRATURE.

SPIRAL *of Pappus*, a spiral formed on the surface of a sphere, by a motion similar to that by which the Spiral of Archimedes is described on a plane. This spiral is so called from its inventor Pappus. Collect. Mathem. lib. 4 prop. 30. Thus, if C be the centre of the sphere, ARBA a great circle, P its pole; and while the quadrant PMA revolves about the pole P with an uniform motion, if a point proceeding from P move with a given velocity along the quadrant, it will trace upon the spherical surface the spiral PZFa.

Now if we suppose the quadrant PMA to make a complete revolution in the same time that the point, which traces the spiral on the surface of the sphere, describes the quadrant, which is the case considered by Pappus; then the portion of the spherical surface terminated by the whole spiral, and the circle ARBA, and the quadrant PMA, will be equal to the square of the diameter AB. In any other case, the area PMAaFZP is to the square of that diameter AB, as the arc Aa is to the whole circumference ARBA. And this area is always to the spherical triangle PAa, as a square is to its circumscribing circle, or as the diameter of a circle is to half its circumference, or as 2 is to 3·14159 &c. See Maclaurin's Fluxions, Introd. pa. 31—33.

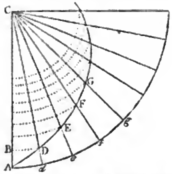
The portion of the spherical surface, terminated by the quadrant PMA, with the arches AR, FR, and the spiral PZF, admits of a perfect quadrature, when the ratio of the arch Aa to the whole circumference can be assigned. See Maclaurin, ibid. pa. 33.

Parabolic SPIRAL. See HELICOID.

Proportional SPIRAL, is generated by supposing the radius to revolve uniformly, and a point from the circumference to move towards the centre with a motion decreasing in geometrical progression. See LOGISTIC.

From the nature of a decreasing geometrical progression, it is easy to conceive that the radius CA may be continually divided; and though each successive division becomes shorter than the next preceding one, yet there must be an infinite number of divisions or terms before the last of them become of no finite magnitude. Whence it follows, that this spiral winds continually round the centre, without ever falling into it in any finite number of revolutions.

It is also evident that any proportional spiral cuts the intercepted radii at equal angles: for if the divisions A*d*, *de*, *ef*, *fg*, &c, of the circumference be very small, the several radii will be so close to one another, that the intercepted parts AD, DE, EF, FG, &c, of the spiral may be taken as right lines; and the triangles CAD, CDE, CEF, &c, will be similar, having equal angles at the point C, and the sides about those angles proportional; therefore the angles at A, D, E, F, &c, are equal, that is, the spiral cuts the radii at equal angles. Robertson's Elem. of Navig. book 2, pa. 87.



Proportional spirals are such spiral lines as the rhumb lines on the terraqueous globe; which, because they make equal angles with every meridian, must also make equal angles with the meridians in the stereographic projection on the plane of the equator, and therefore will be, as Dr. Halley observes, Proportional spirals about the polar point. Whence he demonstrates, that the meridian line is a scale of log. tangents of the half complements of the latitudes. See RHUMB, LOXODROMY, and MERIDIONAL *Parts*.

SPIRAL *Pump*. See *Archimedes's* SCREW.

Spiral, in Architecture and Sculpture, denotes a curve that ascends, winding about a cone, or spire, so that all the points of it continually approach the axis. By this it is distinguished from the helix, which winds in the same manner about a cylinder.

SPORADES, in Astronomy, a name by which the ancients distinguished such stars as were not included in any constellation. These the moderns more usually call unformed, or extraconstellary stars. Many of the sporades of the ancients have been since formed into new constellations: thus, of those between Ursa Major and Leo, Hevelius has formed a constellation named Leo Minor; and of those between Ursa Minor and Auriga, he also formed the Lynx; and of those under the tail of Ursa Minor, another called Canis Venaticus; &c.

SPOTS, in Astronomy, are dark places observed on the disks or faces of the sun, moon, and planets. The spots on the sun are seldom if ever visible, except through a telescope. I have indeed met with persons whose eyes were so strong that they have declared they could distinguish the solar spots; and it is mentioned in Josephus à Costa's Natural and Moral History of the West Indies, book 1, ch. 2, before the use of telescopes, that in Peru there are spots to be seen in the sun, which are not to be seen in Europe. See a memoir by Dr. Zach, in the Astronomical Ephemeris of the Acad. of Berlin for 1788, relating to the discoveries and unpublished papers of Thomas Harriot the celebrated algebraist. In that memoir it is shown, for the first time, that Harriot was also an excellent astronomer, both theoretical and practical; that he made innumerable observations with telescopes from the year 1610, and, among them, 199 observations of the solar spots, with their drawings, calculations, and the determinations of the sun's revolution round his axis. These spots were also discovered near about the same time by Galileo and Scheiner. See Joh. Fabricius Phrysius De Maculis in Sole observatis & apparente eorum cum sole conversione narratio, 1611; also Galileo's Istoria e Demonstrazioni intorno alle Machie Solare e loro accidenti, 1613.

Some distinguish the spots into Maculæ, or dark spots; and Faculæ, or bright spots. They are very changeable as to number, form, &c; and are sometimes in a multitude, and sometimes none at all. Some imagine they may become so numerous, as to hide the whole face of the sun, or at least the greater part of it; and to this they ascribe what Plutarch mentions, viz, that in the first year of the reign of Augustus, the sun's light was so faint and obscure, that one might look steadily at it with the naked eye. To which Kepler adds, that in 1547, the sun appeared reddish, as when viewed through a thick mist; and hence he conjectures that the spots in the sun are a kind of dark smoke, or clouds, floating on his surface.

Some again will have them stars, or planets, passing over the body of the sun: but others, with more probability, think they are opaque bodies, in the manner of crusts, formed like the scums on the surface of liquors.

Mr. Gascoigne, the inventor of the micrometer, and some others, fancied them to be planets revolving very near the sun. But his friend Mr. Crabtrie explained to him very good reasons against such a notion; stating, from his observations, that they are no stars; but mere "fading bodies, unconstant (in regard of their generation) and irregular excrescences arising out of, or proceeding from the sun's body." Abridg. Philos. Trans. vol. 5, pa. 650, &c.

Dr. Derham, from a variety of particulars, which he has recited, concerning the solar spots, and their congruity to what we observe in our own globe, infers, that they are caused by the eruption of some new volcano in the sun, which, pouring out at first a prodigious quantity of smoke and other opaque matter, causeth the spots: and as that fuliginous matter decays and spends itself, and the volcano at last becomes more torrid and flaming, so the spots decay and become umbræ, and at last faculæ: which faculæ he supposes to be no other than more flaming lighter parts than any other parts of the sun. Philos. Trans. vol. 23, pa. 1504, and vol. 27, pa. 270; or my Abridg. vol. 5, pa. 79 and 622.

Dr. Franklin (in his Exper. and Observ. pa. 266.) suggests a conjecture, that the parts of the sun's sulphur separated by fire, rise into the atmosphere, and there being freed from the immediate action of the fire, they collect into cloudy masses, and gradually becoming too heavy to be longer supported, they descend to the sun, and are burnt over again. Hence, he says, the spots appearing on his face, which are observed to diminish daily in size, their consuming edges being of particular brightness.

Dr. Alex. Wilson, of Glasgow, from observations and a train of reasoning, is of opinion that all spots, small as well as great, which consist of a dark nucleus and surrounding umbra, are excavations in the luminous matter of the sun. He has also endeavoured to give a general idea of the production, changes, and decay of the solar spots, considered as excavations in the body of the sun. But concerning the nature of that mighty agency, which occasions those amazing commotions in the luminous matter, or concerning the density, viscidity, and other qualities of the matter, and many other questions, he freely confesses that they far surpass his knowledge. Abridg. Ph. Tr. v. 13, pa. 366, and v. 15, pa. 482.

To this opinion of Dr. Wilson several persons exhibit objections; among others M. Lalande, in the Memoirs of the French Acad. 1776, contends on the contrary, that the spots are phenomena arising from dark bodies like rocks, which, by an alternate flux and reflux of the liquid igneous matter of the sun, sometimes raise their heads above the general surface. That part of the opaque rock, which at any time thus stands above, gives the appearance of the nucleus, while those parts which lie only a little under the igneous matter, appear to us as the surrounding umbra.

Some other respectable remarks on these phenomena are given by Mr. H. Marshall and the Rev. F. Wollaston. See the Abr. Ph. Tr. v. 13, pa. 529, 532.

Dr. Herschel's explanation of these phenomena is different from all the rest. The sun, he supposes, has an atmosphere resembling that of the earth; and this atmosphere consists of various elastic fluids, some of which exhibit a shining brilliancy, while others are merely transparent. Whenever the lucid fluid is removed, the body of the sun may be seen through those that are transparent, as a dark spot. Like as an observer, placed on the moon, sees the solid body of our earth only in those places where the transparent fluids of our atmosphere permit him. In others, the opaque vapours reflect the light of the sun, without permitting his view to penetrate to the surface of our globe. By changes in the atmosphere of Jupiter, Dr. H. accounts for the phenomena of his belts; and on the same principle he illustrates the various appearances of a spot, which he observed on the sun in 1779. This spot extended more than 50 thousand miles; and he says that, 'the idea of its being occasioned by a volcanic explosion, violently driving away a fiery fluid, which on its return would gradually fill up the vacancy, and thus restore the sun in that place to its former splendour, ought to be rejected on many accounts,' Dr. H. apprehends there are considerable inequalities in the surface of the sun; and that there may be elevations not less than 5 or 600 miles high. 'A very high country, or chain of mountains, may oftener become visible, by the removal of the obstructing fluid, than the lower regions, on account of its not being so deeply covered with it; and some of the solar mountains may be high enough occasionally to project above the shining elastic fluid, when, by some agitation, or other cause, it is not of the usual height. And this opinion is much strengthened by the return of some remarkable spots, which served Cassini to ascertain the period of the sun's rotation.—According to Dr. H's hypothesis, the black spots are the opaque ground or body of the sun; and the luminous part is an atmosphere, which, being interrupted or broken, gives us a transient glimpse of the sun itself. These spots appear, with a 7-feet reflector, much depressed below the surface of the luminous part. The faculæ, as Hevelius calls them, are elevated bright places, which appear at different times, and in different circumstances, of very various figures, which, with the lower opaque parts, gives the sun at times a kind of motled appearance. Philos. Trans. Abr. v. 17, pa. 478.

In short, Dr. Herschel, who has paid great attention to the spots of the sun, considers that luminary as similar to the planets, and not a flaming body.—It contains mountains, some of which he supposes to be 200 leagues in height. Its atmosphere is composed of different elastic fluids, some of which are luminous or phosphoric, and others only transparent. The former make the sun appear like a mass of light or fire; but the parts of that atmosphere which are only transparent, suffer his body to be seen. These are the spots. He believes the sun to be inhabited like the other planets.

Lalande, on the other hand, thinks that the sun is really a solid body, but that his surface and part of his mass are composed of an incandescent fluid. This fluid, by any movement, leaves uncovered sometimes a portion of the body of the sun or his mountains, and these are the spots. —— Wilson considers the spots of the sun as eruptions or volcanoes.

For another solution of these phenomena, see MACULÆ. Various other accounts and hypotheses of these spots may be seen in many of the other volumes of the Philos. Trans. In one of these, viz. vol. 57, pa. 398, Dr. Horsley attempts to determine the height of the sun's atmosphere from the height of the solar spots above his surface.

By means of the observations of these spots, has been determined the period of the sun's rotation about his axis, viz. by observing their periodical return.

The lunar spots are fixed: and astronomers reckon about 48 of them on the moon's face; to each of which they have given names. The 21st, called *Tycho*, is one of the most considerable.

Circular SPOTS, in Electricity. See CIRCULAR *Spots* and COLOURS.

Lucid SPOTS, *in the heavens*, are several little whitish spots, that appear magnified, and more luminous when seen through telescopes; and yet without any stars in them. One of these is in Andromeda's girdle, and was first observed in 1612, by Simon Marius: it has some whitish rays near its middle, is liable to several changes, and is sometimes invisible. Another is near the ecliptic, between the head and bow of Sagittarius; it is small, but very luminous. A third is in the back of the Centaur, which is too far south to be seen in Britain. A fourth, of a smaller size, is before Antinous's right foot, having a star in it, which makes it appear more bright. A fifth is in the constellation Hercules, between the stars ζ and η, which is visible to the naked eye, though it is but small, when the sky is clear and the moon absent. It is probable that with more powerful telescopes these lucid spots will be found to be congeries of very minute fixed stars. See NEBULOUS.

Planetary SPOTS, are those of the planets. Astronomers find that the planets are not without their spots. Jupiter, Mars, and Venus, when viewed through a telescope, show several very remarkable ones: and it is by the motion of these spots that the rotation of the planets about their axes is concluded, in the same manner as that of the sun is deduced from the apparent motion of his maculæ.

SPOUT, or *Water* SPOUT, an extraordinary meteor, or appearance, consisting of a moving column or pillar of water; called by the Latins typho, and sipho; and by the French trompe, from its shape, which resembles a speaking trumpet, the widest end uppermost. Its first appearance is in form of a deep cloud, the upper part of which is white, and the lower black. From the lower part of this cloud there hangs, or rather falls down, what is properly called the spout, representing a conical tube, largest at top. Under this tube is always a great agitation of the water of the sea, as in a jet d'eau. For some yards above the surface of the sea, the water stands like a column, or pillar; from the extremity of which it spreads, and goes off, as in a kind of smoke. Frequently the cone descends as low as the middle of this column, and continues for some time contiguous to it; though sometimes it only points to it at some distance, either in a perpendicular, or in an oblique line.

It frequently happens that it can scarcely be distinguished, whether the cone or the column appears the first, both rushing as it were to each other instantaneously. But sometimes the water boils up from the sea to a great height, without any appearance of a spout pointing to it, either perpendicularly or obliquely. Indeed, generally, the boiling or flying up of the water has the priority, this always preceding its being formed into a column. It more commonly happens that the cone does not appear hollow till towards the end, when the sea water is violently thrown up along its middle, as smoke up a chimney: soon after this, the spout or canal breaks and disappears; the boiling up of the water, and even the pillar, continuing to the last, and for some time afterwards; sometimes till the spout form itself again, and appear anew, which it will do several times in a quarter of an hour. See a description of several water-spouts by Mr. Gordon, and by Dr. Stuart, in Phil. Trans. Abr. vol. iv, pa 564, and 647.

M. de la Pryme, from a near observation of two or three spouts in Yorkshire, described in the Philosophical Transactions, num. 281, or Abr. vol. iv, pa. 709, concludes, that the water spout is nothing but a gyration of clouds by contrary winds meeting in a point, or centre; and there, where the greatest condensation and gravitation is, falling down into a pipe, or great tube, somewhat like Archimedes's spiral screw; and, by its working and whirling motion, absorbs and raises the water, in the same manner as the spiral screw does; thus destroying even the largest ships &c.

In the month of June he observed the clouds very much agitated above, and driven together; upon which they became very black, and were hurried round; whence proceeded a most audible whirling noise like that usually heard in a mill. Soon after there issued a long tube, or spout, from the centre of the congregated clouds, in which he observed a spiral motion, like that of a screw, by which the water was raised up.

Again, August 15, 1687, the wind blowing at the same time out of the several quarters, created a great vortex and whirling among the clouds, the centre of which every now and then dropt down, in the shape of a long thin black pipe, in which he could distinctly behold a motion like that of a screw, continually drawing upwards, and screwing up, as it were, wherever it touched.

In its progress it moved slowly over a grove of trees, which bent under it like wands, in a circular motion. Proceeding farther, it tore off the thatch from a barn, bent a huge oak tree, broke one of its greatest branches, and threw it to a considerable distance. He adds, that whereas it is commonly said, the water works and rises in a column, before the tube comes to touch it, this is doubtless a mistake, owing to the fineness and transparency of the tubes, which do most certainly touch the surface of the sea, before any considerable motion can be raised in it; but which do not become opaque and visible, till after they have imbibed a considerable quantity of water.

The dissolution of water spouts he ascribes to the great quantity of water they have gathered: which, by its weight, impeding their motion, upon which their force, and even existence depends, they break, and let go their contents; which frequently proves fatal to whatever is found underneath.

A remarkable instance of this may be seen in the Philosophical Transactions (num. 363, or Abr. vol. vi. pa. 440) related by Dr. Richardson. A spout, in 1718, breaking on Emmotmoor, nigh Coln, in Lancashire, the country was immediately inundated; a brook, in a few minutes, rose six feet perpendicularly high; and the ground upon which the spout fell, which was 66 feet over, was torn up to the very rock, which was no less than 7 feet deep; and a deep gulf was made for above half a mile, the earth being raised in vast heaps on each side. See a description and figure of a water-spout, with an attempt to account for it in Franklin's Exp. and Obs. pa. 226, &c.

Signor Beccaria has taken pains to show that water-spouts have an electrical origin. To make this the more evident, he first describes the circumstances attending their appearance, which are the following.

They generally appear in calm weather. The sea seems to boil, and to send up a smoke under them, rising in a hill towards the spout. At the same time, persons who have been near them have heard a rumbling noise. The form of a water-spout is that of a speaking trumpet, the wider end being in the clouds, and the narrower end towards the sea.

The size is various, even in the same spout. The colour is sometimes inclining to white, and sometimes to black. Their position is sometimes perpendicular to the sea, sometimes oblique; and sometimes the spout itself forms a curve. Their continuance is very various, some disappearing as soon as formed, and some continuing a considerable time. One that he had heard of continued for an hour. But they often vanish, and presently appear again in the same place. The very same things that water-spouts are at sea, are some kinds of whirlwinds and hurricanes by land. They have been known to tear up trees, to throw down buildings, and make caverns in the earth; and in all these cases, to scatter earth, bricks, stones, timber, &c, to great distances in every direction. Great quantities of water have been left, or raised by them, so as to make a kind of deluge; and they have always been attended by a prodigious rumbling noise.

That these phenomena depend upon electricity cannot but appear very probable from the nature of several of them; but the conjecture is made more probable from the following additional circumstances. They generally appear in months peculiarly subject to thunder-storms, and are commonly preceded, accompanied, or followed by lightning, rain, or hail, the previous state of the air being similar. Whitish or yellowish flashes of light have sometimes been seen moving with prodigious swiftness about them. And lastly, the manner in which they terminate exactly resembles what might be expected from the prolongation of one of the uniform protuberances of electrified clouds, mentioned before, towards the sea; the water and the cloud mutually attracting each other: for they suddenly contract themselves, and disperse almost at once; the cloud rising, and the water of the sea under it falling to its level. But the most remarkable circumstance, and the most favourable to the supposition of their depending on electricity, is, that they have been dispersed by presenting to them sharp pointed knives or swords. This, at least, is the constant practice of mariners, in many parts of the world, where these water-spouts abound, and he was assured by several of them, that the method has often been undoubtedly effectual.

The analogy between the phenomena of water-spouts and electricity, he says, may be made visible by hanging a drop of water to a wire communicating with the prime conductor, and placing a vessel of water under it. In these circumstances, the drop assumes all the various appearances of a water-spout, both in its rise, form, and manner of disappearing. Nothing is wanting but the smoke, which may require a great force of electricity to become visible.

Mr. Wilcke also considers the water-spout as a kind of great electrical cone, raised between the cloud strongly electrified, and the sea or the earth, and he relates a very remarkable appearance which occurred to himself, and which strongly confirms his supposition. On the 20th of July 1758, at three o'clock in the afternoon, he observed a great quantity of dust rising from the ground, and covering a field, and part of the town in which he then was. There was no wind, and the dust moved gently towards the east, where appeared a great black cloud, which, when it was near its zenith, electrified his apparatus positively, and to as great a degree as ever he had observed it to be done by natural electricity. This cloud passed his zenith, and went gradually towards the west, the dust then following it, and continuing to rise higher and higher till it composed a thick pillar, in the form of a sugar-loaf, and at length seemed to be in contact with the cloud. At some distance from this, there came, in the same path, another great cloud, together with a long stream of smaller clouds, moving faster than the preceding. These clouds electrified his apparatus negatively, and when they came near the positive cloud, a flash of lightning was seen to dart through the cloud of dust, the positive cloud, the large negative cloud, and, as far as the eye could distinguish, the whole train of smaller negative clouds which followed it. Upon this, the negative clouds spread very much, and dissolved in rain, and the air was presently clear of all the dust. The whole appearance lasted not above half an hour. See Priestley's Electr. vol. i. pa. 438, &c.

This theory of water spouts has been farther confirmed by the account which Mr. Forster gives of one of them, in his Voyage round the World, vol. i, pa. 191, &c. On the coast of New Zealand he had an opportunity of seeing several, one of which he has particularly described. The water, he says, in a space of 50 or 60 fathoms, moved towards the centre, and there rising into vapour, by the force of the whirling motion, ascended in a spiral form towards the clouds. Directly over the whirlpool, or agitated spot in the sea, a cloud gradually tapered into a long slender tube, which seemed to descend to meet the rising spiral, and soon united with it into a straight column of a cylindrical form. The water was whirled upwards with the greatest violence in a spiral, and appeared to leave a hollow space in the centre; so that the water seemed to form a hollow tube, instead of a solid column; and that this was the case, was rendered still more probable by the colour, which was exactly like that of a hollow glass tube. After some time, this last column was incurvated, and broke like the others; and the appearance of a flash of lightning which attended its disjunction, as well as the hail-stones which fell at the time, seemed plainly to indicate, that water-spouts either owe their formation to the electric matter, or, at least, that they have some connexion with it.

In Pliny's time, the seamen used to pour vinegar into the sea, to assuage and lay the spout when it approached them: our modern seamen think to keep it off, by making a noise with filing and scratching violently on the deck; or by discharging great guns to disperse it.

See the figure of a water-spout, fig. 1, plate 33.

SPRING, in Natural History, a fountain or source of water, rising out of the ground.—The most general and probable opinion among philosophers, on the formation of springs, is, that they are formed from the rain-water which penetrates the earth till such time as it meets a clayey soil, or stratum; which proving a bottom sufficiently solid to sustain and stop its descent, it glides along it that way to which the earth declines, till, meeting with a place or aperture on the surface, through which it may escape, it forms a spring, and perhaps the head of a stream or brook. Now, that the rain is sufficient for this effect, appears from hence, that upon calculating the quantity of rain and snow which falls yearly on the tract of ground that is to furnish, for instance, the water of the Seine, it is found that this river does not take up above one-sixth part of it.

Springs commonly rise at the bottom of mountains: the reason is, that mountains collect the most waters, and give them the greatest descent the same way. And if we sometimes see springs on high grounds, and even on the tops of mountains, they must come from other remoter places, considerably higher, along beds of clay, or clayey ground, as in their natural channels. So that if there happen to be a valley between a mountain on whose top is a spring, and the mountain which is to furnish it with water, the spring must be considered as water conducted from a reservoir of a certain height, through a subterraneous channel, to make a jet of an almost equal height.

As to the manner in which this water is collected, so as to form reservoirs of the different kinds of springs, it seems to be this: the tops of mountains usually abound with cavities and subterraneous caverns, formed by nature to serve as reservoirs; and their pointed summits, which seem to pierce the clouds, stop those vapours which float in the atmosphere; which being thus condensed, they precipitate in water, and by their gravity and fluidity easily penetrate through beds of sand and the lighter earth, till they become stopped in their descent by the denser strata, such as beds of clay, stone, &c, where they form a bason or cavern, and working a passage horizontally, or a little declining, they issue out at the sides of the mountains. Many of these springs discharge water, which running down between the ridges of hills, unite their streams, and form rivulets or brooks, and many of these uniting again on the plain, become a river.

The perpetuity of some springs, always yielding the same quantity of water, as well when the least rain or vapour is afforded as when they are the greatest, furnish, in the opinion of some persons, considerable objections to the universality or sufficiency of the above theory. Dr. Derham mentions a spring in his own parish of Upminster, which he could never perceive by his eye was diminished in the greatest droughts, even when all the ponds in the country, as well as an adjoining brook, had been dry for several months together; nor ever to be increased in the most rainy seasons, excepting perhaps for a few hours, or at most for a day, from sudden and violent rains. Had this spring, he thought, derived its origin from rain or vapours, there would be found an increase and decrease of its water corresponding to those of its causes; as we actually find in such temporary springs, as have undoubtedly their rise from rain and vapour.

Some naturalists therefore have recourse to the sea, and derive the origin of springs immediately from thence. But how the sea-water should be raised up to the surface of the earth, and even to the tops of the mountains, is a difficulty, in the solution of which they cannot agree. Some fancy a kind of hollow subterranean rocks to receive the watery vapours raised from channels communicating with the sea, by means of an internal fire, and to act the part of alembics, in freeing them from their saline particles, as well as condensing and converting them into water. This kind of subterranean laboratory, serving for the distillation of sea-water, was the invention of Descartes: see his Princip. part 4, § 64. Others, as Lahire &c (Mem. de l'Acad. 1703) set aside the alembics, and think it enough that there be large subterranean reservoirs of water at the height of the sea, from whence the warmth of the bottom of the earth, &c, may raise vapours; which pervade not only the intervals and fissures of the strata, but the bodies of the strata themselves, and at length arrive near the surface; where, being condensed by the cold, they glide along on the first bed of clay they meet with, till they issue forth by some aperture in the ground. Lahire adds, that the salts of stone and minerals may contribute to the detaining and fixing the vapours, and converting them into water. Again, it is urged by others, that there is a still more natural and easy way of exhibiting the rise of the sea-water up into mountains &c, viz, by putting a little heap of sand, or ashes, or the like, into a bason of water; in which case the sand &c will represent the dry land, or an island; and the bason of water, the sea about it. Here, say they, the water in the bason will rise to the top of the heap, or nearly so, in the same manner, and from the same principle, as the waters of the sea, lakes, &c, rise in the hills. The principle of ascent in both is accordingly supposed to be the same with that of the ascent of liquids in capillary tubes, or between contiguous planes, or in a tube filled with ashes; all which are now generally accounted for by the doctrine of attraction.

Against this last theory, Perrault and others have urged several unanswerable objections. It supposes a variety of subterranean passages and caverns, communicating with the sea, and a complicated apparatus of alembics, with heat and cold, &c, of the existence of all which we have no sort of proof. Besides, the water that is supposed to ascend from the depths of the sea, or from subterranean canals proceeding from it, through the porous parts of the earth, as it rises in capillary tubes, ascends to no great height, and in much too small a quantity to furnish springs with water, as Perrault has sufficiently shown. And though the sand and earth through which the water ascends may acquire some saline particles from it, they are nevertheless incapable of rendering it so fresh as the water of our fountains is generally found to be. Not to add, that in process of time the saline particles of which the water is deprived either by subterranean distillation or filtration, must clog and obstruct those canals and alembics, by which it is supposed to be conveyed to our springs, and the sea must likewise gradually lose a considerable quantity of its salt.

Different kinds of SPRINGS. Springs are either such as run continually, called perennial; or such as run only for a time, and at certain seasons of the year, and therefore called temporary springs. Others again are called intermitting springs, because they flow and then stop, and flow and stop again; and reciprocating springs, whose waters rise and fall, or flow and ebb, by regular intervals.

In order to account for these differences in springs, let ABCDE (fig. 2, pl. 33) represent the declivity of a hill, along which the rain descends; passing through the fissures or channels BF, CG, DH, and LK, into the cavity or reservoir FGHKMI; from this cavity let there be a narrow drain or duct KE, which discharges the water at E. As the capacity of the reservoir is supposed to be large in proportion to that of the drain, it will furnish a constant supply of water to the spring at E. But if the reservoir FGHKMI be small, and the drain large, the water contained in the former, unless it is supplied by rain, will be wholly discharged by the latter, and the spring will become dry: and so it will continue, even though it rains, till the water has had time to penetrate through the earth, or to pass through the channels into the reservoir; and the time necessary for furnishing a new supply to the drain KE will depend on the size of the fissures, the nature of the soil, and the depth of the cavity with which it communicates. Hence it may happen, that the spring at E may remain dry for a considerable time, and even while it rains; but when the water has found its way into the cavity of the hill, the spring will begin to run. Springs of this kind, it is evident, may be dry in wet weather, especially if the duct KE be not exactly level with the bottom of the cavity in the hill, and discharge water in dry weather; and the intermissions of the spring may continue several days. But if we suppose XOP to represent another cavity, supplied with water by the channel NO, as well as by fissures and clefts in the rock, and by the draining of the adjacent earth; and another channel STV, communicating with the bottom of it at S, ascending to T, and terminating on the surface at V, in the form of a siphon; this disposition of the internal cavities of the earth, which we may reasonably suppose that nature has formed in a variety of places, will serve to explain the principle of reciprocating springs; for it is plain, that the cavity XOP must be supplied with water to the height QPT, before it can pass over the bend of the channel at T, and then it will flow through the longer leg of the siphon TV, and be discharged at the end V, which is lower than S. Now if the channel STV be considerably larger than NO, by which the water is principally conveyed into the reservoir XOP, the reservoir will be emptied of its water by the siphon; and when the water descends below its orifice S, the air will drive the remaining water out of the channel STV, and the spring will cease to flow. But in time the water in the reservoir will again rise to the height QPT, and be discharged at V as before. It is easy to conceive, that the diameters of the channels NO and STV may be so proportioned to one another, as to afford an intermission and renewal of the spring V at regular intervals. Thus, if NO communicates with a well supplied by the tide, during the time of flow, the quantity of water conveyed by it into the cavity XOP may be sufficient to fill it up to QPT; and STV may be of such a size as to empty it, during the time of ebb. It is easy to apply this reasoning to more complicated cases, where several reservoirs and siphons communicating with each other, may supply springs with circumstances of greater variety. See Musschenbroek's Introd. ad Phil. Nat. tom. ii. pa. 1010. Desagu. Exp. Phil. vol. ii, pa. 173, &c. And Nicholson's Philos. Journal, v. 35, p. 178, &c.

We shall here observe, that Desaguliers calls those reciprocating springs which flow constantly, but with a stream subject to increase and decrease; and thus he distinguishes them from intermitting springs, which flow or stop alternately. It is said that in the diocese of Paderborn, in Westphalia, there is a spring which disappears after twenty-four hours, and always returns at the end of six hours with a great noise, and with so much force, as to turn three mills, not far from its source. It is called the Bolderborn, or boisterous spring. Phil. Trans. No. 7. There are many springs of an extraordinary nature in our own country, which it is needless to recite, as they are explicable by the general principles already illustrated.

SPRING, *Ver*, in Astronomy and Cosmography, denotes one of the seasons of the year; commencing, in the northern parts of the earth, on the day the sun enters the first degree of Aries, which is about the 21st day of March, and ending when the sun enters Cancer, at the summer solstice, about the 21st of June; spring ending when the summer begins. Or, more strictly and generally, for any part of the earth, or on either side of the equator, the spring season begins when the meridian altitude of the sun, being on the increase, is at a medium between the greatest and least; and ends when the meridian altitude is at the greatest. Or the spring is the season, or time, from the moment of the sun's crossing the equator till he rise to the greatest height above it.

Elater Spring, in Physics, denotes a natural faculty, or endeavour, of certain bodies, to return to their first state, after having been violently put out of the same by compressing, or bending them, or the like. This faculty is usually called by philosophers, elastic force, or elasticity.

Spring, in Mechanics, is used to signify a body of any shape, perfectly elastic, or nearly so.

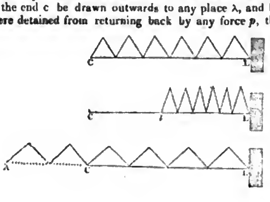
Elasticity of a Spring. See Elasticity.

Length of a Spring, may, from its etymology, signify the length of any elastic body; but it is particularly used by Dr. Jurin to signify the greatest length to which a spring can be forced inwards, or drawn outwards, without prejudice to its elasticity. He observes, this would be the whole length, were the spring considered as a mathematical line; but in a material spring, it is the difference between the whole length, when the spring is in its natural situation, or the situation it will rest in when not disturbed by any external force, and the length or space it takes up when wholly compressed and closed, or when drawn out.

Strength or Force of a Spring, is used for the force or weight which, when the spring is wholly compressed or closed, will just prevent it from unbending itself. Also the force of a spring partly bent or closed, is the force or weight which is just sufficient to keep the spring in that state, by preventing it from unbending itself any farther.

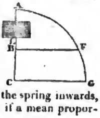
The theory of springs is founded on this principle, ut intensio, sic vis: that is, the intensity is as the compressing force; or if a spring be any way forced or put out of its natural situation, its resistance is proportional to the space by which it is removed from that situation. This principle has been verified by the experiments of Dr. Hooke, and since him by those of others, particularly by the accurate hand of Mr. George Graham. Lectures De Potentia Restitutiva, 1678.

For elucidating this principle, on which the whole theory of springs depends, suppose a spring CL, resting at L against any immoveable support, but otherwise lying in its natural situation, and at full liberty. If this spring be pressed inwards by any force p, or from C towards L, through the space of one inch, and can be there detained by that force p, the resistance of the spring, and the force p, exactly counterbalancing each other; then will the double force $2p$ bend the spring through the space of 2 inches, and the triple force $3p$ through 3 inches, and the quadruple force $4p$ through 4 inches, and so on. The space CL through which the spring is bent, or by which its end C is removed from its natural situation, being always proportional to the force which will bend it so far, and will just detain it when so bent. On the other hand, if the end C be drawn outwards to any place λ, and be there detained from returning back by any force p, the space Cλ, through which it is so drawn outwards, will be also proportional to the force p, which is just able to retain it in that situation.



It may here be observed, that the spring of the air, or its elastic force, is a power of a different nature, and governed by different laws, from that of a palpable rigid spring. For supposing the line LC to represent a cylindrical volume of air, which by compression is reduced to Ll, or by dilation is extended to Lλ, its elastic force will be reciprocally as Ll or Lλ; whereas the force or resistance of a spring is directly as Cl or Cλ.

This principle being premised, Dr. Jurin lays down a general theorem concerning the action of a body striking on one end of a spring, while the other end is supposed to rest against an immoveable support. Thus, if a spring of the strength P, and the length CL, lying at full liberty upon an horizontal plane, rest with one end L against an immoveable support; and a body of the weight M, moving with the velocity V, in the direction of the axis of the spring, strike directly on the other end C, and so force the spring inwards, or bend it through any space CB; and if a mean proportional CG be taken between $\frac{M}{P} \times$ CL and $2a$, where a denotes the height to which a body would ascend in vacuo with the velocity V; and further, if upon the radius R = CG be described the quadrant of a circle GFA: then,



1. When the spring is bent through the right sine CB of any arc GF, the velocity v of the body M is to the original velocity V, as the cosine BF is to the radius CG; that is $v : V :: BF : CG$, or $v = \frac{BF}{R} \times V$.

2. The time t of bending the spring through the same sine CB, is to T, the time of a heavy body's ascending in vacuo with the velocity V, as the corresponding arc is to $2a$; that is $t : T :: GF : 2a$, or $t = \frac{GF}{2a} \times T$.

The doctor gives a demonstration of this theorem, and deduces a great many curious corollaries from it; which he divides into three classes. The first contains such corollaries as are of more particular use when the spring is wholly closed before the motion of the body ceases: the second comprehends those relating to the case, when the motion of the body ceases before the spring is wholly closed: and the third when the motion of the body ceases at the instant that the spring is wholly closed.

3. We shall here mention some of the last class, as being the most simple; having first premised, that P = the strength of the spring, L = its length, V = the initial velocity of the body closing the spring, M = its mass, t = time spent by the body in closing the spring, A = height from which a heavy body will fall in vacuo in a second of time, a = the height to which a body would ascend in vacuo with the velocity V, C = the velocity gained by the fall, m = the circumference of a circle, whose diameter is 1. Then, the motion of the striking body ceasing when the spring is wholly closed, it will be, 1st, 2d, and 3d,

$V = C\sqrt{\frac{PL}{2MA}}$; $Vt = \frac{mCL}{4A} \times 1''$; $MV = C\sqrt{\frac{PL.M}{2A}}$; the first momentum.

4. If a quantity of motion MV bend a spring through its whole length, and be destroyed by it; no other quan-

tity of motion equal to the former, as $nM \times \frac{V}{n}$, will close the same spring, and be wholly destroyed by it.—5. But a quantity of motion, greater or less than MV, in any given ratio, may close the same spring, and be wholly destroyed in closing it; and the time spent in closing the spring will be respectively greater or less, in the same given ratio.—6. The initial vis viva, or MV^2 is $= \frac{c^2PL}{2A}$; and $2aM = PL$; also the initial vis viva is as the rectangle under the length and strength of the spring, that is, MV^2 is as PL.—7. If the vis viva MV^2 bend a spring through its whole length, and be destroyed in closing it; any other vis viva, equal to the former, as $n^2M \times \frac{V^2}{n^2}$, will close the same spring, and be destroyed by it.—8. But the time of closing the spring by vis viva $n^2M \times \frac{V^2}{n}$, will be to the time of closing it by the vis viva MV^2, as n to 1.—9. If the vis viva MV^2 be wholly consumed in closing a spring, of the length L, and strength P; then the vis viva n^2MV^2 will be sufficient to close, 1st, Either a spring of the length L and strength n^2P. 2d, Or a spring of the length nL and strength nP. 3d, Or of the length n^2L and strength P. 4th, Or, if n be a whole number, the number n^2 of springs, each of the length L and strength P.—It may be added, that it appears from hence, that the number of similar and equal springs a given body in motion can wholly close, is always proportional to the squares of the velocity of that body. And it is from this principle that the chief argument, to prove that the force of a body in motion is as the square of its velocity, is deduced. See FORCE.

The theorem given above, and its corollaries, will equally hold good, if the spring be supposed to have been at first bent through a certain space, and by unbending itself to press upon a body at rest, and thus to drive that body before it, during the time of its expansion: only V, instead of being the initial velocity with which the body struck the spring, will now be the final velocity with which the body parts from the spring when totally expanded.

It may also be observed, that the theorem, &c, will equally hold good, if the spring, instead of being pressed inward, be drawn outward by the action of the body. The like may be said, if the spring be supposed to have been already drawn outward to a certain length, and in restoring itself draw the body after it. And lastly, the theorem extends to a spring of any form whatever, provided L be the greatest length it can be extended to from its natural situation, and P the force which will confine it to that length. See Philos. Trans. num. 472, sect. 10, or vol. 43, art. 10.

SPRING is more particularly used, in the Mechanic Arts, for a piece of tempered steel, put into various machines to give them motion, by the endeavour it makes to unbend itself. In watches, it is a fine piece of well-beaten steel, coiled up in a cylindrical case, or frame; which by stretching itself forth, gives motion to the wheels, &c.

SPRING *Arbor*, in a Watch, is that part in the middle of the spring-box, about which the spring is wound or turned, and to which it is hooked at one end.

SPRING *Box*, in a Watch, is the cylindrical case, or frame, containing within it the spring of the watch.

SPRING *Compasses*. See COMPASSES.

SPRING *of the Air*, or its elastic force. See AIR, and ELASTICITY.

SPRING-*Tides*, are the higher tides, about the times of the new and full moon. See TIDE.

SPRINGY, or *Elastic Body*. See ELASTIC *Body*.

SQUARE, in Geometry, a quadrilateral figure, whose angles are right, and sides equal. Or it is an equilateral rectangular parallelogram. A square, and indeed any other parallelogram, is bisected by its diagonal; but the side of a square is incommensurable with its diagonal, being in the ratio of 1 to $\sqrt{2}$.

To find the Area of a SQUARE. Multiply the side by itself, and the product is the area. So, if the side be 10, the area is 100; and if the side be 12, the area is 144.

SQUARE *Foot*, is a square each side of which is equal to a foot, or 12 inches; and the area, or square foot is equal to 144 square inches.

Geometrical SQUARE, a compartment often added on the face of a quadrant. See *Line* of SHADOWS, and QUADRANT.

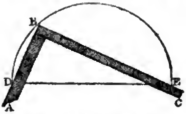
Gunner's SQUARE. See QUADRANT.

Magic SQUARE. See MAGIC *Square*.

SQUARE *Measures*, the squares of the lineal measures; as in the following table of square measures:

Squa. Inches.	Sq. Feet.	Sq. Yards.	Sq Poles.	S Chs.	Acres.	Sq. Miles.
144	1					
1296	9	1				
39204	272¼	30¼	1			
627264	4356	484	16	1		
6272640	43560	4840	160	10	1	
4014489600	27878400	3097600	102400	6400	640	1

Normal SQUARE, is an instrument, made of wood or metal, serving to describe and measure right angles; such is ABC. It consists of two rulers or branches fastened together perpendicularly.—When the two legs are moveable on a joint, it is called a bevel.—

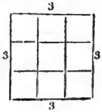


To examine whether the square be exact or not. Describe a semicircle DBE, with any radius at pleasure; in the circumference of which apply the angle of the square to any point as B, and the edge of one leg to one end of the diameter as D, then if the other leg pass just by the other extremity at E, the square is true; otherwise not.

SQUARE *Number*, is the product arising from a number multiplied by itself. Thus, 4 is the square of 2, and 16 the square of 4.

The series of square integers, is 1, 4, 9, 16, 25, 36, &c;
which are the squares of - 1, 2, 3, 4, 5, 6, &c.
Or the square fractions - - $\frac{1}{4}$, $\frac{4}{9}$, $\frac{9}{16}$, $\frac{16}{25}$, $\frac{25}{36}$, $\frac{36}{49}$, &c,
which are the squares of - $\frac{1}{2}$, $\frac{2}{3}$, $\frac{3}{4}$, $\frac{4}{5}$, $\frac{5}{6}$, $\frac{6}{7}$, &c.

A square number is so called, either because it denotes the area of a square, whose side is expressed by the root of the square number; as in the annexed square, which consists of 9 little squares, the side being equal to 3; or else, which is much the same thing, because the points in the number may be ranged



in the form of a square, by making the . . .
root, or factor, the side of it, thus, . . .

Some properties of squares are as follow : . . .

1. Of the
Natural series of squares, $1^2, 2^2, 3^2, 4^2$, &c,
which are equal to $1, 4, 9, 16$, &c;

The mean proportional mn between any two of these squares m^2 and n^2, is equal to the less square plus its root multiplied by the difference of the roots; or also equal to the greater square minus its root multiplied by the said difference of the roots. That is,

$$mn = m^2 + dm = n^2 - dn;$$

where $d = n - m$ is the difference of their roots.

2. An arithmetical mean between any two squares m^2 and n^2, exceeds their geometrical mean, by half the square of the difference of their roots.

That is, $\frac{1}{2}m^2 + \frac{1}{2}n^2 = mn + \frac{1}{2}d^2$.

3. Of three equidistant squares in the series, the geometrical mean between the extremes, is less than the middle square by the square of their common distance in the series, or of the common difference of their roots.

That is, $mp = n^2 - d^2$;

where m, n, p, are in arithmetical progression, the common difference being d.

4. The difference between the two adjacent squares m^2, and n^2, is $n^2 - m^2 = 2m + 1$;
in like manner, $p^2 - n^2 = 2n + 1$, the difference between the next two adjacent squares n^2 and p^2; and so on, for the next following squares. Hence the difference of these differences, or the second difference of the squares, is $2n - 2m = 2 \times (n - m) = 2$ only, because $n - m = 1$; that is, the second differences of the squares are each the same constant number 2: therefore the first differences will be found by the continual addition of the number 2; and then the squares themselves will be found by the continual addition of the first differences; and thus the whole series of squares is constructed by addition only, as here below :

2d Diff.		2	2	2	2	2	2	&c.
1st Diff.	1	3	5	7	9	11	13	&c.
Squares	1	4	9	16	25	36	49	&c.

And this method of constructing the table of square numbers was first noticed by Peletarius, in his Algebra.

5. Another curious property, also noted by the same author, is, that the sum of any number of the cubes of the natural series 1, 2, 3, 4, &c, taken from the beginning, always makes a square number; and that the series of squares, so formed, have for their roots the numbers

1, 3, 6, 10, 15, 21, &c,

the diffs. of which are 1, 2, 3, 4, 5, 6, &c,

viz, $1^3 = 1^2$,
$1^3 + 2^3 = 3^2$,
$1^3 + 2^3 + 3^3 = 6^2$,
$1^3 + 2^3 + 3^3 + 4^3 = 10^2$; and in general
$1^3 + 2^3 + 3^3 + n^3 = (1+2+3+n)^2 = \frac{1}{2}n(n+1)$;
where n is the number of the terms or cubes.

6. Every odd square number, when divided by 8, leaves a remainder 1. Or every odd square is of the form $8n+1$.

7. Every even square is of the form $4n$. Therefore no number of the form $4n+2$, or $4n+3$, is a square number.

8. No number of the form $2t^2 \pm 3n^2$, can be a square. No number of the form $2t^2 \backsim 5n^2$ can be a square. The following table shows many of the impossible forms for square number, arranged according to every modulus from 2 to 11; that is, no number contained in any one of these forms can be a square.

TABLE
Of the impossible Forms for square numbers.

In this table it is only necessary to remark that q must always be taken prime to the modulus.

SQUARE *Root*, a number considered as the root of a second power or square number : or a number which multiplied by itself, produces the given number. See EXTRACTION *of Roots*, and also the article ROOT, where tables of squares and roots are inserted.

T. SQUARE, or *Tee* SQUARE, an instrument used in drawing, so called from its resemblance to the capital letter T. This instrument consists of two straight rulers AB and CD, fixed at right angles to each other. To which is sometimes added a third EF, moveable about the pin C, to set it to make any angle with CD.— It is very useful for drawing parallel and perpendicular lines, on the face of a smooth drawing-board.

SQUARED-*square*, SQUARED *cube*, &c. See POWER.

SQUARING. See QUADRATURE.

SQUARING *the Circle*, is the making or finding a square whose area shall be equal to that of a given circle. The best mathematicians have not yet been able to resolve this problem accurately, and perhaps never will. But they can easily come to any proposed degree of approximation whatever; for instance, so near as not to err so much in the area, as a grain of sand would cover, in a circle whose diameter is equal to that of the orbit of Saturn. The following proportion is near enough the truth for any real use, viz, as 1 is to ·88622692, so is the diameter of any circle, to the side of the square of an equal area. Therefore, if the diameter of the circle be called d, and the side of the equal square s;

then is $s = \cdot 88622692d = \frac{39}{44}d$ nearly,

and $d = \frac{s}{\cdot 88622692} = \frac{44}{39}s$ nearly.

See CIRCLE, DIAMETER, and QUADRATURE.

STADIUM, an ancient Greek long measure, said to contain 125 geometrical paces, or 625 Roman feet; corresponding to our furlong. Eight stadia make a geometrical or Roman mile; and 20, according to Dacier, a French league: but according to others, 800 stadia make 41⅔ leagues.—Guilletiere observes, that the stadium was only 600 Athenian feet, which amount to 625 Roman, or 566 French, or 604 English feet: so that the stadium should have been only 113 geometrical paces. It must be observed however, that the stadium was different at different times and places.

Thus, according to the measures of Hipparchus, 769 stades make a degree on a great circle of the earth, or about 11⅙ to the English mile. By the result of Ptolemy's measures 716⅔ stades make a degree, or 10⅜ an English mile. According to Vernon, Stuart, and Chandler, all of whom measured it, the Panathenæan stade was rather more than 600 Greek feet in length. Now the Greek foot is to the English, as 107·29 to 100; therefore the length of that stade was about 604 English feet, or 9⅜ nearly Panathæan stades were equal to an English mile.—For an interesting disquisition on the different kinds of stades, see the Quarterly Review, vol. 5, p. 278 &c.

Eratosthenes, in his measurement of the earth, makes the circumference of it equal to 90,000,000 stadia, or one degree equal to 250,000 stadia. Now if in this valuation we make use of the Egyptian stadium, 60 of which make 3024 toises, we shall have for the length of the degree about 35,000 toises, which is too little by the modern measurement, its true length being about 57050 toises.

The Olympic stadium, it is said, was about 94 feet 3 inches French measure; and supposing this to have been that employed by Eratosthenes, we should have for the length of a terrestrial degree 65625 toises, which is much too great.

It follows therefore, either that we are unacquainted with the true length of the stadium, at least that employed by Eratosthenes, or that this celebrated ancient astronomer was much deceived in his measurement: both of those are probable; and perhaps some of the other stadia, which are mentioned by different authors, are in a great measure the result only of their own imagination: thus, M. Picard, after supposing this measurement of Eratosthenes to be exact, thence deduces the value of the stadium, making it equal to 51 toises 10 inches.

STANLEY (THOMAS), F. R. S. a learned writer, son of Sir Thomas Stanley, of Hertfordshire, died in Westminster April 12, 1678. He studied at Pembroke Hall in the university of Cambridge, with great credit, where he took the degree of A. M. 1640, after which he went on his travels. On his return he entered of the Middle Temple, but did not follow the law. He was one of the early fellows of the Royal Society, being elected in July 1661, and was esteemed a very learned and worthy member. He edited some of the ancient classics, with notes; and published several ingenious poems of his own, as well as some translations. But the work on account of which he claims a place in this Dictionary, is his History of Philosophy and Lives of Philosophers, in folio. This was first published in 3 parts, in 1655, 1656, and 1660. And in 1662 came out his Chaldaic Philosophy also.

STAR, STELLA, in Astronomy, a general name for all the heavenly bodies. The stars are distinguished into fixed and erratic or wandering.

Erratic or *Wandering* STARS, are those which are continually changing their places and distances, with regard to each other. These are what are properly called planets. Though to the same class may likewise be referred comets or blazing stars.

Fixed STARS, called also barely Stars, by way of eminence, are those which have usually been observed to keep the same distance, with regard to each other. The chief circumstances observable in the fixed stars, are their distance, magnitude, number, nature, and motion.

Distance of the Fixed STARS. The fixed stars are so extremely remote from us, that we have no distances in the planetary system to compare to them. Their immense distance appears from hence, that they have no sensible parallax; that is, that the diameter of the earth's annual orbit, which is nearly 190 millions of miles, bears no sensible proportion to their distance.

Mr. Huygens (Cosmotheor. lib. 4) attempts to determine the distance of the stars, by making the aperture of a telescope so small, that the sun through it appears no larger than Sirius; which he found to be only as 1 to 27664 of his diameter, when seen with the naked eye. So that, were the sun's distance 27,664 times as much as it is, it would then be seen of the same diameter with Sirius. And hence, supposing Sirius to be a sun of the same magnitude with our sun, the distance of Sirius will be found to be 27,664 times the distance of the sun, or 345 million times the earth's diameter.

Dr. David Gregory investigated the distance of Sirius by supposing it of the same magnitude with the sun, and of the same apparent diameter with Jupiter in opposition: as may be seen at large in his Astronomy, lib. 3, prop. 47.

Cassini (Mem. Acad. 1717), by comparing Jupiter and Sirius, when viewed through the same telescope, inferred, that the diameter of that planet was 10 times as great as that of the star; and the diameter of Jupiter being 50″, he concluded that the diameter of Sirius was about 5″; supposing then the real magnitude of Sirius to be equal to that of the sun, and the distance of the sun from us 12,000 diameters of the earth, and the apparent diameter of Sirius being to that of the sun as 1 to 384, the distance of Sirius becomes equal to 4,608,000 diameters of the earth.

These methods of Huygens, Gregory, and Cassini, are conjectural and precarious; both because the sun and Sirius are supposed of equal magnitude, and also because it is supposed the diameter of Sirius is determined with sufficient exactness.

Mr. Michell has proposed an inquiry into the probable parallax and magnitude of the fixed stars, from the quantity of light which they afford us, and the peculiar circumstances of their situation. With this view he supposes, that they are, on a medium, equal in magnitude and natural brightness to the sun; and then proceeds to inquire, what would be the parallax of the sun, if he were to be removed so far from us, as to make the quantity of the light, which we should then receive from him, no more than equal to that of the fixed stars. Accordingly, he assumes Saturn in opposition, as equal, or nearly equal in light to the brightest fixed star. As the mean distance of Saturn from the sun is equal to about 2082 of the sun's semidiameters, the density of the sun's light at Saturn will consequently be less than at his own surface, in the ratio of the square of 2082 or 4,334,724 to 1: if Saturn therefore reflected all the light that falls upon him, he would be less luminous in the same proportion. And besides, his apparent diameter, in the opposition, being but about the 105th part of that of the sun, the quantity of light which we receive from him must be again diminished in the ratio of the square of 105 or 11,025 to 1. Consequently, by multiplying these two numbers together, we shall have the whole of the light of the sun to that of Saturn, as the square nearly of 220,000 or 48,400,000,000 to 1. Hence, removing the sun to 220,000 times his present distance, he would still appear at least as bright as Saturn, and his whole parallax upon the diameter of the earth's orbit would be less than 2 seconds: and this must be assumed for the parallax of the brightest of the fixed stars, on the supposition that their light does not exceed that of Saturn.

By a like computation it may be found, that the distance, at which the sun would afford us as much light as we receive from Jupiter, is not less than 46,000 times his present distance, and his whole parallax in that case, on the diameter of the earth's orbit, would not be more than 9 seconds; the light of Jupiter and Saturn, as seen from the earth, being in the ratio of about 22 to 1, when they are both in opposition, and supposing them to reflect equally in proportion to the whole of the light that falls upon them. But if Jupiter and Saturn, instead of reflecting the whole of the light that falls upon them, should really reflect only a part of it, as a 4th, or a 6th, which may be the case, the above distances must be increased in the ratio of 2 or 2½ to 1, to make the sun's light no more than equal to theirs; and his parallax would be less in the same proportion. Supposing then that the fixed stars are of the same magnitude and brightness with the sun, it is no wonder that their parallax should hitherto have escaped observation; since in this case it could hardly amount to 2 seconds, and probably not more than one in Sirius himself, though he had been placed in the pole of the ecliptic; and in those that appear much less luminous, as γ Draconis, which is only of the 3d magnitude, it could hardly be expected to be sensible with such instruments as have hitherto been used. However, Mr. Michell suggests, that it is not impracticable to construct instruments capable of distinguishing even to the 20th part of a second, provided the air will admit of that degree of exactness. This ingenious writer apprehends that the quantity of light which we receive from Sirius, does not exceed the light we receive from the least fixed star of the 6th magnitude, in a greater ratio than that of 1000 to 1, nor less than that of 400 to 1; and the smaller stars of the 2d magnitude seem to be about a mean proportional between the other two. Hence the whole parallax of the least fixed stars of the 6th magnitude, supposing them of the same size and native brightdess with the sun, should be from about 2‴ to 3‴, and their distance from about 8 to 12 million times that of the sun: and the parallax of the smaller stars of the 2d magnitude, on the same supposition, should be about 12‴, and their distance about 2 million times that of the sun.

This author further suggests, that, from the apparent situation of the stars in the heavens, it is highly probable that the stars are collected together in clusters in some places, where they form systems, while in others there are either few or none of them; whether this disposition be owing to their mutual gravitation, or to some other law or appointment of the Creator. Hence it may be inferred, that such double stars, &c, as appear to consist of two or more stars placed very near together, do really consist of stars placed near together, and under the influence of some general law: and he proceeds to inquire whether, if the stars be collected into systems, the sun does not likewise make one of some system, and which fixed stars those are that belong to the same system with him.

Those stars, he apprehends, which are found in clusters, and surrounded by many others at a small distance from them, belong probably to other systems, and not to ours. And those stars, which are surrounded with nebulæ, are probably only very large stars which, on account of their superior magnitude, are singly visible, while the others, which compose the remaining parts of the same system, are so small as to escape our sight. And those nebulæ in which we can discover either none or only a few stars, even with the assistance of the best telescopes, are probably systems that are still more distant than the rest. For other particulars of this inquiry, see Philos. Trans. vol. 57.

As the distance of the fixed stars is best determined by their parallax, various methods have been pursued, though hitherto without success, for investigating it; the result of the most accurate observations having given us little more than a distant approximation; from which however we may conclude, that the nearest of the fixed stars cannot be less than 40 thousand diameters of the whole annual orbit of the earth distant from us.

The method pointed out by Galileo, and attempted by Hooke, Flamsteed, Molyneux, and Bradley, of taking the distances of such stars from the zenith as pass very near it, has given us a more just idea of the immense distance of the stars, and furnished an approximation to their parallax, much nearer the truth, than any we had before.

Dr. Bradley assures us (Philos. Trans. No. 406) that had the parallax amounted to a single second, or two at most, he should have perceived it in the great number of observations which he made, especially upon γ Draconis; and that it seemed to him very probable, that the annual parallax of this star does not amount to a single second, and consequently that it is above 400 thousand times further from us than the sun.

But Dr. Herschel, to whose industry and ingenuity, in exploring the heavens, astronomy is so much indebted, remarks, that the instrument used on this occasion, being the same with the present zenith sectors, can hardly be allowed capable of showing an angle of one or even two seconds, with accuracy: and besides, the star on which the observations were made, is only a bright star of the 3d magnitude, or a small star of the 2d; and that therefore its parallax is probably much less than that of a star of the first magnitude. So that we are not warranted in inferring, that the parallax of the stars in general does not exceed 1″, whereas those of the first magnitude may have, notwithstanding the result of Dr. Bradley's observations, a parallax of several seconds.

As to the method of zenith distances, it is liable to considerable errors, on account of refraction, the change of position of the earth's axis, arising from nutation, precession of the equinoxes, or other causes, and the aberration of light.

Dr. Herschel has proposed another method, by means of double stars, which is free from these errors, and of such a nature, that the annual parallax, even if it should not exceed the 10th part of a second, may still become visible, and be ascertained at least much nearer than heretofore. This method, which was first proposed in an imperfect manner by Galileo, and has been also mentioned by other authors, is capable of every improvement which the telescope and mechanism of micrometers can furnish. To give a general idea of it, let O and E be two opposite points of the annual orbit, taken in the same plane with two stars, A, B, of unequal magnitudes. Let the angle AOB be observed when the earth is at O, and AEB be observed when the earth is at E. From the difference of these angles, when there is any, the parallax of the stars may be computed, according to the theory subjoined. These two stars ought to be as near as possible to each other, and also to differ as much in magnitude as we can find them.

This theory of the annual parallax of double stars, with the method of computing from thence what is usually called the parallax of the fixed stars, or of single stars of the first magnitude, such as are nearest to us, supposes 1st, that the stars are all about the size of the sun; and 2dly, that the difference in their apparent magnitudes, is owing to their different distances, so that a star of the 2d, 3d, or 4th magnitude, is 2, 3, or 4 times as far off as one of the first. These principles, which Dr. Herschel premises as postulata, have so great a probability in their favour, that they will scarcely be objected to by those who are in the least acquainted with the doctrine of chances. See Mr. Michell's Inquiry, &c, already cited. And Philos. Trans. vol. 57, pa. 234 - - - - 240. Also Dr. Halley, on the Number, Order, and Light of the fixed Stars, in the Philos. Trans. vol. 31.

Therefore, let EO be the whole diameter of the earth's annual orbit; and let A, B, C be three stars situated in the ecliptic, in such a manner, that they may appear all in one line OABC when the earth is at O. Now if OA, AB, BC be equal to each other, A will be a star of the first magnitude, B of the second, and C of the third. Let us next suppose the angle OAE, or parallax of the whole orbit of the earth, to be 1″ of a degree; then, because very small angles, having the same subtense EO, may be considered as in the inverse ratio of the lines OA, OB, OC, &c, we shall have EBO = $\frac{1}{2}$″, and ECO = $\frac{1}{3}$″, &c, also because EA = AB nearly, the angle AEB = ABE = $\frac{1}{2}$″; and because BC = $\frac{1}{2}$BO = $\frac{1}{2}$BE nearly, the angle BEC = $\frac{1}{2}$BCE = $\frac{1}{6}$″, and hence AEC = $\frac{1}{2}$ + $\frac{1}{6}$ = $\frac{2}{3}$″; whence it follows that, when the earth is at E, the stars A and B appear at $\frac{1}{2}$″ distant from each other, the stars A and C at $\frac{2}{3}$″ distant, and the stars B and C only $\frac{1}{6}$″ distant. In like manner may be deduced a general expression for the parallax that will become visible in the change of distance between the two stars, by the removal of the earth from one extreme of her orbit to the other. Let P denote the total parallax of a fixed star of the magnitude of the M order, and m the number of the order of a smaller star, p denoting the partial parallax to be observed by the change in the distance of a double star; then is $p = \frac{m - M}{m}P$, or $P = \frac{mp}{m - M}$, which gives P, when p is found by observation.

For Ex. Suppose a star of the 1st magnitude should have a small star of the 12th magnitude near it; then will the partial parallax we are to expect to see be $\frac{12 - 1}{12}P = \frac{11}{12}P$, or $\frac{11}{12}$ of the total parallax of the larger star; and if we should, by observation, find the partial parallax between two such stars to amount to 1″, then will the total parallax $P = \frac{12}{11}p = 1''\frac{1}{11}$. Again, if the stars be of the 3d and 24th magnitude, the total parallax will be $P = \frac{24}{24 - 3}p = \frac{24}{21}p = \frac{8}{7}p$; so that, if by observation p be found to be $\frac{1}{10}$ of a second, the whole parallax P will amount $\frac{8}{70} = 0{\cdot}11428''$.

Further, the stars being still in the ecliptic, suppose they should appear in one line, when the earth is in some other part of her orbit between E and O; then will the parallax be still expressed by the same algebraic formula, and one of the maxima will still lie at E, the other at O; but the whole effect will be divided into two parts, which will be in proportion to each other, as radius − sine to radius + sine, of the star's distance from the nearest conjunction or opposition.

When the stars are any where out of the ecliptic, situated so as to appear in one line OABC perpendicular to EO, the maximum of parallax will still be expressed by $\frac{m-M}{m}P$; but there will arise another additional parallax in the conjunction and opposition, which will be to that which is found 90° before or after the sun, as the sine (s) of the latitude of the stars seen at O, is to radius (1); and the effect of this parallax will be divided into two parts; half of it lying on one side of the large star, the other half on the other side of it. And this latter parallax will also be compounded with the former, so that the distance of the stars in the conjunction and opposition will then be represented by the diagonal of a parallelogram, whose sides are the two semiparallaxes; a general expression for which will be $\frac{m-M}{2m}P\sqrt{1+s^2}$, or $\frac{1}{2}p\sqrt{1+s^2}$.

When the stars are in the pole of the ecliptic, s will be $= 1$, and the last formula becomes $\frac{1}{2}p\sqrt{2} = \cdot 7071p$.

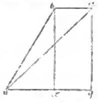
Again, let the stars be at some distance, as 5″, from each other, and let them be both in the ecliptic. This case is resolvable into the first; for imagine the star A to be situated at I; then the angle AEI may be accounted equal to AOI; and as the foregoing formula, $p = \frac{m-M}{m}P$, gives us the angles AEB, AEC, we are to add AEI or 5″ to AEB, which will give IEB. In general, let the distance of the stars be d, and let the observed distance at E be D; then will $D = d + p$, and therefore the whole parallax of the annual orbit will be expressed by $\frac{D-d}{m-M}Dd = P$.

Suppose now the stars to differ only in latitude, one being in the ecliptic, the other at some distance as 5″ north, when seen at O. This case may also be resolved by the former; for imagine the stars B and C to be elevated at right angles above the plane of the figure, so that AOB, or AOC, may make an angle of 5″ at O; then instead of the lines OABC, EA, EB, EC, imagine them all to be planes at right angles to the figure; and it will appear that the parallax of the stars in longitude, must be the same as if the small star had been without latitude. And since the stars B, C, by the motion of the earth from O to E, will not change their latitude, we shall have the following construction for finding the distance of the stars AB and AC at E, and from thence the parallax P.

Let the triangle $ab\beta$ represent the situation of the stars; ab is the subtense of 5″, the angle under which they are supposed to be seen at O. The quantity $b\beta$ by the former theorem is found $= \frac{m-M}{m}P$, which is the partial parallax, that would have been seen by the earth's moving from O to E, if both stars had been in the ecliptic; but, on account of the difference in latitude, it will now be represented by $a\beta$, the hypothenuse of the triangle $ab\beta$: therefore in general, putting $ab = d$, $a\beta = D$, we have

$\frac{m}{m-M}\sqrt{D^2 - d^2} = P$. Hence, D being found by observation, and the three d, m, M given, the total parallax is obtained.

When the stars differ in longitude as well as latitude, this case may be resolved in the following manner. Let the triangle $ab\beta$ represent the situation of the stars, $ab = d$ being their distance seen at O, $a\beta = D$ their distance seen at E. That the change $b\beta$, which is produced by the earth's motion, will be truly expressed by $\frac{m-M}{m}P$, may be proved as before, by supposing the star a to have been placed at α. Now let the angle of position $ba\alpha$ be taken by a micrometer, or by any other method sufficiently exact; then, by resolving the triangle $ab\alpha$, we obtain the longitudinal and latitudinal differences $a\alpha$ and $b\alpha$ of the



two stars. Put $a\alpha = x$, $b\alpha = y$, and it will be $x + b\beta = aq$, whence

$$D = \sqrt{((x + \frac{m-M}{m}P)^2 + y^2)}; \text{ and } P = \frac{\sqrt{(D^2-y^2)}-x}{m-M}m.$$

If neither of the stars should be in the ecliptic, nor have the same longitude or latitude, the last theorem will still serve to calculate the total parallax, whose maximum will lie in E. There will also arise another parallax, whose maximum will be in the conjunction and opposition, which will be divided, and lie on different sides of the large star; but as the whole parallax is extremely small, it is not necessary to investigate every particular case of this kind; for by reason of the division of the parallax, which renders observations taken at any other time, except where it is greatest, very unfavourable, the formula would be of little use.

Dr. Herschel closes his account of this theory, with a general observation on the time and place where the maxima of parallax will happen. Thus, when two unequal stars are both in the ecliptic, or, not being in the ecliptic, have equal latitudes, north or south, and the larger star has most longitude, the maximum of the apparent distance will be when the sun's longitude is 90° more than the star's, or when observed in the morning: and the minimum, when the longitude of the sun is 90° less than that of the star, or when observed in the evening. But when the small star has most longitude, the maximum and minimum, as well as the time of observation, will be the reverse of the former. And when the stars differ in latitude, this makes no alteration in the place of the maximum or minimum, nor in the time of observation; that is, it is immaterial which of the two stars has the greater latitude. Philos. Trans. vol. 72, art. 11.

The distance of the star γ Draconis appears, by Bradley's observations, already recited, to be at least 400,000 times that of the sun, and the distance of the nearest fixed star, not less than 40,000 diameters of the earth's annual orbit: that is, the distance from the earth, of the former at least - - 38,000,000,000,000 miles, and the latter not less than - 7,600,000,000,000 miles. As these distances are immensely great, it may both be amusing, and assist in giving a more familiar idea, to compare them with the velocity of some moving body, by which they may be measured.

The swiftest motion we know of, is that of light, which passes from the sun to the earth in about 8 minutes; and yet even this would be above 6 years traversing the first space, and near a year and a quarter in passing from the nearest fixed star to the earth. But a cannon ball, moving on a medium at the rate of about 20 miles in a minute, would be 3 million 8 hundred thousand years in passing from γ Draconis to the earth, and 760 thousand years in passing from the nearest fixed star. Sound, which moves at the rate of about 13 miles in a minute, would be 5 million 600 thousand years in traversing the former distance, and 1 million 128 thousand, in passing through the latter.

The celebrated Huygens pursued speculations of this kind so far, as to believe it not impossible, that there may be stars at such inconceivable distances, that their light has not yet reached the earth since their creation.

Dr. Halley has also advanced, what he says seems to be a metaphysical paradox (Philos. Trans. number 364), viz, that the number of fixed stars must be more than finite, and some of them at more than a finite distance from others: and Addison has justly observed, that this thought is far from being extravagant, when we consider that the universe is the work of infinite power, prompted by infinite goodness, and having an infinite space to exert itself in; so that our imagination can set no bounds to it.

Magnitude of the fixed STARS. The magnitudes of the stars appear to be very different from one another; which difference may probably arise, partly from a diversity in their real magnitude, but principally from their different distances. To the bare eye, the stars appear of some sensible magnitude, owing to the glare of light arising from the numberless reflections from the aërial particles &c about the eye; this makes us imagine the stars to be much larger than they would appear, if we saw them only by the few rays which come directly from them, so as to enter our eyes without being intermixed with others. Any person may be sensible of this, by looking at a star of the first magnitude through a long narrow tube; which, though it takes in as much of the sky as would hold a thousand such stars, scarce renders that one visible.

The stars, on account of their apparently various sizes, have been distributed into several classes, called magnitudes. The 1st class, or stars of the first magnitude, are those that appear largest, and may probably be nearest to us. Next to these, are those of the 2d magnitude; and so on to the 6th, which comprehends the smallest stars visible to the naked eye. All beyond these, that can be perceived by the help of telescopes, are called telescopic stars. Not that all the stars of each class appear exactly of the same magnitude; there being great difference in this respect; and those of the first magnitude appearing almost all different in lustre and size. There are also other stars, of intermediate magnitudes, which astronomers cannot refer to one class more than another, and therefore they place them between the two. Procyon, for instance, which Ptolemy makes of the first magnitude, and Tycho of the 2d, Flamsteed lays down as between the 1st and 2d. So that, instead of 6 magnitudes, we may say there are almost as many orders of stars, as there are stars; on account of the great variations observable in the magnitude, colour, and brightness of them.

There seems to be but little probability of discovering with certainty the real size of any of the fixed stars; we must therefore be content with an approximation, deduced from their parallax, if this should ever be found; and the quantity of light they afford us, compared with that of the sun. And to this purpose, Dr. Herschel informs us, that with a magnifying power of 6450, and by means of his new micrometer, he found the apparent diameter of α Lyræ to be 0″·355.

The stars are also distinguished, with regard to their situation, into asterisms, or constellations; which are only assemblages of several neighbouring stars, considered as constituting some determinate figure, as of an animal, &c, from which it is therefore denominated; a division as ancient as the book of Job, in which mention is made of Orion, the Pleiades, &c.

Besides the stars thus distinguished into magnitudes and constellations, there are others not reduced to either. Those not reduced into constellations, are called informes, or unformed stars; of which kind several, so left at large by the ancients, have since been formed into new constellations by the modern astronomers, and especially by Hevelius. Those not reduced to classes or magnitudes, are called nebulous stars; but such as only appear faintly in clusters, in form of little lucid spots, nebulæ, or clouds.

Ptolemy mentions five of such nebulæ, viz, one at the extremity of the right hand of Perseus, which appears through the telescope, thick set with stars; one in the middle of the crab, called Præsepe, or the Manger, in which Galileo counted above 40 stars; one unformed near the sting of the Scorpion; another in the eye of Sagittarius, in which two stars may be seen in a clear sky with the naked eye, and several more with the telescope; and the fifth in the head of Orion, in which Galileo counted 21 stars.

Flamsteed observed a cloudy star before the bow of Sagittarius, which consists of a great number of small stars; and the star *d* above the right shoulder of this constellation is encompassed with several more. Flamsteed and Cassini also discovered one between the great and little dog, which is very full of stars, that are visible only by the telescope.

But the most remarkable of all the cloudy stars, is that in the middle of Orion's sword, in which Huygens and Dr. Long observed 12 stars, 7 of which (3 of them, now known to be 4, being very close together) seem to shine through a cloud, very lucid near the middle, but faint and ill defined about the edges. But the greatest discoveries of nebulæ and clusters of stars, we owe to the powerful telescopes of Dr. Herschel, who has given accounts of some thousands of such nebulæ, in many of which the stars seem to be innumerable, like grains of sand on the sea shore, or, as Milton has so beautifully described the milky way, they seem powdered with stars. See Philos. Trans. 1784, 1785, 1786, 1789. See GALAXY, and MAGELLANIC *Clouds*, and *lucid* SPOTS.

Cassini is of opinion, that the brightness of these proceeds from stars so minute, as not to be distinguished by the best glasses: and this opinion is fully confirmed by the observations of Dr. Herschel, whose powerful telescopes show those lucid specks to be composed entirely of masses of small stars, like heaps of sand.

There are also many stars which, though they appear single to the naked eye, are yet discovered by the telescope to be double, triple, &c. Of these, several have been observed by Cassini, Hooke, Long, Maskelyne, Hornsby, Pigott, Mayer, &c; but Dr. Herschel has been much the most successful in observations of this kind; and his success has been chiefly owing to the very extraordinary magnifying powers of the Newtonian 7 feet reflector which he has used, and the advantage of an excellent micrometer of his own construction. The powers which he has used, have been 146, 227, 278, 460, 754, 932, 1159, 1536, 2010, 3168, and even 6450. He has already formed a catalogue, containing 269 double stars, 227 of which, as far as he knows, have not been noticed by any other person. Among these there are also some stars that are treble, double-double, quadruple, double-treble, and multiple. His catalogue comprehends the names of the stars, and the number in Flamsteed's catalogue, or such a description of those that are not contained in it, as will be found sufficient to distinguish them; also the comparative size of the stars; their colours as they appeared to his view; their distances determined in several different ways; their angle of position with regard to the parallel of declination; and the dates when he first perceived the stars to be double, treble, &c. His observations appear to commence with the year 1776, but almost all of them were made in the years 1779, 1780, 1781.

Dr. Herschel has distributed the double stars contained in his catalogue, into 6 different classes. In the first he has placed all those which require a very superior telescope, with the utmost clearness of air, and every other favourable circumstance, to be seen at all, or well enough to judge of them; and there are 24 of these. To the 2d class belong all those double stars that are proper for estimations by the eye, and very delicate measures by the micrometer; the number being 38. The 3d class comprehends all those double stars, that are between 5" and 15" asunder; the number of them being 46. The 4th, 5th, and 6th classes contain double stars that are from 15" to 30", and from 30" to 1', and from 1' to 2' or more asunder; of which there are 44 in the 4th class, 51 in the 5th class, and 66 in the 6th class: the last of this class is α Tauri, number 87 of Flamsteed, whose apparent diameter, on the meridian measured with a power of 460 at a mean of two observations 1" 46‴, and with a power of 932 at a mean of two observations 1" 12‴. See the list at large, Philos. Trans. vol. 72, art. 12.

The stars are also distinguished, in each constellation, by numbers, or by the letters of the alphabet. This kind of distinction was introduced by John Bayer, in his Uranomettia, 1654; where he denotes the stars, in each constellation, by the letters of the Greek alphabet, α, β, γ, δ, ϵ, &c, viz, the most remarkable star of each by α, the 2d by β, the 3d by γ, &c; and when there are more stars in a constellation than the characters in the Greek alphabet, he denotes the rest, in their order, by the Roman letters A, b, c, d, &c. But as the number of the stars, that have been observed and registered in catalogues, since Bayer's time, is greatly increased, as by Flamsteed and others, the additional ones have been marked by the ordinal numbers 1, 2, 3, 4, 5, &c.

The *Number of* STARS. The number of the stars appears to be immensely great, perhaps infinite; yet have astronomers long since ascertained the number of such as are visible to the eye, which are much fewer than at first sight could be imagined. See CATALOGUE *of the Stars*.—Of the 3000 contained in Flamsteed's catalogue, there are many that are only visible through a telescope; and a good eye scarce ever sees more than a thousand at the same time in the clearest heaven; the appearance of that immense number which are frequent in clear winter nights, arising from our sight's being deceived by their twinkling, and from our viewing them confusedly, and not reducing them to any order. But nevertheless we cannot but imagine that the stars are almost, if not altogether, infinite. See Halley, on the number, order, and light of the fixed stars, Philos. Trans. number 364.

Riccioli, in his New Almagest, affirms, that a man who shall say there are above 20 thousand times 20 thousand, would say nothing improbable. For a good telescope, directed indifferently to almost any point of the heavens, discovers multitudes that are lost to the naked eye; particularly in the milky way, which some take to be an assemblage of stars, too remote to be seen singly, but so closely disposed as to give a luminous appearance to that part of the heavens where they are. And this fact has been confirmed by Herschel's observations: though it is disputed by others, who contend that the milky way must be owing to some other cause.

In the single constellation of the Pleiades, instead of 6, 7, or 8 stars seen by the best eye; Dr. Hooke, with a telescope 12 feet long, told 78, and with larger glasses many more, of different magnitudes. And F. de Rheita affirms, that he has observed above 2000 stars in the single constellation of Orion. The same author found above 188 in the Pleiades. And Huygens, looking at the star in the middle of Orion's sword, instead of one, found that there were 12. Galileo found 80 in the space of the belt of Orion's sword, 21 in the nebulous star of his head, and above 500 in another part of him, within the compass of one or two degrees space, and more than 40 in the nebulous star Præsepe.

The Changes that have happened in the STARS are very considerable. The first change that is on record, was about 120 years before Christ; when Hipparchus, discovering a new star to appear, was first induced to make a catalogue of the stars, that posterity might perceive any future changes of the like nature.

In the year 1572, Cornelius Gemma and Tycho Brahé observed another new star in the constellation Cassiopeia, which was likewise the occasion of Tycho's making a new catalogue. At first its magnitude and brightness exceeded the largest of the stars, Sirius and Lyra; and even equalled the planet Venus when nearest the earth, and was seen in fair day-light. It continued 16 months; towards the latter end of which it began to dwindle, and at length, in March 1574, it totally disappeared, without any change of place in all that time.

Leovicius tells us of another star appearing in the same constellation, about the year 945, which resembled that of 1572; and he quotes another ancient observation, by which it appears that a new star was seen about the same place in 1264. Dr. Keil thinks these were all the same star; and indeed the periodical intervals, or distance of time between these appearances, were nearly equal, being from 318 to 319 years; and if so, its next appearance may be expected about 1890.

Fabricius, in 1596, discovered another new star, called the stella mira, or wonderful star, in the neck of the whale, which has since been found to appear and disappear periodically, 7 times in 6 years, continuing in its greatest lustre for 15 days together; and is never quite extinguished. Its course and motion are described by Bulliald, in a treatise printed at Paris in 1667. Dr. Herschel has lately, viz, in the years 1777, 1778, 1779, and 1780, made several observations on this star, an account of which may be seen in the Philos. Trans. vol. 70, art. 21.

In the year 1600, William Jansen discovered a changeable star in the neck of the Swan, which gradually decreased till it became so small as to be thought to disappear entirely, till the years 1657, 1658, and 1659, when it regained its former lustre and magnitude; but soon decayed again, and is now of the smallest size.

In the year 1604, a new star was seen by Kepler, and several of his friends, near the heel of the right foot of Serpentarius, which was particularly bright and sparkling; and it was observed to be every moment changing into some of the colours of the rainbow, except when it is near the horizon, at which time it was generally white. It surpassed Jupiter in magnitude, but was easily distinguished from him, by the steady light of the planet. It disappeared about the end of the year 1605, and has not been seen since that time.

Simon Marius discovered another in Andromeda's girdle, in 1612 and 1613; though Bulliald says it had been seen before, in the 15th century.

In July 1670, Hevelius discovered a second changeable star in the Swan, which was so diminished in October as to be scarce perceptible. In April following it regained its former lustre, but wholly disappeared in August. In March 1672 it was seen again, but appeared very small, and has not been visible since.

In 1686 a third changeable star was discovered by Kirchius in the Swan, viz, the star χ of that constellation, which returned periodically in about 405 days.

In 1672 Cassini saw a star in the neck of the Bull, which he thought was not visible in Tycho's time, nor when Bayer made his figures.

It is certain, from the old catalogues, that many of the ancient stars are not now visible. This has been particularly remarked with regard to the Pleiades.

M. Montanari, in his letter to the Royal Society in 1670, observes that there are now wanting in the heavens two stars of the 2d magnitude, in the stern of the ship Argo, and its yard, which had been seen till the year 1664. When they first disappeared is not known; but he assures us there was not the least glimpse of them in 1668. He adds, that he has observed many more changes in the fixed stars, even to the number of a hundred. And many other changes of the stars have been noticed by Cassini, Maraldi, and other observers. See Gregory's Astron. lib. 2, prop. 30.

But the greatest numbers of variable stars have been observed of late years, and the most accurate observations made on their periods, &c, by Herschel, Goodricke, Pigott, &c, in the late volumes of the Philos. Trans. particularly in the vol. for 1786, where the last of these gentlemen has given a catalogue of all that have been hitherto observed, with accounts of the observations that have been made upon them.

Various hypotheses have been devised to account for such changes and appearances in the stars. It is not probable they could be comets, as they had no parallax, even when largest and brightest. It has been supposed that the periodical stars have vast dark spots, or dark sides, and very slow rotations on their axes, by which means they must disappear when the darker side is turned towards us. And as for those which break out suddenly with such lustre, these may perhaps be suns whose fuel is almost spent, and again supplied by some of their comets falling upon them, and occasioning an uncommon blaze and splendor for some time; which it is conjectured may be one use of the cometary part of our system.

Maupertuis, in his Dissertation on the Figures of the Celestial Bodies (pa. 61—63), is of opinion that some stars, by their prodigious swift rotation on their axes, may not only assume the figures of oblate spheroids, but that by the great centrifugal force arising from such rotations, they may become of the figures of mill-stones, or be reduced to flat circular planes, so thin as to be quite invisible when their edges are turned towards us, as Saturn's ring is in such position. But when very excentric planets or comets go round any flat star in orbits much inclined to its equator, the attraction of the planets or comets in their perihelions must alter the inclination of the axis of that star; on which account it will appear more or less large and luminous, as its broad side is more or less turned towards us. And thus he imagines we may account for the apparent changes of magnitude and lustre of those stars, and also for their appearing and disappearing.

Hevelius apprehends (Cometograph. pa. 380), that the sun and stars are surrounded with atmospheres, and that by whirling round their axes with great rapidity, they throw off great quantities of matter into those atmospheres, and so cause great changes in them; and that thus it may come to pass that a star, which, when its atmosphere is clear, shines out with great lustre, may at another time, when it is full of clouds and thick vapours, appear greatly diminished in brightness and magnitude, or even become quite invisible.

Nature of the fixed STARS. The immense distance of the stars leaves us greatly at a loss about the nature of them. What we can gather for certain from their phenomena, is as follows: 1st, That the fixed stars are greater than our earth: because if that were not the case, they could not be visible at such an immense distance. 2nd, The fixed stars are farther distant from the earth than the farthest of the planets. For we frequently find the fixed stars hid behind the body of the planets: and besides, they have no parallax, which the planets have. 3rd, The fixed stars shine with their own light; for they are much farther from the sun than Saturn, and appear much smaller than Saturn; but since, notwithstanding this, they are found to shine much brighter than that planet, it is evident they cannot borrow their light from the same source as Saturn does, viz, the sun; but since we know of no other luminous body beside the sun, whence they might derive their light, it follows that they shine with their own native light.

Besides, it is known, that the more a telescope magnifies, the less is the aperture through which the star is seen; and consequently, the fewer rays it admits into the eye. Now since the stars appear less in a telescope which magnifies two hundred times, than they do to the naked eye, insomuch that they seem to be only indivisible points, it proves at once that the stars are at immense distances from us, and that they shine by their own proper light. If they shone by borrowed light, they would be as invisible without telescopes as the satellites of Jupiter are; for these satellites appear larger when viewed with a good telescope than the largest fixed stars. Hence, 1. We deduce, that the fixed stars are so many suns; for they have all the characters of suns. 2. That in all probability the stars are not smaller than our sun. 3. That it is highly probable each star is the centre of a system, and has planets or earths revolving round it, in the same manner as round our sun, i. e. it has opaque bodies illuminated, warmed, and cherished by its light and heat. As we have incomparably more light from the moon than from all the stars together, it is absurd to imagine that the stars were made for no other purpose than to cast a faint light upon the earth; especially since many more require the assistance of a good telescope to find them out, than are visible without that instrument. Our sun is surrounded by a system of planets and comets, all which would be invisible from the nearest fixed star; and from what we already know of the immense distance of the stars, it is easy to infer, that the sun, seen from such a distance, would appear no larger than a star of the first magnitude.

From all this it is highly probable, that each star is a sun to a system of worlds moving round it, though unseen by us; especially as the doctrine of a plurality of worlds is rational, and greatly manifests the power, the wisdom, and the goodness of the great Creator. How immense, then, does the universe appear! Indeed, it must either be infinite, or infinitely near it.

Kepler, it is true, denies that each star can have its system of planets as ours has; and takes them all to be fixed in the same surface or sphere; urging, that were one twice or thrice as remote as another, it would be twice or thrice as small, supposing their real magnitudes equal; whereas there is no difference in their apparent magnitudes, justly observed, at all. But to this it is opposed, that Huygens has not only shown, that fires and flames are visible at distances where other bodies, comprehended under equal angles, disappear; but it should likewise seem, that the optic theorem about the apparent diameters of objects, being reciprocally proportional to their distances from the eye, does only hold while the object has some sensible ratio to its distance.

For periodical stars, &c, see CHANGES, *&c, of Stars*, supra.

Motion of the STARS. The fixed stars have several kinds of apparent motion; one called the first, common, or diurnal motion, arising from the earth's rotation about its axis; and by which they seem to be carried along with the sphere or firmament, in which they appear fixed, round the earth, from east to west, in the space of 24 hours.

The other, called the second, or proper motion, is that by which they appear to go backwards from west to east, round the poles of the ecliptic, with an exceeding slow motion, as describing a degree of their circle only in the space of 71½ years, or 50¼ seconds in a year. This apparent motion is owing to the recession of the equinoctial points, which is 50¼ seconds of a degree in a year backward, or contrary to the order of the signs of the zodiac. In consequence of this second motion, the longitude of the stars will be always increasing. Thus, for example, the longitude of Cor Leonis was found at different periods, to be as follows: viz,

	Year.	Long.
By Ptolemy, in	138 to be	2° 30′
By the Persians, in	1115	17 30
By Alphonsus, in	1364	20 40
By Prince of Hesse, in	1586	24 11
By Tycho, in	1601	24 17
By Flamsteed, in	1690	25 31½

Whence the proper motion of the stars, according to the order of the signs, in circles parallel to the ecliptic, is easily inferred.

It was Hipparchus who first suspected this motion, on comparing his own observations with those of Timocharis and Aristyllus. Ptolemy, who lived three centuries after Hipparchus, demonstrated the same by undeniable arguments. The increase of longitude in a century, as stated by different astronomers, is as follows:

By Tycho Brahé	1°	25′	0″
Copernicus	1	23	40½
Flamsteed and Riccioli	1	23	20
Bulliald	1	24	54
Hevelius	1	24	46½
Dr. Bradley, &c.	1	23	55

which is at the rate of 50¼ seconds per year.

From these data, the increase in the longitude of a star for any given time, is easily found, and thence its longitude at any time: ex. gr. the longitude of Sirius, in Flamsteed's tables, for the year 1690, being 9° 49′ 1″, its longitude for the year 1800, is found by multiplying the interval of time, viz, 110 years, by 50¼, the product 5537″, or 1° 32′ 17″, added to the given longitude 9° 49′ 1″ gives the longitude 11° 21′ 18″ for the year 1800.

The chief phenomena of the fixed stars, arising from their common and proper motion, besides their longitude, are their altitudes, right ascensions, declinations, occultations, culminations, risings, and settings.

Some have supposed that the latitudes of the stars are invariable. But this supposition is founded on two assumptions, which are both controverted among astronomers. The one of these is, that the orbit of the earth continues unalterably in the same plane, and consequently that the ecliptic is invariable; the contrary of which is now very generally allowed.

The other assumption is, that the stars are so fixed as to keep their places immoveably. Ptolemy, Tycho, and others, comparing their observations with those of the ancient astronomers, have adopted this opinion. But from the result of the comparison of the best modern observations, with such as were formerly made with any tolerable degree of exactness, there appears to have been a real change in the position of some of the fixed stars, with respect to each other; and several stars of the first magnitude have already been observed, and others suspected, to have a proper motion of their own.

Dr. Halley (Philos. Trans. No. 355), has observed, that the three following stars, the Bull's eye, Sirius, and Arcturus, are now found to be above half a degree more southerly than the ancients reckoned them: that this difference cannot arise from the errors of the transcribers, because the declinations of the stars, set down by Ptolemy, as observed by Timocharis, Hipparchus, and himself, show their latitudes given by him are such as those authors intended: and it is scarce to be believed that those three observers could be deceived in so plain a matter. To this he adds, that the bright star in the shoulder of Orion has, in Ptolemy, almost a whole degree more southerly latitude than at present: that an ancient observation, made at Athens in the year 509, as Bulliald supposes, of an appulse of the moon to the Bull's eye, shows that star to have had less latitude at that time than it now has: that as to Sirius, it appears by Tycho's observations, that he found him 4½′ more northerly than he is at this time. All these observations, compared together, seem to favour an opinion, that some of the stars have a proper motion of their own, which changes their places in the sphere of the heavens: this change of place, as Dr. Halley observes, may show itself in so long a time as 1800 years, though it be entirely imperceptible in the space of one single century; and it is likely to be soonest discovered in such stars as those just now mentioned; because they are all of the first magnitude, and may, therefore, probably be some of the nearest to our solar system. Arcturus, in particular, affords a strong proof of this: for if its present declination be compared with its place, as determined either by Tycho or Flamsteed, the difference will be found to be much greater than what can be suspected to arise from the uncertainty of their observations. See ARCTURUS, and Mr. Hornsby's inquiry into the quantity and direction of the proper motion of Arcturus, Phil. Trans. vol. 63, part 1, pa 93, &c.

For an account of Dr. Bradley's observations, see the sequel of this article, also ABERRATION.

Dr. Herschel has also lately observed, that the distance of the two stars forming the double star γ Draconis, is

54″ 48‴, and their position 44° 19′ N. preceding. Whereas, from the right ascension and declination of these stars in Flamsteed's catalogue, their distance, in his time, appears to have been 1′ 11″·418, and their position 44° 23′ N. preceding. Hence he infers, that as the difference in the distance of these two stars is so considerable, we can hardly account for it, otherwise than by admitting a proper motion in one or the other of the stars, or in our solar system: most probably he says, neither of the three is at rest. He also suspects a proper motion in one of the double stars, in Cauda Lyncis Media, and in e Ceti. Phil. Trans. vol. 72, part 1, pa. 117, 143, 150.

It is reasonable to expect, that other instances of the like kind must also occur among the great number of visible stars, because their relative positions may be altered by various means. For if our own solar system be conceived to change its place with respect to absolute space, this might, in process of time, occasion an apparent change in the angular distances of the fixed stars; and in such a case, the places of the nearest stars being more affected than of those that are very remote, their relative position might seem to alter, though the stars themselves were really immoveable; and vice versa, we may surmise from the observed motion of the stars, that our sun, with all its planets and comets, may have a motion towards some particular part of the heavens, on account of a greater quantity of matter collected in a number of stars and their surrounding planets there situated, which may perhaps occasion a gravitation of our whole solar system towards it. If this surmise should have any foundation, as Dr. Herschel observes, ubi supra, pa. 103, it will show itself in a series of some years; since from that motion there will arise another kind of hitherto unknown parallax (suggested by Mr. Michell, Philos. Trans. vol. 57, pa. 252), the investigation of which may account for some part of the motions already observed in some of the principal stars; and for the purpose of determining the direction and quantity of such a motion, accurate observations of the distance of stars, that are near enough to be measured with a micrometer, and a very high power of telescopes, may be of considerable use, as they will undoubtedly give us the relative places of those stars to a much greater degree of accuracy than they can be had by instruments or sectors, and thereby much sooner enable us to discover any apparent change in their situation, occasioned by this new kind of secular or systematical parallax, if we may so express the change arising from the motion of the whole solar system.

And, on the other hand, if our system be at rest, and any of the stars really in motion, this might likewise vary their apparent positions, and the more so, the nearer they are to us, or the swifter their motions are; or the more proper the direction of the motion is to be rendered perceptible by us. Since then the relative places of the stars may be changed from such a variety of causes, considering the amazing distance at which it is certain some of them are placed, it may require the observations of many ages to determine the laws of the apparent changes, even of a single star; much more difficult, therefore, must it be to settle the laws relating to all the most remarkable of them.

When the causes which affect the places of all the stars in general are known; such as the precession, aberration, and nutation, it may be of singular use to examine nicely the relative situations of particular stars, and especially of those of the greatest lustre, which, it may be presumed, lie nearest to us, and may therefore be subject to more sensible changes, either from their own motion, or from that of our system. And if, at the same time the brighter stars are compared with each other, we may likewise determine the relative positions of some of the smallest that appear near them, whose places can be ascertained with sufficient exactness, we may perhaps be able to judge to what cause the change is owing, if any be observable. The uncertainty that we are at present under, with respect to the degree of accuracy with which former astronomers could observe, makes us unable to determine several things relating to this subject; but the improvements, which have of late years been made in the methods of taking the places of the heavenly bodies, are so great, that a few years may hereafter be sufficient to settle some points, which cannot now be settled; by comparing even the earliest observations with those of the present age.

Dr. Hooke communicated several observations on the apparent motions of the fixed stars; and as this was a matter of great importance in astronomy, several of the learned were desirous of verifying and confirming his observations. An instrument was accordingly contrived by Mr. George Graham, and executed with surprising exactness.

With this instrument the star γ, in the constellation Draco, was frequently observed by Messrs. Molyneux, Bradley, and Graham, in the years 1725, 1726; and the observations were afterwards repeated by Dr. Bradley with an instrument contrived by the same ingenious person, Mr. Graham, and so exact, that it might be depended on to half a second. The result of these observations was, that the star did not always appear in the same place, but that its distance from the zenith varied, and that the difference of the apparent places amounted to 21 or 22 seconds. Similar observations were made on other stars, and a like apparent motion was found in them, proportional to the latitude of the star. This motion was by no means such as was to have been expected, as the effect of a parallax, and it was some time before any way could be found of accounting for this new phenomenon. At length Dr. Bradley resolved all its variety, in a satisfactory manner, by the motion of light and the motion of the earth compounded together. See Aberration and Light, and Phil. Trans. No. 406, pa. 364.

That excellent astronomer had no sooner discovered the cause, and settled the laws of aberration of the fixed stars, than his attention was again excited by another new phenomenon, viz. an annual change of declination in some of the fixed stars, which appeared to be sensibly greater than a precession of the equinoctial points, of 50¼″ in a year, would have occasioned. This apparent change of declination was observed in the stars near the equinoctial colure; and there appearing at the same time an effect of a quite contrary nature, in some stars near the solstitial colure, which seemed to alter their declination less than a precession of 50″ required, Dr. Bradley was thereby convinced, that all the phenomena in the different stars could not be accounted for merely by supposing that he had assumed a wrong quantity for the precession of the equinoctial points. He had also, after many trials, sufficient reason to conclude, that these second unexpected deviations of the stars were not owing to any imperfection of his instruments. At length, from repeated observations he began to guess at the real cause of these phenomena.

It appeared from the Doctor's observations, during his residence at Wansted, from the year 1727 to 1732, that some of the stars near the solstitial colure had changed their declinations 9″ or 10″ less than a precession of 50″ would have produced; and, at the same time, that others near the equinoctial colure had altered theirs about the same quantity more than like a precession would have occasioned: the north pole of the equator seeming to have approached the stars, which come to the meridian with the sun about the vernal equinox, and the winter solstice; and to have receded from those which come to the meridian with the sun about the autumnal equinox and the summer solstice.

From the consideration of these circumstances, and the situation of the ascending node of the moon's orbit when he first began to make his observations, he suspected that the moon's action on the equatorial parts of the earth might produce these effects. For if the precession of the equinox be, according to Sir Isaac Newton's principles, caused by the actions of the sun and moon on those parts; the plane of the moon's orbit, being at one time, above 10 degrees more inclined to the plane of the equator, than at another, it was reasonable to conclude, that the part of the whole annual precession which arises from her action, would, in different years, be varied in its quantity; whereas the plane of the ecliptic, in which the sun appears, keeping always nearly the same inclination to the equator, that part of the precession which is owing to the sun's action, may be the same every year; and from hence it would follow, that though the mean annual precession, proceeding from the joint actions of the sun and moon, were 50″; yet the apparent annual precession might sometimes exceed, and sometimes fall short of that mean quantity, according to the various situations of the nodes of the moon's orbit.

In the year 1727, the moon's ascending node was near the beginning of Aries, and consequently her orbit was as much inclined to the equator as it can at any time be; and then the apparent annual precession was found, by the Doctor's first year's observations, to be greater than the mean; which proved, that the stars near the equinoctial colure, whose declinations are most of all affected by the precession, had changed theirs, above a tenth part more than a precession of 50″ would have caused. The succeeding year's observations proved the same thing; and, in three or four years' time, the difference became so considerable as to leave no room to suspect it was owing to any imperfection either of the instrument or observation.

But some of the stars, that were near the solstitial colure, having appeared to move, during the same time, in a manner contrary to what they ought to have done by an increase of the precession; and the deviations in them being as remarkable as in the others, it was evident that something more than a mere change in the quantity of the precession would be requisite to solve this part of the phenomenon. On comparing the observations of stars near the solstitial colure, that were almost opposite to each other in right ascension, they were found to be equally affected by this cause. For whilst γ Draconis appeared to have moved northward, the small star, which is the 35th Camelopardali Hevelii, in the British catalogue, seemed to have gone as much towards the south; which showed, that this apparent motion in both those stars might proceed from a nutation of the earth's axis; whereas the comparison of the Doctor's observations of the same stars formerly enabled him to draw a different conclusion, with respect to the cause of the annual alterations arising from the motion of light. For the apparent alteration in γ Draconis, from that cause, being as large again as in the other small star, proved, that that did not proceed from a nutation of the earth's axis; as, on the contrary, this might.

On making the like comparison between the observations of other stars, that lie nearly opposite in right ascension, whatever their situations were with respect to the cardinal points of the equator, it appeared, that their change of declination was nearly equal, but contrary; and such as a nutation or motion of the earth's axis would effect.

The moon's ascending node being now returned to the beginning of Capricorn in the year 1732, the stars near the equinoctial colure appeared about that time to change their declinations no more than a precession of 50″ required; while some of those near the solstitial colure altered theirs above 2″ in a year less than they ought. Soon after the annual change of declination of the former was perceived to be diminished, so as to become less than 50″ of precession would cause; and it continued to diminish till the year 1736, when the moon's ascending node was about the beginning of Libra, and her orbit had the least inclination to the equator. But by this time, some of the stars near the solstitial colure had altered their declinations 18″ less since the year 1727, than they ought to have done from a precession of 50″. For γ Draconis, which in those 9 years would have gone about 8″ more southerly, was observed, in 1736, to appear 10″ more northerly than it did in the year 1727.

As this appearance in γ Draconis indicated a diminution of the inclination of the earth's axis to the plane of the ecliptic, and as several astronomers had supposed that inclination to diminish regularly; if this phenomenon depended on such a cause, and amounted to 18″ in 9 years, the obliquity of the ecliptic would, at that rate, alter a whole minute in 30 years; which is much faster than any observations before made would allow. The Doctor had therefore reason to think, that some part of this motion at least, if not the whole, was owing to the moon's action on the equatorial parts of the earth, which he conceived might cause a libratory motion of the earth's axis. But as he was unable to judge, from only 9 years' observation, whether the axis would entirely recover the same position that it had in the year 1727, he found it necessary to continue his observations through a whole period of the moon's nodes; at the end of which he had the satisfaction to see, that the stars returned into the same positions again, as if there had been no alteration at all in the inclination of the earth's axis; which fully convinced him, that he had guessed rightly as to the cause of the phenomenon. This circumstance proves likewise, that if there be a gradual diminution of the obliquity of the ecliptic, it does not arise only from an alteration in the position of the earth's axis, but rather from some change in the plane of the ecliptic itself; because the stars, at the end of the period of the moon's nodes, appeared in the same places, with respect to the equator, as they ought to have done if the earth's axis had retained the same inclination to an invariable plane.

The Doctor having communicated these observations, and his opinion of their cause, to the late Mr. Machin, that excellent geometrician soon after sent him a table, containing the quantity of the annual precession in the various positions of the moon's nodes, as also the corresponding nutations of the earth's axis; which was computed on the supposition that the mean annual precession is 50″, and that the whole is governed by the pole of the moon's orbit only; and therefore Mr. Machin imagined, that the numbers in the table would be too large, as, in fact, they were found to be. But it appeared that the changes which Dr. Bradley had observed, both in the annual precession and nutation, kept the same law, as to increasing and decreasing, with the numbers of Mr. Machin's table. Those were calculated on the supposition, that the pole of the equator, during a period of the moon's nodes, moved round in the periphery of a little circle, whose centre was 23° 29′ distant from the pole of the ecliptic; having itself also an angular motion of 50″ in a year about the same pole. The north pole of the equator was conceived to be in that part of the small circle which is farthest from the north pole of the ecliptic, at the same time when the moon's ascending node is in the beginning of Aries; and in the opposite point of it, when the same node is in Libra.

If the diameter of the little circle, in which the pole of the equator moves, be supposed equal to 18″, which is the whole quantity of the nutation, as collected from Dr. Bradley's observations of the star γ Draconis, then all the phenomena of the several stars which he observed will be very nearly solved by this hypothesis. But for the particulars of his solution, and the application of his theory to the practice of astronomy, we must refer to the excellent author himself; our intention being only to give the history of the invention.

The corrections arising from the aberration of light, and from the nutation of the earth's axis, must not be neglected in astronomical observations; since such neglects might produce errors of near a minute in the polar distance of some stars. As to the allowance to be made for the aberration of light, Dr. Bradley assures us, that having again examined those of his own observations, which were most proper to determine the transverse axis of the ellipsis, which each star seems to describe, he found it to be nearest to 40″: and this is the number he makes use of in his computations relating to the nutation. Dr. Bradley says, in general, that experience has taught him, that the observations of such stars as lie nearest the zenith, generally agree best with one another, and are therefore fittest to prove the truth of any hypothesis. Phil. Trans. num. 485, vol. 45, pa. 1, &c. See our article Nutation.

M. Dalembert has published a treatise, entitled, Recherches sur la Precession des Equinoxes, et sur la Nutation de la Terre dans le Systeme Newtonien, 4to. Paris, 1749. The calculations of this learned gentleman agree in general with Dr. Bradley's observations. But M. Dalembert finds, that the pole of the equator describes an ellipsis in the heavens, the ratio of whose axes is that of 4 to 3; whereas, according to Dr. Bradley, the curve described is either a circle or an ellipsis, the ratio of whose axis is as 9 to 8.

The several stars in each constellation, as in Taurus, Bootes, Hercules, &c, see under the proper article of each constellation, Taurus, Bootes, Hercules, &c.—To learn to know the several fixed stars by the globe, see Globe.

Circumpolar Stars. See Circumpol r.

Morning Star. See Morning.

Place of a Star. See Place.

Pole Star. See Pole.

Twinkling of the Stars. See Twinkling.

Unformed Stars. See Informes.

Catalogues of the stars, with their situations in right-ascension and declination, may be seen in Mr. Vince's and most other books on Astronomy; also in Zach's and Wollaston's tables, and the French Connoissance des Tems, &c.

Star, in Electricity, denotes the appearance of the electric matter on a point into which it enters. Beccaria supposes that the Star is occasioned by the difficulty with which the electric fluid is extricated from the air, which is an electric substance. See Brush.

Star, in Fortification, denotes a small fort, having 5 or more points, or saliant and re-entering angles, flanking one another, and their faces 90 or 100 feet long.

Star, in Pyrothechny, a composition of combustible matters; which being borne, or thrown aloft into the air, exhibits the appearance of a real star.—Stars are chiefly used as appendages to rockets, a number of them being usually inclosed in a conical cap, or cover, at the head of the rocket, and carried up with it to its utmost height, where the stars, taking fire, are spread around, and exhibit an agreeable spectacle.

To make Stars.—Mix 3lbs of saltpetre, 11 ounces of sulphur, one of antimony, and 3 of gunpowder dust: or, 12 ounces of sulphur, 6 of saltpetre, 5½ of gunpowder dust, 4 of olibanum, one of mastic, camphor, sublimate of mercury, and half an ounce of antimony and orpiment. Moisten the mass with gumwater, and make it into little balls, of the size of a chesnut; which dry either in the sun, or in the oven. These being set on fire in the air, will represent stars.

Star-*Board* denotes the right hand side of a ship, when a person on board stands with the face looking forward towards the head or fore part of the ship. In contradistinction from Larboard, which denotes the left hand side of the ship in the same circumstances.—They say, Starboard the helm, or Helm a starboard, when the man at the helm should put the helm to the right hand side of the ship.

Falling Star, or *Shooting* Star, a luminous meteor darting rapidly through the air, and resembling a Star falling.—The explication of this phenomenon has puzzled all philosophers, till the modern discoveries in electricity have led to the most probable account of it. Signior Beccaria makes it pretty evident, that it is an electrical appearance, and recites the following fact in proof of it. About an hour after sunset, he and some friends that were with him, observed a falling star directing its course towards them, and apparently growing larger and larger, but it disappeared not far from them; when it left their faces, hands, and clothes, the earth, and all the neighbouring objects, suddenly illuminated with a diffused and lambent light, not attended with any noise at all. During their surprise at this appearance, a servant informed them that he had seen a light shine suddenly in the garden, and especially upon the streams which he was throwing to water it. All these appearances were evidently electrical; and Beccaria was confirmed in his conjecture, that electricity was the cause of them, by the quantity of electric matter which he had seen gradually advancing towards his kite, which had very much the appearance of a falling star. Sometimes also he saw a kind of glory round the kite, which followed it when it changed its place, but left some light, for a small space of time, in the place it had quitted. Priestley's Elect. vol. 1, pa. 434, 8vo. See IGNIS *Fatuus*.

STAR-*fort*, or *Redoubt*, in Fortification. See STAR, REDOUBT, and FORT.

STARLINGS, or STERLINGS, or *Jettees*, a kind of case made about a pier built on stilts, &c, to secure it. See STILTS.

STATICS, a branch of mathematics which considers weight or gravity, and the motion of bodies resulting from it. Those who define mechanics, the science of motion, make statics a part of it; viz, that part which considers the motion of bodies arising from gravity. Others make them two distinct doctrines; restraining mechanics to the doctrine of motion and weight, as depending on, or connected with, the power of machines; and statics to the doctrine of motion, considered merely as arising from the weight of bodies, without any immediate respect to machines. In this way, statics should be the doctrine or theory of motion; and mechanics, the application of it to machines.

For the laws of statics, see GRAVITY, DESCENT, &c.

STATION, or STATIONARY, in Astronomy, the position or appearance of a planet in the same point of the zodiac, for several days. This happens from the observer being situated on the earth, which is far out of the centre of their orbits, by which they seem to proceed irregularly; being sometimes seen to go forwards, or from west to east, which is their natural direction; sometimes to go backwards, or from east to west, which is their retrogradation; and between these two states there must be an intermediate one, where the planet appears neither to go forwards nor backwards, but to stand still, and keep the same place in the heavens, which is called her Station, and the planet is then said to be Stationary.

Apollonius Pergæus has shown how to find the stationary point of a planet, according to the old theory of the planets, which supposes them to move in epicycles; which was followed by Ptolemy in his Almag. lib. 12, cap. 1, and others, till the time of Copernicus. Concerning this, see Regiomontanus in Epitome Almagesti, lib. 12, prop. 1; Copernicus's Revolutiones Cœlest. lib. 5, cap. 35 and 36; Kepler in Tabulis Rudolphinis, cap. 24; Riccioli's Almag. lib. 7, sect. 5, cap. 2: Herman in Miscellan. Berolinens. pa. 197. Dr. Halley, Mr. Facio, Mr. Demoivre, Dr. Keil, and others have treated on this subject. See also the articles RETROGRADE and STATIONARY in this Dictionary.

STATION, in Practical Geometry &c, is a place pitched upon to make an observation, or take an angle, or such like, as in surveying, measuring heights-and-distances, levelling, &c. An accessible height is taken from one station; but an inaccessible height or distance is only to be taken by making two stations, from two places whose distance asunder is known. In constructing maps of counties, provinces, &c, stations are fixed upon certain eminences &c of the country, and angles taken from thence to the several towns, villages, &c.—In surveying, the instrument is to be adjusted by the needle, or otherwise, to answer the points of the horizon at every station; the distance from hence to the last station is to be measured, and an angle is to be taken to the next station; which process repeated includes the chief practice of surveying.—In levelling, the instrument is rectified, or placed level at each station, and observations made forwards and backwards.

There is a method of measuring distances at one station, in the Philos. Trans. numb. 7, by means of a telescope. I have heard of another, by Mr. Ramsden; and have seen other ingenious ways by Mr. Green, &c, consisting of a permanent scale of divisions, placed at any point whose distance is required; then the number of divisions seen through the telescope, gives the distance sought.

STATION-*Line*, in Surveying, and *Line of Station*, in Perspective. See LINE.

STATIONARY, in Astronomy, the state of a planet when, to an observer on the earth, it appears for some time to stand still, or remain immoveable in the same place in the heavens. For as the planets, to such an observer, have sometimes a progressive motion, and sometimes a retrograde one, there must be some point between the two where they must appear stationary. Now a planet will be seen stationary, when the line that joins the centres of the earth and planet is constantly directed to the same point in the heavens, which is when it keeps parallel to itself. For all right lines drawn from any point of the earth's orbit, parallel to one another, do all point to the same star; the distance of these lines being insensible, in comparison of that of the fixed stars.

The planet Herschel is seen stationary at the distance of 104° from the sun; Saturn at somewhat more than 90°; Jupiter at the distance of 52°; and Mars at a much greater distance; Venus at 47°, and Mercury at 28°.

Herschel is stationary 12 days, Saturn 8, Jupiter 4, Mars 2, Venus $1\frac{1}{2}$, and Mercury $\frac{1}{2}$ a day: though the several stations are not always equal; because the orbits of the planets are not circles which have the sun in their centre.

STEAM, the vapour arising from water, or any other liquid or moist body, when considerably heated. Subterranean steams often affect the surface of the earth in a remarkable manner, and promote or prevent vegetation more than any thing else. It has been imagined that steams may be the generative cause of both minerals and metals, and of all the peculiarities of springs. See Philos. Trans. vol. 5, pa. 1154.—Of the use of the air to elevate the steams of bodies, see pa. 2048 and 297 ib.—Concerning the warm and fertilizing temperature and steams of the earth, see Philos. Trans. vol. 10, pa. 307 and 357. See also Dr. Hamilton "On the Ascent of Vapours."

The steam raised from hot water is an elastic fluid, which, like air, has its elasticity proportional to its density when the heat is the same, or proportional to the heat when the density is the same. The steam raised with the ordinary heat of boiling water, is nearly 3000 times rarer than water, or about $3\frac{1}{4}$ times rarer than air, having its elasticity about equal to that of the common air of the atmosphere. And by great heat it has been found that the steam may be expanded into 14000 times the space of water, or may be made about 5 times stronger than the atmosphere. But from some accidents that have happened, it appears that steam, suddenly raised from water, or moist substances, by the immediate application of strong heat, is vastly stronger than the atmosphere, or even than gunpowder itself. We have an instance of this in what happened at a foundery of cannon at Moorfields, when upon the hot metal first running into the mould in the earth, some small quantity of water in the bottom of it was suddenly changed into steam, which by its explosion, blew the foundery to atoms. I remember another such accident at a foundery at Newcastle; the founder having purchased, among some old brass, a hollow brass ball that had been used for many years as a valve in a pump, withinside of which it seems some water had insinuated itself; and having put it into his fire to melt, when it had become very hot, it suddenly burst with a prodigious noise, and blew the adjacent parts of the furnace in pieces.

The observations on the different degrees of temperature acquired by water in boiling, under different pressures of the atmosphere, and the formation of the vapour from water under the receiver of an air-pump, when, with the common temperatures, the pressure is diminished to a certain degree, have taught us that the expansive force of vapour or steam is different in the different temperatures, and that in general it increases in a variable ratio as the temperature is raised.

But there was wanting, on this important subject, a series of exact and direct experiments, by means of which, having given the degree of temperature in boiling water, we might know the expansive force of the steam rising from it; and vice versa. There was wanting also an analytical theorem, expressing the relation between the temperature of boiling water, and the pressure with which the force of its steam is in equilibrium. This has now been accomplished by M. Betancourt, an ingenious Spanish philosopher, the particulars of which are described in a memoir communicated to the French Academy of Sciences in 1790, and ordered to be printed in their collection of the Works of Strangers.

The apparatus which M. Betancourt makes use of, is a copper vessel or boiler, with its cover firmly soldered on. The cover has three holes, which close up with screws: the first is to put the water in and out; through the second passes the stem of a thermometer, which has the whole of its scale or graduations above the vessel, and its ball within, where it is immersed either in the water or the steam according to the different circumstances; through the third hole passes a tube forming a communication between the cavity of the boiler and one branch of an inverted syphon, which, containing mercury, acts as a barometer for measuring the pressure of the elastic vapour within the boiler. There is a fourth hole, in the side of the vessel, into which is inserted a tube, with a turn-cock, making a communication with the receiver of an air-pump, for extracting the air from the boiler, and to prevent its return.

The apparatus being prepared in good order, and distilled water introduced into the boiler by the first hole, and then stopped, as well as the end of the inverted syphon or barometer, M. Betancourt surrounded the boiler with ice, to lower the temperature of the water to the freezing point, and then extracting all the air from the boiler by means of the air-pump, the difference between the columns of mercury in the two branches of the barometer is the measure of the spring of the vapour arising from the water in that temperature. Then, lighting the fire below the boiler, he raised gradually the temperature of the water from 0 to 110 degrees of Reaumur's thermometer; being the same as from 32 to 212 degrees of Fahrenheit's; and for each degree of elevation in the temperature, he observed the height of the column of mercury which measured the elasticity or pressure of the vapour.

The results of M. Betancourt's experiments are contained in a table of four columns, which are but little different, according to the different quantities of water in the vessel. It is here observable, that the increase in the expansive force of the vapour, is at first very slow; but gradually increasing faster and faster, till at last it becomes very rapid. Thus, the strength of the vapour, at 80 degrees, is only equal to 28 French inches of mercury; but at 110 degrees it is equal to no less than 98 inches, that is 3 times and a half more for the increase of only 30 degrees of heat.

To express analytically the relation between the degrees of temperature of the vapour, and its expansive force, this author employs a method devised by M. Prony; which consists in conceiving the heights of the columns of mercury, measuring the expansive force, to represent the ordinates of a curve, and the degrees of heat as the abscisses of the same; making the ordinates equal to the sum of several logarithmic ones, which contain two indeterminates, and determining these quantities so that the curve may agree with a sufficient number of observations taken throughout their whole extent. Then constructing the curve which results immediately from the experiments, and that given by the formula, these two curves are found to coincide almost perfectly together; the small differences being doubtless owing to the little irregularities in the experiments and in dividing the scale; so that the phenomena may be considered as truly represented by the formula.

M. Betancourt made also experiments with the vapour from spirit of wine, similar to those made with water; constructing the curve, and giving the formula proper to the same. From which is derived this remarkable result, that, for any one and the same degree of heat, the strength of the vapour of spirit of wine, is to that of water, always in the same constant ratio, viz. that of 7 to 3 very nearly; the strength of the former being always $2\frac{1}{3}$ times the strength of the latter, with the same degree of heat in the liquid.

Of the Formula, or Equation to the Curve.

The equation to the curve of temperature and pressure, denoting the relation between the abscisses and ordinates, or between the temperature of the vapour and its strength, is, for water,

$$y = b^{a + cx} - b^{a + c'x} - b^{e + c''x} + b^{d + c'''x}.$$

Where x denotes the abscisses of the curve, or the degrees of Reaumur's thermometer; and y the corresponding ordinates, or the heights of the column of mercury in Paris inches, representing the strength or elasticity of the vapour answering to the number x of degrees of the thermometer. Then, by comparing this formula with a proper number of the experiments, the values of the constant quantities come out as below:

$$\begin{aligned} b &= 10\cdot \\ a &= 0\cdot068831 \\ c &= 0\cdot019438 \\ c' &= 0\cdot013490 \\ e &= -\,4\cdot689760 \\ c'' &= 0\cdot058622 \\ d &= -\,3\cdot937600 \\ c''' &= 0\cdot049220 \end{aligned}$$

Hence it is evident by inspection, that the terms of the equation are very easy to calculate. For, b being the radix or root of the common system of logarithms, and all the terms on the second side of the equation being the powers of b, these terms are consequently the tabular natural numbers having the variable exponents for their logarithms. Now as x rises only to the first power, and is multiplied by a constant number, and another constant number being added to the product, gives the variable exponent, or logarithm; to which then is immediately found the corresponding natural number in the table of logarithms.

In the above formula, the two last terms may be entirely omitted, as very small, as far as to the 90th degree of the thermometer; and even above that temperature those two terms make but a small part of the whole formula.

And for the spirit of wine the formula is

$$y = b^{a + cx} + b^{d + c'x} - b^{e + c''x} + b^{e' + c'''x} - A.$$

Where x and y, as before, denote the absciss and ordinate of the curve, or the temperature and expansive force of the vapour from the spirit of wine; also the values of the constant quantities are as below:

$b = 10'$
$a = -\ 0{\cdot}04853$
$c = 0{\cdot}02393$
$d = -\ 0{\cdot}63414$
$c' = -\ 0{\cdot}096532$
$e = -\ 2{\cdot}509542$
$c'' = 0{\cdot}046473$
$e' = -\ 1{\cdot}790192$
$c''' = 0{\cdot}029448$
$A = 1{\cdot}12647$

This formula is of the same nature as the former, having also the like ease and convenience of calculation; and perhaps more so; as the second term $b^{d + c'x}$, having its exponent wholly negative, soon diminishes to no value, so as to be omitted from the 10th degree of temperature; also the difference between the last two terms $-\ b^{e + c''x} + b^{e' + c'''x}$ may be omitted till the 70th degree, for the same reason. So that, to the 10th degree of temperature the theorem is only $y = b^{a + cx} + b^{d + c'x} - A$; and from the 10th to the 70th degree it is barely $y = b^{a + cx} - A$; after which, for the last 15 or 20 degrees, for great accuracy, the last two terms may be taken in.

A compendium of the table of the experiments here follows, for the vapour of both water and spirit of wine, the temperature by Reaumur's thermometer, and the barometer in French inches.

Table of the Temperature and Strength of the Vapour of Water and Spirit of Wine, by Reaumur's Thermometer and French Inches.

M. Betancourt deduces several useful and ingenious consequences and applications from this course of experiments. He shows, for instance, that the effect of steam engines must, in general, be greater in winter than in summer; owing to the different degrees of temperature in the water of injection. And from the very superior strength of the vapour of spirit of wine, over that of water, he argues that, by trying other fluids, some may be found, not very expensive, whose vapour may be so much stronger than that of water, with the same degree of heat, that it may be substituted instead of water in the boilers of steam-engines, to the great saving in the very heavy expence of fuel: nay, he even declares, that spirit of wine itself might thus be employed in a machine of a particular construction, which, with the same quantity of fuel, and without any increase of expence in other things, shall produce an effect greatly superior to what is obtained from the steam of water. He makes several other observations on the working and improvement of steam-engines.

Another use of these experiments, deduced by M. Betancourt, is, to measure the height of mountains, by means of a thermometer, immersed in boiling water, which he thinks may be done with a precision equal, if not superior, to that of the barometer. As soon as I had obtained exact results of my experiments, says he, and was convinced that the degree of heat received by water depends absolutely on the pressure upon its surface, I endeavoured to compare my observations with such as have been made on mountains of different heights, to know what is the degree of heat which water can receive when the barometer stands at a determinate height; but from so few observations having been made of this kind, and the different ways employed in graduating instruments, it is difficult to draw any certain consequences from them.

The first observation which M. Betancourt compared with his experiments, is one mentioned in the Memoirs of the Academy of Sciences, anno 1740, page 92. It is there said, that M. Monnier having made water boil upon the mountain of Canigou, where the barometer stood at 20·18 inches, the thermometer immersed in this water stood at a point answering to 71 degrees of Reaumur: whereas in M. Betancourt's table of experiments, at an equal pressure upon the surface of the water, the thermometer stood at 73·7 degrees. This difference he thinks is owing partly to the want of precision in the observation, and partly to the different method of graduating the thermometer, and the neglect of purging the barometer tube of air.

M. Betancourt next compared his experiments with some observations made by M. Deluc on the tops of several mountains; in which, after reducing the scales of this gentleman to the same measures as his own, he finds a very great degree of coincidence between them. The following table contains a specimen of these comparisons, the instances being taken at random from Deluc's treatise on the Modifications of the Atmosphere.

Degrees of Heat in Boiling Water upon the Tops of Mountains, observed by Deluc.				Heat of the Water in M. Betancourt's Experiments.
Places of Observation.	Heat of the air.	Height of the Bar.	Heat of the Water by Th.	
Beaucaire - -	14¾	28·248	80·37	80·29

Where it is remarkable, that the difference between the two is of no consequence in such matters.

Many other advantages might be deduced from the exact knowledge of the effect which the pressure of the atmosphere has upon the heat which water can receive: one of which, M. Betancourt observes, is of too great importance in physics not to be mentioned. As soon as the thermometer became known to philosophers, almost every one endeavoured to find out two fixed points to direct them in dividing the scale of the instrument; having found that those of the freezing and boiling of water were nearly constant in different places, they gave these the preference over all others: but having discovered that water is capable of receiving a greater or less quantity of heat, according to the pressure of the atmosphere upon its surface, they felt the necessity of fixing a certain constant value to that pressure, which it was almost generally agreed should be equal to a column of 28 French inches of mercury. This agreement however did not remove all the difficulties. For instance, if it were required to construct at Madrid a thermometer that might be comparable with another made at Paris, the thing would be found impossible by the means hitherto known, because the barometer never rises so high as 27 inches at Madrid; and it was not certainly known how much the scale of the thermometer ought to be increased to have the point of boiling water in a place where the barometer is at 28 inches. But by making use of the foregoing observations, the thing appears very easy, and it is to be hoped that by the general knowledge of them, thermometers may be brought to great perfection, the accurate use of which is of the greatest importance in physics.

Besides, without being confined to the height of the barometer in the open air, in a given place, we may regulate a thermometer according to any one assigned heat of water, by means of such an apparatus as M. Betancourt's. For, in order to graduate a thermometer, having a barometer ready divided; it is evident that by knowing, from the foregoing table of experiments, the degree of heat answering to any one expansive force, we can thence assign the degree of the thermometer corresponding to a certain height of the barometer. A determination admitting of great precision, especially in the higher temperatures, where the motion of the barometer is so considerable in respect to that of the barometer.

Steam *Engine*, an engine originally invented for raising water by means of the expansive force of the steam, or vapour, produced from water or other liquids in a state of ebullition. This has been often called the fire-engine, because of the fire used in boiling the liquid: but the latter term has of late been properly confined to machines for extinguishing fires. The steam-engine is justly esteemed one of the most curious, important, and serviceable, mechanical inventions, not only of modern, but of any times; particularly when it is considered with regard to some of its late improvements, which render it applicable to all kinds of mill-work, to plaining, sawing, boring, and rolling machines, and indeed to almost every purpose that requires a powerful first mover, the energy of which may be modified at the pleasure of the mechanist.

The steam-engine for raising water is commonly a forcing pump, having its rod fixed to one end of a lever, which is worked by the weight or pressure of the atmosphere upon a piston, at the other end, a temporary vacuum being made below it, by suddenly condensing the steam, that had been let into the cylinder in which this piston works, by a jet of cold water thrown into it. A partial vacuum being thus made, the weight of the atmosphere presses down the piston, and raises the other end of the straight lever with the water from the well &c. Then immediately a hole is uncovered in the bottom of the cylinder, by which a fresh supply of hot steam rushes in from a boiler of water below it, which proves a counterbalance for the atmosphere above the piston, on which the weight of the pump rods at the other end of the lever carries that end down, and raises the piston of the steam cylinder. Immediately the steam hole is shut, and the cock opened for injecting the cold water into the cylinder of steam, which condenses it to water again, and thus making another vacuum below the piston, the atmosphere above it presses it down, and raises the pump-rods with another lift of water; and so on continually. This is the common principle: but there are also other modes of applying the force of the steam, as we shall see in the following short history of this invention and its various improvements.

The earliest account to be met with of the invention of this engine, is in the marquis of Worcester's small book entitled a Century of Inventions (being a description of 100 notable discoveries), published in the year 1663, where he proposed the raising of great quantities of water by the force of steam, raised from water by means of fire; and he mentions an engine of that kind, of his own contrivance, which could raise a continual stream like a fountain 40 feet high, by means of two cocks which were alternately and successively turned by a man to admit the steam, and to re-fill the vessel with cold water, the fire being continually kept up.

Sir Samuel Morland also wrote a book on this engine; in which he not only showed the practicability of the plan, but went so far as to calculate the power of different cylinders. This book is now extant in manuscript, in the Harleian collection, in the British Museum, the description of which is found in the improved Harleian catalogue, vol. iii, num. 5771; and it is also pointed out in the preface to that volume, sect. 22. Morland dates his invention in 1682, being 17 years prior to Savery's patent mentioned below. It was presented to the French king in 1683, at which time experiments were actually shown at St. Germain's. As Morland held places under king Charles the 2nd, it is natural to conclude that he would not have gone over to France, to offer the invention to Louis 14th, had he not found it slighted at home. It seems to have remained obscure in both countries till 1699, when Savery, who probably knew more of Morland's invention than he owned, obtained a patent; and in the very same year, M. Amontons proposed something similar to the French Academy seemingly as his own.

This invention then not meeting with encouragement, probably owing to the confused state of public affairs at that time, it was neglected, and lay dormant several years, until one Captain Thomas Savery, having read the marquis of Worcester's books, several years afterwards, tried many experiments on the force and power of steam; and at last hit upon a method of applying it to raise water. He then bought up and destroyed all the marquis's books that could be got, and claimed the honour of the invention to himself, and obtained a patent for it, pretending that he had discovered this secret of nature by accident. He contrived an engine which, after many experiments, he brought to some degree of usefulness, so as to raise water in small quantities; but he could not succeed in raising it to any great height, or in large quantities, for the draining of mines; to effect which by his method, the steam was required to be so strong as would have burst all his vessels; so that he was obliged to limit himself to raising the water only to a small height, or in small quantities. The largest engines he erected, was for the York-buildings Company in London, for supplying the inhabitants in the Strand and that neighbourhood with water.

The principle of this machine was as follows: H (fig. 3, pl. 33) represents a copper boiler placed on a furnace; E is a strong iron vessel, communicating with the boiler by means of a pipe at top, and with the main pipe AB by means of a pipe I at bottom; AB is the main pipe immersed in the water at B; D and C are two fixed valves, both opening upwards, one being placed above, and the other below the pipe of communication I. Lastly, at G is a cock that serves occasionally to wet and cool the vessel E, by water from the main pipe, and F is a cock in the pipe of communication between the vessel E and the boiler.

The engine is set to work, by filling the copper in part with water, and also the upper part of the main pipe above the valve C, the fire in the furnace being lighted at the same time. When the water boils strongly, the cock F is opened, the steam rushes into the vessel E, and expels the air from thence through the valve C. The vessel E thus filled, and violently heated by the steam, is suddenly cooled by the water which falls upon it by turning the cock C; the cock F being at the same time shut, to prevent any fresh accession of steam from the boiler. Hence, the steam in E becoming condensed, it leaves the cavity within nearly a vacuum: and therefore the pressure of the atmosphere at B forces the water through the valve D till the vessel E is nearly filled. The condensing cock G is then shut, and the steam cock F again opened; hence the steam, rushing into E, expels the water through the valve C, as it before did the air. Thus E becomes again filled with hot steam, which is again cooled and condensed by the water from G, the supply of steam being cut off by shutting F, as in the former operation: the water consequently rushes through D, by the pressure of the atmosphere at B, and E is again filled. This water is forced up the main pipe through C, by opening F and shutting G, as before. And thus it is easy to conceive, that by the alternate operation of opening and shutting the cocks, water will be continually raised, as long as the boiler continues to supply the steam.

For the sake of perspicuity, the drawing is divested of the apparatus that serves to turn the two cocks at once, and of the contrivances for filling the copper to the proper quantity. But it may be found complete, with a full account of its uses and application, in Mr. Savery's book intituled the Miner's Friend, and in Dr. Gregory's Mechanics, vol. 2. The engines of this construction were usually made to work with two receivers or steam vessels, one to receive the steam, while the other was raising water by the condensation. This engine has been since improved, by admitting the end of the condensing pipe G into the vessel E, by which means the steam is more suddenly and effectually condensed than by water on the outside of the vessel.

The advantages of this engine are, that it may be erected in almost any situation, that it requires but little room, and is subject to very little friction in its parts.—Its disadvantages are, that great part of the steam is condensed and loses its force upon coming into contact with the water in the vessel E, and that the heat and elasticity of the steam must be increased in proportion to the height that the water is required to be raised to. On both these accounts a large fire is required, and the copper must be very strong, when the height is considerable, otherwise there is danger of its bursting.

While captain Savery was employed in perfecting his engine, Dr. Papin of Marburg was contriving one on the same principles, which he describes in a small book published in 1707, intitled Ars Nova ad Aquam Ignis adminiculo efficacissime elevandam. Captain Savery's engine however was much more complete than that proposed by Dr. Papin.

About the same time also Mons. Amontons of Paris was engaged in the same pursuit: but his method of applying the force of steam was different from those before-mentioned; for he intended it to drive or turn a wheel, which he called a fire-mill, that was to work pumps for raising water; but he never brought it to perfection. Each of these three gentlemen claimed the originality of the invention; but it is most probable they all took the hint from the book published by the marquis of Worcester, as before-mentioned.

In this imperfect state it continued, without further improvements, till the year 1705, when Mr. Newcomen, an ironmonger, and Mr. John Ceudley, a glazier, both of Dartmouth, contrived another way to raise water by steam, bringing the engine to work with a beam and piston, and where the steam, even at the greatest depths of mines, is not required to be greater than the pressure of the atmosphere: and this structure of the engine is that which has since been chiefly used. These gentlemen obtained a patent for the sole use of this invention, for 14 years. The first proposal they made for draining of mines by this engine, was in the year 1711; but they were very coldly received by many persons in the south of England, who did not understand the nature of it. In 1712 they came to an agreement with the owners of a colliery at Griff in Warwickshire, where they erected an engine with a cylinder of 22 inches diameter. At first they were under great difficulties in many things; but by the assistance of some good workmen they got all the parts put together in such a manner, as to answer their intention tolerably well: and this was the first engine of the kind erected in England. There was at first one man to attend the steam-cock, and another to attend the injection-cock: but they afterwards contrived a method of opening and shutting them by some small machinery connected with the working beam. The next engine erected by these patentees, was at a colliery in the county of Durham, about the year 1718, where was concerned, as an agent, Mr. Henry Beighton, F. R. S. and conductor of the Ladies' Diary from the year 1714 to the 1744: this gentleman, not approving of the intricate manner of opening and shutting the cocks by strings and catches, as in the former engine, substituted the hanging-beam for that purpose as at present used, and likewise made improvements in the pipes, valves, and some other parts of the engine.

In a few years afterwards, these engines became better understood than they had been; and their advantages, especially in draining of mines, became more apparent; and from the great number of them erected, they received additional improvements from different persons, till they arrived at their present degree of perfection: as will appear in the sequel, after we have a little considered the general principles of this engine, which are as follow.

Principles of the Steam Engine.

The principles on which this engine acts, are truly philosophical; and when all the parts of the machine are proportioned to each other according to these principles, it never fails to answer the intention of the engineer.

1. It has been proved in pneumatics, that the pressure

of the atmosphere on a square inch at the earth's surface, is about $14\frac{3}{4}$lb avoirdupois at a medium, or $11\frac{1}{4}$lb on a circular inch, that is on a circle of an inch diameter. And,

2. If a vacuum be made by any means in a cylinder, which has a moveable piston suspended at one end of a lever equally divided, the air will endeavour to rush in, and will press down the piston, with a force proportionate to the area of the surface, and will raise an equal weight at the other end of the lever.

3. Water may be rarefied near 14000 times by being expanded into steam, and violently heated: the particles of it are so strongly repellent, as to drive away air of the common density, only by a heat sufficient to keep the water in a boiling state, when the steam is almost 3000 times rarer than water, or $3\frac{1}{2}$ times rarer than air, as appears by an experiment of Mr. Beighton's: by increasing the heat, the steam may be rendered much stronger; but this requires great strength in the vessels. This steam may be again condensed into its former state by a jet of cold water dispersed through it; so that 14000 cubic inches of steam admitted into a cylinder, may be reduced into the space of one cubic inch of water only, by which means a partial vacuum is obtained.

4. Though the pressure of the atmosphere be about $14\frac{3}{4}$ pounds upon every square inch, or $11\frac{1}{4}$ pounds upon a circular inch; yet, on account of the friction of the several parts, the resistance from some air which is unavoidably admitted with the jet of cold water, and from some remainder of steam in the cylinder, the vacuum is very imperfect, and the piston does not descend with a force exceeding 8 or 9 pounds upon every square inch of its surface.

5. The gallon of water of 282 cubic inches weighs $10\frac{1}{5}$ pounds avoirdupois, or a cubic foot $62\frac{1}{2}$ pounds, or 1000 ounces. The piston being pressed by the atmosphere with a force proportional to its area in inches, multiplied by about 8 or 9 pounds, depresses that end of the lever, and raises a column of water in the pumps of equal weight at the other end, by means of the pump-rods suspended to it. When the steam is again admitted, the pump-rods sink by their superior weight, and the piston rises; and when that steam is condensed, the piston descends, and the pump-rods lift; and so on alternately as long as the piston works.

It has been observed above, that the piston does not descend with a force exceeding 8 or 9 pounds on every square inch of its surface; but by reason of accidental frictions, and alterations in the density of the air, it will be safest, in calculating the power of the cylinder, to allow something less than 8 pounds for the pressure of the atsphere upon every square inch, viz, 7lb. 10 oz. = 7·64lb, or just 6lb. upon every circular inch; and it being allowed that the gallon of water, of 282 cubic inches, weighs $10\frac{1}{5}$lb, from these premises the dimensions of the cylinder, pumps, &c, for any steam-engine, may be deduced as follows:— Suppose

c = the cylinder's diameter in inches,
p = the pump's ditto,
f = the depth of the pit in fathoms,
g = gallons drawn by a stroke of 6 feet or a fathom,
h = the hogsheads drawn per hour,
s = the number of strokes per minute.

Then c^2 is the area of the cylinder in circular inches, therefore $6c^2$ is the power of the cylinder in pounds.

And $\frac{p^2 \times \cdot 7854 \times 72}{282}$ or $\frac{1}{5}p^2$ is $= g$ the gallons contained in one fathom or 72 inches of any pump; which multiplied by f fathoms, gives $\frac{1}{5}p^2f$ for the gallons contained in f fathoms of any pump whose diameter is p. Hence $\frac{1}{5}p^2f \times 10\frac{1}{5}$lb. gives $2p^2f$ nearly, for the weight in pounds of the column of water which is to be equal to the power of the cylinder, which was before found equal to $6c^2$. Hence then we have the 2d equation, viz, $6c^2 = 2p^2f$, or $3c^2 = p^2f$; the first equation being $\frac{1}{5}p^2 = g$, or $p^2 = 5g$. From which two equations, any particular circumstance may be determined.

Or if, instead of 6lb, for the pressure of the air on each circular inch of the cylinder, that force be supposed any number as a pounds; then will the power of the cylinder be ac^2, and the 2d equation becomes $ac^2 = 2p^2f = 10fg$, by substituting $5g$ instead of p^2.

And farther, $63h = 60gs$, or $21h = 20gs$.

From a comparison of these equations, the following theorems are derived, which will determine the size of the cylinder and pumps of any steam-engine capable of drawing a certain quantity of water from any assigned depth, with the pressure of the atmosphere on each circular inch of the cylinder's area.

These theorems are more particularly adapted to one pump in a pit. But it often happens in practice, that an engine has to draw several pumps of different diameters from different depths; and in this case, the square of the diameter of each pump must be multiplied by its depth, and double the sum of all the products will be the weight of water drawn at each stroke, which is to be used instead of $2p^2f$ for the power of the cylinder.

The following is a table, calculated from the foregoing theorems, of the powers of cylinders from 30 to 70 inches diameter; and the diameters and lengths of pumps which those cylinders are capable of working, from a 6 inch bore to that of 20 inches, together with the quantity of water drawn per stroke and per hour, allowing the engine to make 12 strokes of 6 feet per minute, and the pressure of the atmosphere at the rate of 7lb 10oz per square inch, or 6 lb per circular inch.

A Table *of* Theorems *for the readier computing the Powers of a* Steam-Engine.

Let us now describe the several parts of an engine, and exemplify the application of the foregoing principles, in the construction of one of the completest of the modern engines. See fig. 4. pl. 33.

A represents the fire-place under the boiler, for the boiling of the water, and the ash-hole below it.

B, the boiler, filled with water about 3 feet above the bottom, made of iron plates.

C, the steam pipe, through which the steam passes from the boiler into the receiver.

D, the receiver, a close iron vessel, in which is the regulator or steam-cock, which opens and shuts the hole of communication at each stroke.

E, the communication pipe between the receiver and the cylinder; it rises 5 or 6 inches up, in the inside of the cylinder bottom, to prevent the injected water from descending into the receiver.

F, the cylinder, of cast iron, about 10 feet long, bored smooth in the inside; it has a broad flanch in the middle on the outside, by which it is supported when hung in the cylinder-beams.

G, the piston, made to fit the cylinder exactly: it has a flanch rising 4 or 5 inches upon its upper surface, between which and the side of the cylinder a quantity of junk or oakum is stuffed, and kept down by weights, to prevent the entrance of air or water and the escaping of steam.

H, the chain and piston shank, by which it is connected to the working beam.

I I, the working beam or lever: it is made of two or more large logs of timber, bent together at each end, and kept at the distance of 8 or 9 inches from each other in the middle by the gudgeon, as represented in the Plate. The arch heads, II, at the ends, are for giving a perpendicular direction to the chains of the piston and pump-rods.

K, the pump-rod which works in the sucking pump.

L, and draws the water from the bottom of the pit to the surface.

M, a cistern, into which the water drawn out of the pit is conducted by a trough, so as to keep it always full: and the superfluous wateris carried off by another trough.

N, the jack-head pump, which is a sucking-pump wrought by a small lever or working-beam, by means of a chain connected to the great beam or lever near the arch *g* at the inner end, and the pump-rod at the outer end. This pump commonly stands near the corner of the front of the house, and raises the column of water up to the cistern O, into which it is conducted by a trough.

O, the jack-head cistern for supplying the injection, which is always kept full by the pump N: it is fixed so high as to give the jet a sufficient velocity into the cylinder when the cock is opened. This cistern has a pipe on the opposite side for conveying away the superfluous water.

P P, the injection-pipe, of 3 or 4 inches diameter, which turns up in a curve at the lower end, and enters the cylinder bottom: it has a thin plate of iron upon the end *d*, with 3 or 4 adjutage holes in it, to prevent the jet of cold water of the jack-head cistern from flying up against the piston, and yet to condense the steam each stroke, when the injection-cock is open.

e, a valve upon the upper end of the injection-pipe within the cistern, which is shut when the engine is not working, to prevent any waste of the water.

f, a small pipe which branches off from the injection-pipe, and has a small cock to supply the piston with a little water to keep it air-tight.

Q, the working plug, suspended by a chain to the arch *g* of the working beam. It is usually a heavy piece of timber, with a slit vertically down its middle, and holes bored horizontally through it, to receive pins for the purpose of opening and shutting the injection and steam cocks, as it ascends and descends by the motion of the working beam.

h, the handle of the steam-cock or regulator, it is fixed to the regulator by a spindle which comes up through the top of the receiver. The regulator is a circular plate of brass or cast iron, which is moved horizontally by the handle *h*, and opens or shuts the communication at the lower end of the pipe E within the receiver. It is represented in the plate by a circular dotted line.

i i, the spanner, which is a long rod or plate of iron for communicating motion to the handle of the regulator: to which it is fixed by means of a slit in the latter, and some pins put through to fasten it.

k l, the vibrating lever, called the Y, having the weight *k* at one end and two legs at the other end. It is fixed to an horizontal axis, moveable about its centre-pins or pivots *mn*, by means of the two shanks *op* fixed to the same axis, which are alternately thrown backwards and forwards by means of two pins in the working plug; one pin on the outside depressing the shank *o*, throws the loaded end *k* of the Y from the cylinder into the position represented in the plate, and causes the leg *l* to strike against the end of the spanner; which forcing back the handle of the regulator or steam cock, opens the communication, and permits the steam to fly into the cylinder. The piston immediately rising by the admission of the steam, the working beam I I rises; which also raises the working-plug, and another pin which goes through the slit raises the shank *p*, which throws the end *k* of the Y towards the cylinder, and, striking the end of the spanner, forces it forward, and shuts the regulator steam-cock.

q r, the lever for opening and shutting the injection-cock, called the F. It has two toes from its centre, which take between them the key of the injection-cock. When the working-plug has ascended nearly to its greatest height, and shut the regulator, a pin catches the end *q* of the F and raises it up, which opens the injection-cock, admits a jet of cold water to fly into the cylinder, and condensing the steam, makes a vacuum; then the pressure of the atmosphere bringing down the piston in the cylinder, and also the plug-frame, another pin fixed in it catches the end of the lever in its descent, and, by pressing it down, shuts the injection-cock, at the same time the regulator is opened to admit steam, and so on alternately; when the regulator is shut the injection is open, and when the former is open the latter is shut.

R, the hot-well, a small cistern made of planks, which receives all the waste water from the cylinder.

S, the sink-pit to convey away the water which is injected into the cylinder at each stroke. Its upper end is even with the inside of the cylinder bottom; its lower end has a lid or cover moveable on a hinge which serves as a valve to let out the injected water, and shuts close each stroke of the engine, to prevent the water being forced up again when the vacuum is made.

T, the feeding-pipe, to supply the boiler with water from the hot-well. It has a cock to let in a large or small quantity of water as occasion requires, to make up for what is evaporated: it goes nearly down to the boiler bottom.

U, two gage-cocks, the one larger than the other, to try when a proper quantity of water is in the boiler: on opening the cocks, if one give steam and the other water, it is right; if they both give steam, there is too little water in the boiler; and if they both give water, there is too much.

W, a plate which is screwed on to a hole on the side of the boiler, to allow a passage into the boiler for the convenience of cleaning or repairing it.

X, the steam-clack or puppet valve, a brass valve on the top of a pipe opening into the boiler, to let off the steam when it is too strong. It is loaded with lead, at the rate of one pound to an inch square; and when the steam is nearly strong enough to keep it open, it will do for the working of the engine.

f, the snifting valve, by which the air is discharged from the cylinder each stroke, which was admitted with the injection, and would otherwise obstruct the due operation of the engine.

tt, the cylinder-beams; which are strong joists going through the house for supporting the cylinder.

v, the cylinder cap of lead, soldered on the top of the cylinder, to prevent the water upon the piston from flashing over when it rises too high.

w, the waste-pipe, which conducts the superfluous water from the top of the cylinder to the hot-well.

xx, iron bars, called the catch-pins, fixed horizontally through each arch-head, to prevent the beam descending too low in case the chain should break.

yy, two strong wooden springs, to weaken the blow given by the catch-pins when the stroke is too long.

zz, two friction-wheels, on which the gudgeon or centre of the great beam is hung; they are the third or fourth part of a circle, and move a little each way as the beam vibrates. Their use is to diminish the friction of the axis, which, in so heavy a lever, would otherwise be very great.

When this engine is to be set to work, the boiler must be filled about 3 or 4 feet deep with water, and a large fire made under it; and when the steam is found to be of a sufficient strength by the puppet-clack, then by thrusting back the spanner, which opens the regulator or steam-cock, the steam is admitted into the cylinder, which raises the piston to the top of the cylinder, and forces out all the air at the snifting valve; then by turning the key of the injection-cock, a jet of cold water is admitted into the cylinder, which condenses the steam and produces a vacuum; the atmosphere then pressing upon the piston, forces it down to the lower part of the cylinder, and makes a stroke by raising the column of water at the other end of the beam. After two or three strokes are made in this manner, by a man opening and shutting the cocks to try if they be right, the pins may then be put into the pin-holes in the working plug, and the engine left to turn the cocks of itself; which it will do with greater exactness than can be done by a man.

There are in some engines, methods of shutting and opening the cocks different from the one above described, but perhaps none better adapted to the purpose; and as the principles on which they all act are originally the same, any difference in the mechanical construction of the small machinery will have no influence of consequence on the total effect of the grand machine.

The furnace or fire-place should not have the bars so close as to prevent the free admission of fresh air to the fire, nor so open as to permit the coals to fall easily through them; for which purpose two inches or thereabouts is sufficient for the distance betwixt the bars. The size of the furnace depends on that of the boiler; but in every case the ash-hole ought to be capacious to admit the air, and the greater its height the better. If the flame is conducted in a flue or chimney round the outside of the boiler, or in a pipe round the inside of it, it ought to be gradually diminished from the entrance at the furnace to its egress at the chimney; and the section of the chimney at that place should not exceed the section of the flue or pipe, and should also be somewhat less at the chimney-top.

The boiler or vessel in which the water is rarefied by the force of fire, may be made of iron plates or cast iron, or such other materials as can withstand the effects of the fire, and the elastic force of the steam. It may be considered as consisting of two parts; the upper part which is exposed to the steam, and the under part which is exposed to the fire. The form of the latter should be such as to receive the full force of the fire in the most advantageous manner, so that a certain quantity of fuel may have the greatest possible effect in heating and evaporating the water; which is best done by making the sides cylindrical, and the bottom a little concave, and then conducting the flame by an iron flue or pipe round the inside of the boiler beneath the surface of the water, before it reach the chimney. For, by this means, after the fire in the furnace has heated the water by its effect on the bottom, the flame heats it again by the pipe being wholly included in the water, and having every part of its surface in contact with it; which is preferable to carrying it in a flue or chimney round the outside of the boiler, as a third or a half of the surface of the flame only could be in contact with the boiler, the other being spent upon the brick-work. This lower cylindric part may be less in its diameter than the upper part, and may contain from 4 to 6 feet perpendicular depth of water in it.

The upper part of the boiler is best made hemispherical, for resisting the elasticity of the steam; yet any other form may do, provided it be of sufficient strength for the purpose. The quick motion of the engine depends much on the capaciousness of the boiler-top; for if it be too small, it requires the steam to be heated to a great degree, to increase its elastic force so much as to work the engine. If the top is so capacious as to contain eight or ten times the quantity of steam used each stroke, it will require no more fire to preserve its elasticity than is sufficient to keep the water in a proper state of boiling; this, therefore, is the best size for a boiler top. If the diameter of the cylinder be c, and works a six-foot stroke, and the diameter of the boiler be supposed b, then

$$200c^2 = b^3, \text{ or } b = \sqrt[3]{200c^2}.$$

The effect of the injection in condensing the steam in the cylinder, depends on the height of the reservoir and the diameter of the adjutage. If the engine makes a 6 feet stroke, then the jackhead cistern should be 12 feet perpendicular above the bottom of the cylinder or the adjutage. The size of the adjutage may be from 1 to 2 inches in diameter; or if the cylinder be very large, it is proper to have three or four holes rather than one large one, in order that the jet may be dispersed the more effectually over the whole area of the cylinder. The injection pipe, or pipe of conduct, should be so large as to supply the injection freely with water; if the diameter of the injection pipe be called p, and the diameter of the adjutage, a, then $4a^2 = p^2$, and $a^2 = \frac{1}{4}p^2$, or $a = \frac{1}{2}p$.

For a further account of these engines, see Desaguliers's Exp. Philos. vol. 2, sect. 14, pa. 465, &c; or for an abstract, Martin's Phil. Brit. number 461, or Nicholson's Nat. Philos. pa. 83 &c. And for an account of the improvement made in the fire-engine by Mr. Payne, see Philos. Trans. number 461, or Martin's Philos. Brit. pa. 87 &c. See also Gregory's Mechanics, vol. 2, for a particular description of different steam-engines, containing the latest improvements that they have undergone.

Mr. Blakey communicated to the Royal Society, in 1752, remarks on the best proportions for steam-engine cylinders of a given content: and Mr. Smeaton describes an engine of this kind, invented by Mr. De Moura of Portugal, being an improvement of Savery's construction, to render it capable of working itself: for both which accounts, see Philos. Trans. vol. 47, art. 29 and 72.

We are informed in the new edit. of the Biograph. Brit. under the article Brindley, that in 1756 this gentleman, so well known for his concern in our inland navigations, undertook to erect a steam-engine near Newcastle-under-Line, on a new plan. The boiler of it was made with brick and stone, instead of iron plates, and the water was heated by iron flues of a peculiar construction; by which contrivances the consumption of fuel, necessary for working a steam-engine, was reduced one half. He introduced also into his engine wooden cylinders, made in the manner of cooper's ware, instead of iron ones; the former being both cheaper and more easily managed in the shafts: and he likewise substituted wood for iron in the chains which worked at the end of the beam. He had formed designs of introducing other improvements into the construction of this useful engine; but was discouraged by obstacles that were thrown in his way.

Mr. Blakey, some years ago, obtained a patent for his improvement of Savery's steam-engine, by which it is excellently adapted for raising water out of ponds, rivers, wells, &c, and for forcing it up to any height wanted for supplying houses, gardens, and other places; though it has not power sufficient to drain off the water from a deep mine. The principles of his construction are explained by Mr. Ferguson, in the Supplement to his Lectures, pa. 19; and a more particular description of it, accompanied with a drawing, is given by the patentee himself in the Gentleman's Magazine for 1769, pa 392.

Mr. Blakey, it is said, is the first person who ever thought of making use of air as an intermediate body between steam and water; by which means the steam is always kept from touching the water, and consequently from being condensed by it: and on this new principle he has obtained a patent. The engine may be built at a trifling expence, in comparison of the common steam-engine now in use; it will seldom need repairs, and will not consume half so much fuel. And as it has no pumps with pistons, it is clear of all their friction; and the effect is equal to the whole strength or compressive force of the steam; which the effect of the common engine never is, on account of the great friction of the pistons in their pumps.

Ever since Mr. Newcomen's invention of the steam fire-engine, the great consumption of fuel with which it is attended, has been complained of as an immense drawback on the profits of our mines. It is a known fact, that every engine of considerable size consumes to the amount of three thousand pounds worth of coals in a year. Hence many of our engineers have endeavoured, in the construction of these engines, to save fuel. For this purpose, the fire-place has been diminished, the flame has been carried round from the bottom of the boiler in a spiral direction, and conveyed through the body of the water in a tube before its arrival at the chimney; some have used a double boiler, so that fire might act in every possible point of contact; and some have built a moor-stone boiler, heated by three tubes of flame passing through it. But the most important improvements which have been made in the steam-engine for more than forty years past, we owe to the skill of Mr. James Watt; of which we shall give some account: premising, that the internal structure of his new engines so much resembles that of the common ones, that those who are acquainted with them will not fail to understand the mechanism of his from the following description: He has contrived to observe a uniform heat in the cylinder of his engines, by suffering no cold water to touch it, and by protecting it from the air, or other cold bodies, by a surrounding case filled with steam, or with hot air or water, and by coating it over with substances that transmit heat slowly. He makes his vacuum to approach nearly to that of the barometer, by condensing the steam in a separate vessel, called the condenser, which may be cooled at pleasure without cooling the cylinder, either by an injection of cold water, or by surrounding the condenser with it, and generally by both. He extracts the injection water, and detached air, from the cylinder or condenser by pumps, which are wrought by the engine itself, or blows them out by the steam. As the entrance of air into the cylinder would stop the operation of the engines, and as it is hardly to be expected that such enormous pistons as those of steam-engines can move up and down, and yet be absolutely tight as in the common engines; a stream of water is kept always running upon the piston, which prevents the entry of the air: but this mode of securing the piston, though not hurtful in the common ones, would be highly prejudicial to the new engines. Their piston is therefore made more accurately; and the outer cylinder, having a lid, covers it, the steam is introduced above the piston; and when a vacuum is produced under it, acts upon it by its elasticity, as the atmosphere does upon common engines by its gravity. This way of working effectually excludes the air from the inner cylinder, and gives the advantage of adding to the power, by increasing the elasticity of the steam.

In Mr. Watt's engines, the cylinder, the great beams, the pumps, &c, stand in their usual positions. The cylinder is smaller than usual, in proportion to the load, and is very accurately bored. In the most complete engines, it is surrounded at a small distance, with another cylinder, furnished with a bottom and a lid. The interstice between the cylinders communicates with the boilers by a large pipe, open at both ends: so that it is always filled with steam, and thereby maintains the inner cylinder always of the same heat with the steam, and prevents any condensation within it, which would be more detrimental than an equal condensation in the outer one. The inner cylinder has a bottom and piston as usual: and as it does not reach up quite to the lid of the outer cylinder, the steam in the interstice has always free access to the upper side of the piston. The lid of the outer cylinder has a hole in its middle; and the piston rod, which is truly cylindrical, moves up and down through that hole, which is kept steam-tight by a collar of oakum screwed down upon it. At the bottom of the inner cylinder, there are two regulating valves, one of which admits the steam to pass from the interstice into the inner cylinder below the piston, or shuts it out at pleasure: the other opens or shuts the end of a pipe, which leads to the condenser. The condenser consists of one or more pumps furnished with clacks and buckets (nearly the same as in common pumps) which are wrought by chains fastened to the great working beam of the engine. The pipe, which comes from the cylinder, is joined to the bottom of these pumps, and the whole condenser stands immersed in a cistern of cold water supplied by the engine. The place of this cistern is either within the house or under the floor, between the cylinder and the lever wall; or without the house between that wall and the engine shaft, as conveniency may require. The condenser being exhausted of air by blowing, and both the cylinders being filled with steam, the regulating valve which admits the steam into the inner cylinder is shut, and the other regulator which communicates with the condenser is opened, and the steam rushes into the vacuum of the condenser with violence: but there it comes into contact with the cold sides of the pumps and pipes, and meets a jet of cold water, which was opened at the same time with the exhaustion regulator; these instantly deprive it of its heat, and reduce it to water; and the vacuum remaining perfect, more steam continues to rush in, and is condensed until the inner cylinder is exhausted. Then the steam which is above the piston, ceasing to be counteracted by that which was below it, acts upon the piston with its whole elasticity, and forces it to descend to the bottom of the cylinder, and so raises the buckets of the pumps which are hung to the other end of the beam. The exhaustion regulator is now shut, and the steam one opened again, which, by letting in the steam, allows the piston to be pulled up by the superior weight of the pump rods; and so the engine is ready for another stroke.

But the nature of Mr. Watt's improvement will be perhaps better understood from the following description of it as referred to a figure.—The cylinder or steam vessel A, of this engine (fig. 5, pl. 33), is shut at bottom and opened at top as usual; and is included in an outer cylinder or case BB, of wood or metal, covered with materials which transmit heat slowly. This case is at a small distance from the cylinder, and close at both ends. The cover C has a hole in it, through which the piston rod E slides; and near the bottom is another hole F, by which the steam from the boiler has always free entrance into this case or outer cylinder, and by the interstice GG between the two cylinders has access to the upper side of the piston HH. To the bottom of the inner cylinder A is joined a pipe I, with a cock or valve K, which is opened and shut when necessary, and forms a passage to another vessel L called a condenser, made of thin metal. This vessel is immersed in a cistern M full of cold water, and it is contrived so as to expose a very great surface externally to the water, and internally to the steam. It is also made air-tight, and has pumps N wrought by the engine, which keep it always exhausted of air and water.

Both the cylinders A and BB being filled with steam, the passage K is opened from the inner one to the condenser L, into which the steam violently rushes by its elasticity, because that vessel is exhausted; but as soon as it enters it, coming into contact with the cold matter of the condenser, it is reduced to water, and, the vacuum still remaining, the steam continues to rush in till the inner cylinder A below the piston is left empty. The steam which is above the piston, ceasing to be counteracted by that which is below it, acts upon the piston HH, and forces it to descend to the bottom of the cylinder, and so raises the bucket of the pump by means of the lever. The passage K between the inner cylinder and the condenser is then shut, and another passage O is opened, which permits the steam to pass from the outer cylinder, or from the boiler into the inner cylinder under the piston; and then the superior weight of the bucket and pump rods pulls down the outer end of the lever or great beam, and raises the piston, which is suspended to the inner end of the same beam.

The advantages that accrue from this construction are, first, that the cylinder being surrounded with the steam from the boiler, it is kept always uniformly as hot as the steam itself, and is therefore incapable of destroying any part of the steam, which should fill it, as the common engines do. Secondly, the condenser being kept always as cold as water can be procured, and colder than the point at which it boils in vacuo, the steam is perfectly condensed, and does not oppose the descent of the piston; which is therefore forced down by the full power of the steam from the boiler, which is somewhat greater than that of the atmosphere.

In the common steam-engines, when they are loaded to 7 pounds upon the inch, and are of a middle size, the quantity of steam which is condensed in restoring to the cylinder the heat which it had been deprived of by the former injection of cold water, is about one full of the cylinder, besides what it really required to fill that vessel; so that twice the full of the cylinder is employed to make it raise a column of water equal to about 7 pounds for each square inch of the piston: or, to take it more simply, a cubic foot of steam raises a cubic foot of water about 8 feet high, besides overcoming the friction of the engine, and the resistance of the water to motion.

In the improved engine, about one full and a fourth of the cylinder is required to fill it, because the steam is one-fourth more dense than in the common engine. This engine raises a load equal to 12 pounds and a half upon the square inch of the piston; and each cubic foot of steam of the density of the atmosphere, raises one cubic foot of water 22 feet high. The working of these engines is more regular and steady than the common ones, and from what has been said, their other advantages seem to be very considerable.

It is said, that the savings amount at least to two-thirds of the fuel, which is an important object, especially where coals are dear. The new engines will raise from twenty thousand to twenty-four thousand cubic feet of water, to the height of 24 feet by one hundred weight of good pit coal: and Mr. Watt has proposed to produce engines on the same principles, though somewhat differing in construction, which will require still much less fuel, and be more convenient for the purposes of mining, than any kind of engine yet used. Mr. Watt has also contrived a kind of mill wheel, which turns round by the power of steam exerted within it.

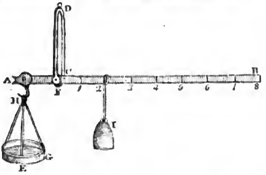
The improvements above recited were invented by Mr. James Watt, at Glasgow, in Scotland, in 1764: he obtained the king's letters patent for the sole use of his invention in 1768; but meeting with difficulties in the execution of a large machine, and being otherwise employed, he laid aside the undertaking till the year 1774, when, in conjunction with Mr. Boulton near Birmingham, he completed both a reciprocating and rotative or wheel engine. He then applied to parliament for a prolongation of the term of his patent, which was granted by an act passed in 1775. Since that time, Mr. Watt and Mr. Boulton have erected several engines in various parts of England. The terms they offer to the public are, to take in lieu of all profits, one-third part of the annual savings in fuel, which their engine makes when compared with a common engine of the same dimensions in the neighbourhood. The engines are built at the expence of those who use them, and Messrs. Boulton and Watt furnish such drawings, directions, and attendance, as may be necessary to enable a resident engineer to complete the machine. See the appendix to Pryce's Mineralogia, &c, 1778.

Mr. Hornblower and others have also made ingenious improvements on the steam-engine.

See another view of a steam engine at fig. 3, pl. 31.

Steam-*Boat*, &c. Besides the steam-engines employed for drawing the water out of deep-mines, (and without the discovery of such machines the country now would have been almost deprived of the use of coals,) steam has been gradually applied, as a power, to give motion to various other machines, and for other purposes where great and œconomical powers are required, with the best effects; such as saw-mills, pile-driving, deepening and cleansing of rivers and canals, the draft of numerous waggons on rail-ways, with many other useful and beneficial purposes; and lastly to the purposes of navigation, by impelling large vessels on rivers and canals, for the cheap and expeditious conveyance of passengers and goods of all kinds. Many vessels of this kind are now employed in this way, in this country, and in North America, and elsewhere. As early as the year 1801, such a vessel was tried on the Forth and Clyde inland navigation; but was laid aside, among other reasons, on account of the injury it threatened the banks of the canal by the agitation of the water. In America, the first steam-boat was launched at New-York on the 3d of October 1807, and began to ply on the river between that city and Albany, a distance of about 160 miles; and now numerous large vessels of that kind are employed on the navigation between New York and Canada, as well as on the Mississippi, and several other rivers in that country. The first attempt, on a large scale, to navigate by steam on the river Clyde, was made in the year 1812; and many other vessels, of great burden, are now daily employed there, conveying at each time several hundred tons of goods, or many hundred passengers, in a commodious, cheap, and expeditious manner. Vessels of the same kind are also successively establishing on many other rivers in the country; as on the Thames, the Tyne, &c, &c, and even coasting on the sea.—Accounts of these vessels and navigations have been given in several publications; particularly in the Monthly Magazine in many places of the volumes 36 and 37, as also in the Philos. Magazine, vol. 45, in both cases accompanied with drawings and descriptions of the machinery.

STEELYARD, or STILYARD, in Mechanics, a kind of balance, called also, Statera Romana, or the Roman Balance, by means of which the weights of different bodies are discovered by using one single weight only.



The common steelyard consists of an iron beam AB, in which is assumed a point at pleasure, as C, on which is raised a perpendicular CD. On the shorter arm AC is hung a scale to receive the bodies weighed: the moveable weight I is shifted backward and forward on the beam, till it be a counterbalance to 1, 2, 3, 4, &c pounds placed in the scale; and the points are noted where the constant weight I weighs, as 1, 2, 3, 4, &c pounds. From this construction of the steelyard, the manner of using it is evident.

These instruments in the hands of designing men are easily converted to the purpose of deception; as, one cannot so readily know whether they be truly constructed or not, as we can with the common balance; on which account, and some other inconveniencies attending the use of them, they are not very generally employed in mercantile transactions.

These imperfections in the common steelyard, led C. Paul, inspector of weights at Geneva, to employ his thoughts on so far improving steelyards, that either in the delicate operations of the arts, or in those of the same kind which are often so necessary in the practice of physical sciences, those instruments might be substituted with advantage for common balances.

It would be contrary to our plan to enter at any length upon the description of the instrument which Mr. Paul has constructed for this purpose, being merely a mechanical contrivance; it is however very ingenious, a description of which may be seen in Gregory's Mechanics, vol. 2, pa. 405, and in the Philosophical Magazine, vol. 3, where there is also a representation of the instrument.

Chinese STEELYARD. The Chinese carry this statera about them to weigh their gems, and other things of value. The beam or yard is a small rod of wood or ivory, about a foot in length: upon this are three rules of measure, made of a fine silver-studded work; they all begin from the end of the beam, whence the first is extended 8 inches, the second $6\frac{1}{4}$, the third $8\frac{1}{2}$. The first is the European measure, the other two seem to be Chinese measures. At the other end of the yard hangs a round scale, and at three several distances from this end are fastened so many slender strings, as different points of suspension. The first distance makes $1\frac{3}{5}$ or $\frac{8}{5}$ of an inch, the second $3\frac{1}{5}$ or double the first, and the third $4\frac{4}{5}$ or triple of the first. When they weigh any thing, they hold up the yard by some one of these strings, and hang a sealed weight, of about $1\frac{3}{4}$oz troy weight, upon the respective divisions of the rule, as the thing requires. Grew's Museum, pa. 369.

Spring STEELYARD, is a kind of portable balance, serving to weigh any matter, from 1 to about 40 pounds. It is composed of a brass or iron tube, into which goes a rod, and about that is wound a spring of tempered steel in a spiral form. On this rod are the divisions of pounds and parts of pounds, which are made by successively hanging on, to a hook fastened to the other end, 1, 2, 3, 4, &c, pounds.

Now the spring being fastened by a screw to the bottom of the rod; the greater the weight is that is hung upon the hook, the more will the spring be contracted, and consequently a greater part of the rod will come out of the tube; the proportions or quantities of which greater weights are indicated by the figures appearing against the extremity of the tube.

STEELYARD-*Swing*. In the Philos. Trans. (No. 462, sect. 5) is given an account of a steelyard-swing, proposed as a mechanical method for assisting children labouring under deformities, owing to the contraction of the muscles on one side of the body. The crooked person is suspended with cords under his arm, and these are placed at equal distances from the centre of the beam. It is supposed that the gravity of the body will affect the contracted side, so as to put the muscles upon the stretch; and hence by degrees the defect may be remedied.

STEEPLE, a building usually raised on the western end of a church to contain the bells.—Steeples are denominated from their form, either spires, or towers. The first are such as rise continually diminishing like a cone or other pyramid. The latter are mere parallelopipedons, or some other prism, and are covered at top with a platform.—In each kind there is usually a sort of windows, or loop-holes, to let out the sound, and so contrived as to throw it downward.

Masius, in his treatise on bells, treats also of steeples. The most remarkable in the world, it is said, is that at Pisa, which leans so much to one side, that you fear every moment it will fall; yet is in no danger. This odd disposition, he observes, is not owing to a shock of an earthquake, as is generally imagined; but was contrived so at first by the architect; as is evident from the ceilings, windows, doors, &c, which are all in the bevel.

STEERAGE, in a ship, that part next below the quarter-deck, before the bulk-head of the great cabin, where the steersman stands in most ships of war. In large ships of war it is used as a hall, through which it is necessary to pass to or from the great cabin. In merchant ships it is mostly the habitation of the lower officers and ship's crew.

STEERAGE, in Sea-language, is also used to express the effort of the helm: and hence

STEERAGE-*way* is that degree of progressive motion communicated to a ship, by which she becomes susceptible of the effect of the helm to govern her course.

STEERING, in Navigation, the art of directing the ship's way by the movements of the helm; or of applying its efforts to regulate her course when she advances. The perfection of steering consists in a vigilant attention to the motion of the ship's head, so as to check every deviation from the line of her course in the first instant of its motion; and in applying as little of the power of the helm as possible. By this means she will run more uniformly in a straight path, or decline less to the right and left; whereas, if a greater effort of the helm be employed, it will produce a greater declination from the course, and not only increase the difficulty of steering, but also make a crooked and irregular path through the water.

The helmsman, or steersman, should diligently watch the movements of the head by the land, clouds, moon, or stars; because, though the course is in general regulated by the compass, yet the vibrations of the needle are not so quickly perceived, as the sallies of the ship's head to the right or left, which, if not immediately restrained, will acquire additional velocity in every instant of their motion, and require a more powerful impulse of the helm to reduce them; the application of which will operate to turn her head as far on the contrary side of her course.

The phrases used in steering a ship, vary according to the relation of the wind to her course. Thus, when the wind is large or fair, the phrases used by the pilot or officer who superintends the steerage, are port, starboard, and steady: the first of which is intended to direct the ship's course further to the right; the second to the left; and the last is designed to keep her exactly in the line on which she advances, according to the intended course. The excess of the first and second movement is called hard-a-port, and hard-a-starboard; the former of which gives her the greatest possible inclination to the right, and the latter an equal tendency to the left.—If, on the contrary, the wind be scant or foul, the phrases are luff, thus, and no nearer: the first of which is the order to keep her close to the wind; the second, to retain her in her present situation; and the third, to keep her sails full.

STELLA. See STAR.

STENTOROPHONIC *Tube*, a speaking trumpet, or tube employed to speak to a person at a great distance. It has been so called from Stentor, a person mentioned in the 5th book of the Iliad, who, as Homer tells us, could call out louder than 50 men. With the celebrated stentorophonic horn of Alexander the Great, it is said, he could give orders to his army at the distance of 100 stadia, which is about 12 English miles.

The present speaking trumpet, it is said, was invented by Sir Samuel Moreland. But Derham, in his Physico-Theology, lib. 4, chap. 3, says, that Kircher found out this instrument 20 years before Moreland, and published it in his Mesurgia; and it is further said that Gaspar Schottus had seen one at the Jesuits' College at Rome. Also one Conyers, in the Philos. Trans. No. 141, gives a description of an instrument of this kind, different from those commonly made. Gravesande, in his Philosophy, disapproves of the usual figures of these instruments; he would have them to be parabolic conoids, with the focus of one of its parabolic sections at the mouth.—Concerning this instrument, see Sturmy's Collegium Curiosum, Pt. 2, Tentam. 8; also Philos. Trans. vol. 6, pa. 3056, vol. 12, pa. 1027.

STEREOGRAPHIC *Projection of the Sphere*, is that in which the eye is supposed to be placed in the surface of the sphere. Or it is the projection of the circles of the sphere on the plane of some one great circle, when the eye, or a luminous point, is placed in the pole of that circle.—For the fundamental principles and chief properties of this kind of projection, see PROJECTION.

STEREOGRAPHY, is the art of drawing the forms of solids upon a plane.

STEVIN, STEVINUS (SIMON), a Flemish mathematician of Bruges, who died in 1633. He was master of mathematics to prince Maurice of Nassau, and inspector of the dykes in Holland. It is said he was the inventor of the sailing chariots, sometimes made use of in Holland. He was a good practical mathematician and mechanist, and was author of several useful works: as, treatises on Arithmetic, Algebra, Geometry, Statics, Optics, Trigonometry, Geography, Astronomy, Fortification, and many others, in the Dutch language, which were translated into Latin, by Snellius, and printed in 2 volumes folio. There are also two editions in the French language, in folio, both printed at Leyden, the one in 1608, and the other in 1634, with curious notes and additions, by Albert Girard.—For a particular account of Stevin's inventions and improvements in Algebra, which were many and ingenious, see our article Algebra, vol. 1, pa. 89.

STEWART (the Rev. Dr. MATTHEW), late professor of mathematics in the university of Edinburgh, was the son of the reverend Mr. Dugald Stewart, minister of Rothsay in the Isle of Bute, and was born at that place in the year 1717. After having finished his course at the grammar school, being intended by his father for the church, he was sent to the university of Glasgow, and was entered there as a student in 1734. His academical studies were prosecuted with diligence and success; and he was so happy as to be particularly distinguished by the friendship of Dr. Hutcheson, and Dr. Simson the celebrated geometrician, under whom he made great progress in that science.

Mr. Stewart's views made it necessary for him to attend the lectures in the university of Edinburgh in 1741; and that his mathematical studies might suffer no interruption, he was introduced by Dr. Simson to Mr. Maclaurin, who was then teaching with so much success, both the geometry and the philosophy of Newton, and under whom Mr. Stewart made that proficiency which was to be expected from the abilities of such a pupil, directed by those of so great a master. But the modern analysis, even when thus powerfully recommended, was not able to withdraw his attention from the relish of the ancient geometry, which he had imbibed under Dr. Simson. He still kept up a regular correspondence with this gentleman, giving him an account of his progress, and of his discoveries in geometry, which were now both numerous and important, and receiving in return many curious communications with respect to the Loci Plani, and the Porisms of Euclid. Mr. Stewart pursued this latter subject in a different and new direction. In doing which, he was led to the discovery of those curious and interesting propositions, which were published, under the title of General Theorems, in 1746. They were given without the demonstrations; but did not fail to place their discoverer at once among the geometricians of the first rank. They are, for the most part, porisms, though Mr. Stewart, careful not to anticipate the discoveries of his friend, gave them only the name of theorems. They are among the most beautiful, as well as most general propositions, known in the whole compass of geometry, and are perhaps only equalled by the remarkable locus to the circle in the second book of Apollonius, or by the celebrated theorem of Mr. Cotes.

Such is the history of the invention of these propositions; and the occasion of the publication of them was as follows. Mr. Stewart, while engaged in them, had entered into the church, and become minister of Roseneath. It was in that retired and romantic situation, that he discovered the greater part of those theorems. In the summer of 1746, the mathematical chair in the university of Edinburgh became vacant, by the death of Mr. Maclaurin. The General Theorems had not yet appeared; Mr. Stewart was known only to his friends; and the eyes of the public were naturally turned on Mr. Stirling, who then resided at Leadhills, and who was well known in the mathematical world. He however declined appearing as a candidate for the vacant chair; and several others were named, among whom was Mr. Stewart. On this occasion he printed the General Theorems, which gave their author a decided superiority above all the other candidates. He was accordingly elected professor of mathematics in the university of Edinburgh, in September 1747.

The duties of this office gave a turn somewhat different to his mathematical pursuits, and led him to think of the most simple and elegant means of explaining those difficult propositions, which were hitherto only accessible to men deeply versed in the modern analysis. In doing this, he was pursuing the object which, of all others, he most ardently wished to attain, viz, the application of geometry to such problems as the algebraic calculus alone had been thought able to resolve. His solution of Kepler's problem was the first specimen of this kind which he published; and it was perhaps impossible to have produced one more to the credit of the method he followed, or of the abilities with which he applied it. Among the excellent solutions hitherto given of this famous problem, there were none of them at once direct in its method, and simple in its principles. Mr. Stewart was so happy as to attain both these objects. He founds his solution on a general property of curves, which, though very simple, had perhaps never been observed; and by a most ingenious application of that property, he shows how the approximation may be continued to any degree of accuracy, in a series of results which converge with great rapidity.

This solution appeared in the second volume of the Essays of the Philosophical Society of Edinburgh, for the year 1756. In the first volume of the same collection, there are some other propositions of Mr. Stewart's, which are an extension of a curious theorem in the 4th book of Pappus. They have a relation to the subject of Porisms, and one of them forms the 91st of Dr. Simson's Restoration.

It has been already mentioned, that Dr. Stewart had formed the plan of introducing into the higher parts of mixed mathematics, the strict and simple form of ancient demonstration. The prosecution of this plan produced the Tracts Physical and Mathematical, which were published in 1761. In the first of these, Dr. Stewart lays down the doctrine of centripetal forces, in a series of propositions, demonstrated (if we admit the quadrature of curves) with the utmost rigour, and requiring no previous knowledge of the mathematics, except the elements of plane Geometry, and of Conic Sections. The good order of these propositions, added to the clearness and simplicity of the demonstrations, renders this tract perhaps the best elementary treatise of Physical Astronomy that is any where to be found.

In the three remaining tracts, our author had it in view to determine, by the same rigorous method, the effect of those forces which disturb the motions of a secondary planet. From this he proposed to deduce, not only a theory of the moon, but a determination of the sun's distance from the earth. The former, it is well known, is the most difficult subject to which mathematics have been applied, and the resolution required and merited all the clearness and simplicity which our author possessed in so eminent a degree. It must be regretted therefore, that the decline of Dr. Stewart's health, which began soon after the publication of the tracts, did not permit him to pursue this investigation.

The other object of the tracts was, to determine the distance of the sun, from his effect in disturbing the motions of the moon; and Dr. S.'s inquiries into the lunar irregularities had furnished him with the means of accomplishing it.

The theory of the composition and resolution of forces enables us to determine what part of the solar force is employed in disturbing the motions of the moon; and therefore, could we measure the instantaneous effect of that force, or the number of feet by which it accelerates or retards the moon's motion in a second, we should be able to determine how many feet the whole force of the sun would make a body, at the distance of the moon, or of the earth, descend in a second of time, and consequently how much the earth is, in every instant, turned out of its rectilineal course. Thus the curvature of the earth's orbit, or, which is the same thing, the radius of that orbit, that is, the distance of the sun from the earth, would be determined. But the fact is, that the instantaneous effects of the sun's disturbing force are too minute to be measured; and that it is only the effect of that force, continued for an entire revolution, or some considerable portion of a revolution, which astronomers are able to observe.

There is yet a greater difficulty which embarrasses the solution of this problem. For as it is only by the difference of the forces exerted by the sun on the earth and on the moon, that the motions of the latter are disturbed, the farther off the sun is supposed to be, the less will be the force by which he disturbs the moon's motions; yet that force will not diminish beyond a fixed limit, and a certain disturbance would obtain, even if the distance of the sun were infinite. Now the sun is actually placed at so great a distance, that all the disturbances, which he produces on the lunar motions, are very near to this limit, and therefore a small mistake in estimating their quantity, or in reasoning about them, may give the distance of the sun infinite, or even impossible. But all this did not deter Dr. Stewart from undertaking the solution of the problem, with no other assistance than that which geometry could afford. Indeed the idea of such a problem had first occurred to Mr. Machin, who, in his book on the laws of the moon's motion, has just mentioned it, and given the result of a rude calculation (the method of which he does not explain), which assigns 8″ for the parallax of the sun. He made use of the motion of the nodes; but Dr. Stewart considered the motion of the apogee, or of the longer axis of the moon's orbit, as the irregularity best adapted to his purpose. It is well known that the orbit of the moon is not immoveable; but that, in consequence of the disturbing force of the sun, the longer axis of that orbit has an angular motion, by which it goes back about 3 degrees in every lunation, and completes an entire revolution in 9 years nearly. This motion, though very remarkable and easily determined, has the same fault, with respect to the present problem, that was ascribed to the other irregularities of the moon: for a very small part of it only depends on the parallax of the sun; and of this Dr. Stewart seems not to have been perfectly aware.

The propositions however which defined the relation between the sun's distance and the mean motion of the apogee, were published among the tracts, in 1761. The transit of Venus happened also in that year: and the astronomers returned, who had viewed that curious phenomenon, from the most distant stations; and no very satisfactory result was obtained from a comparison of their observations. Dr. Stewart then resolved to apply the principles he had already laid down; and, in 1763, he published his essay on the Sun's Distance, where the computation being actually made, the parallax of the sun was found to be no more than 6″·9, and consequently his distance almost 29875 semidiameters of the earth, or nearly 119 millions of miles.

A determination of the sun's distance, that so far exceeded all former estimations of it, was received with surprise, and the reasoning on which it was founded was likely to undergo a severe examination. But, even among astronomers, it was not every one who could judge in a matter of such difficult discussion. Accordingly, it was not till about 5 years after the publication of the sun's distance, that there appeared a pamphlet, under the title of Four Propositions, intended to point out certain errors in Dr. Stewart's investigation, which had given a result much greater than the truth. From his desire of simplifying, and of employing only the geometrical method of reasoning, he was reduced to the necessity of rejecting quantities, which were considerable enough to have a great effect on the last result. An error was thus introduced, which, had it not been for certain compensations, would have become immediately obvious, by giving the sun's distance near three times as great as that which has been mentioned.

The author of the pamphlet, referred to above, was the first who remarked the dangerous nature of these simplifications, and who attempted to estimate the error to which they had given rise. This author remarked what produced the compensation above mentioned, viz, the immense variation of the sun's distance, which corresponds to a very small variation of the motion of the moon's apogee. And it is but justice to acknowledge that, besides being just in the points already mentioned, they are very ingenious, and written with much modesty and good temper. The author, who at first concealed his name, but has now consented to its being made public, was Mr. Dawson, a surgeon at Sedberg in Yorkshire, and one of the most ingenious mathematicians and philosophers this country now possesses.

A second attack was soon after this made on the Sun's Distance, by Mr. Landen; but by no means with the same good temper which has been remarked in the former. He fancied to himself errors in Dr. Stewart's investigation, which have no existence; he exaggerated those that were real, and seemed to triumph in the discovery of them with unbecoming exultation. If there are any subjects on which men may be expected to reason dispassionately, they are certainly the properties of number and extension; and whatever pretexts moralists or divines may have for abusing one another, mathematicians can lay claim to no such indulgence. The asperity of Mr Landen's animadversions ought not therefore to pass uncensured, though it be united with sound reasoning and accurate discussion. But Mr. Landen, in the zeal of correction, brings many other charges against Dr. Stewart, the greater part of which seem to have no good foundation. Such are his objections to the second part of the investigation, where Dr. Stewart finds the relation between the disturbing force of the sun, and the motion of the apses of the lunar orbit. For this part, instead of being liable to objection, is deserving of the greatest praise, since it resolves, by geometry alone, a problem which had eluded the efforts of some of the ablest mathematicians, even when they availed themselves of the utmost resources of the integral calculus. Sir Isaac Newton, though he assumed the disturbing force very near the truth, computed the motion of the apses from thence only at one half of what it really amounts to; so that, had he been required, like Dr. Stewart, to invert the problem, he would have committed an error, not merely of a few thousandth parts, as the latter is alleged to have done, but would have brought out a result double of the truth. (Princip. Math. lib. 3, prop. 3.) Machin and Callendrini, when commenting on this part of the Principia, found a like inconsistency between their theory and observation. Three other celebrated mathematicians, Clairaut, Dalembert, and Euler, severally experienced the same difficulties, and were led into an error of the same magnitude. It is true, that, on resuming their computations, they found that they had not carried their approximations to a sufficient length, which when they had at last accomplished, their results agreed exactly with observation. Mr. Walmsley and Dr. Stewart were, I think, the first mathematicians who, employing in the solution of this difficult problem, the one the algebraic calculus, and the other the geometrical method, were led immediately to the truth; a circumstance so much for the honour of both, that it ought not to be forgotten. It was the business of an impartial critic, while he examined our author's reasonings, to have remarked and to have weighed these considerations.

The Sun's Distance was the last work which Dr. Stewart published; and though he lived to see the animadversions made on it, that have been taken notice of above, he declined entering into any controversy. His disposition was far from polemical; and he knew the value of that quiet, which a literary man should rarely suffer his antagonists to interrupt. He used to say, that the decision of the point in question was now before the public; that if his investigation was right, it would never be overturned, and that if it was wrong, it ought not to be defended.

A few months before he published the Essay just mentioned, he gave to the world another work, entitled Propositiones More Veterum Demonstratæ. It consists of a series of geometrical theorems, mostly new; investigated, first by an analysis, and afterwards synthetically demonstrated by the inversion of the same analysis. This method made an important part in the analysis of the ancient geometricians; but few examples of it have been preserved in their writings, and those in the Propositiones Geometricæ are therefore the more valuable.

Dr. Stewart's constant use of the geometrical analysis had put him in possession of many valuable propositions, which did not enter into the plan of any of the works that have been enumerated. Of these, not a few have found a place in the writings of Dr. Simson, where they will for ever remain, to mark the friendship of these two mathematicians, and to evince the esteem which Dr. Simson entertained for the abilities of his pupil. Many of these are in the work upon the Porisms, and others in the Conic Sections, viz, marked with the letter *x*; also a theorem in the edition of Euclid's data.

Soon after the publication of the Sun's Distance, Dr. Stewart's health began to decline, and the duties of his office became burdensome to him. In the year 1772, he retired to the country, where he afterwards spent the greater part of his life, and never resumed his labours in the university. He was however so fortunate as to have a son to whom, though very young, he could commit the care of them with the greatest confidence. Mr. Dugald Stewart, having begun to give lectures for his father from the period above-mentioned, was elected joint professor with him in 1775, and gave an early specimen of those abilities, which have not been confined to a single science.

After mathematical studies (on account of the bad state of health into which Dr. Stewart was falling) had ceased to be his business, they continued to be his amusement. The analogy between the circle and hyperbola had been an early object of his admiration. The extensive views which that analogy is continually opening; the alternate appearance and disappearance of resemblance in the midst of so much dissimilitude, make it an object that astonishes the experienced, as well as the young geometrician. To the consideration of this analogy therefore the mind of Dr. Stewart very naturally returned, when disengaged from other speculations. His usual success still attended his investigations; and he has left among his papers some curious approximations to the areas, both of the circle and hyperbola. For some years toward the end of his life, his health scarcely allowed him to prosecute study even as an amusement. He died the 23d of January 1785, at 68 years of age.

The habits of study, in a man of original genius, are objects of curiosity, and deserve to be remembered. Concerning those of Dr. Stewart, his writings have made it unnecessary to remark, that from his youth he had been accustomed to the most intense and continued application. In consequence of this application, added to the natural vigour of his mind, he retained the memory of his discoveries in a manner that will hardly be believed. He seldom wrote down any of his investigations, till it became necessary to do so for the purpose of publication. When he discovered any proposition, he would set down the enunciation with great accuracy, and on the same piece of paper would construct very neatly the figure to which it referred. To these he trusted for recalling to his mind, at any future period, the demonstration, or the analysis, however complicated it might be. Experience had taught him that he might place this confidence in himself without any danger of disappointment; and for this singular power, he was probably more indebted to the activity of his invention, than to the mere tenaciousness of his memory.

Though Dr. Stewart was extremely studious, he read but few books, and thus verified the observation of Dalembert, that, of all the men of letters, mathematicians read least of the writings of one another. Our author's own investigations occupied him sufficiently; and indeed the world would have had reason to regret the misapplication of his talents, had he employed, in the mere acquisition of knowledge, that time which he could dedicate to works of invention.

It was Dr. Stewart's custom to spend the summer at a delightful retreat in Ayrshire, where, after the academical labours of the winter were ended, he found the leisure necessary for the prosecution of his researches. In his way thither, he often made a visit to Dr. Simson of Glasgow, with whom he had lived from his youth in the most cordial and uninterrupted friendship. It was pleasing to observe, in these two excellent mathematicians, the most perfect esteem and affection for each other, and the most entire absence of jealousy, though no two men ever trode more nearly in the same path. The similitude of their pursuits served only to endear them to each other, as it will ever do with men superior to envy. Their sentiments and views of the science they cultivated, were nearly the same; they were both profound geometricians; they equally admired the ancient mathematicians, and were equally versed in their methods of investigation; and they were both apprehensive that the beauty of their favourite science would be forgotten, for the less elegant methods of algebraic computation. This innovation they endeavoured to oppose; the one, by reviving those books of the ancient geometry which were lost; the other, by extending that geometry to the most difficult inquiries of the moderns. Dr. Stewart, in particular, had remarked the intricacies, in which many of the greatest of the modern mathematicians had involved themselves in the application of the calculus, which a little attention to the ancient geometry would certainly have enabled them to avoid. He had observed too the elegant synthetical demonstrations that, on many occasions, may be given of the most difficult propositions, investigated by the inverse method of fluxions. These circumstances had perhaps made a stronger impression than they ought, on a mind already filled with admiration of the ancient geometry, and produced too unfavourable an opinion of the modern analysis. But if it be confessed that Dr. Stewart rated, in any respect too high, the merit of the former of these sciences, this may well be excused in the man whom it had conducted to the discovery of the General Theorems, to the solution of Kepler's Problem, and to an accurate determination of the Sun's disturbing force. His great modesty made him ascribe to the method he used, that success which he owed to his own abilities.

The foregoing account of Dr. Stewart and his writings, is chiefly extracted from the learned history of them, by Mr. Playfair, in the 1st volume of the Edinburgh Philosophical Transactions, pa. 57, &c.

STIFEL, STIFELIUS (MICHAEL), a Protestant minister, and very skilful mathematician, was born at Eslingen, a town in Germany; and died at Jena in Thuringia, in the year 1567, at 58 years of age according to Vossius, but some others say 80. Stifel was one of the best mathematicians of his time. He published, in the German language, a treatise on Algebra, and another on the Calendar or Ecclesiastical computation. But his chief work, is the Arithmetica Integra, a complete and excellent treatise, in Latin, on arithmetic and algebra, printed in 4to at Norimberg 1544. In this work there are a number of ingenious inventions, both in common arithmetic and in algebra; of which, those relating to the latter are amply explained under the article Algebra in this dictionary, vol. 1.; to which may be added some particulars concerning the arithmetic, from the first volume of my Tracts, pa. 231, &c. In this original work are contained many curious things, some of which have mistakingly been ascribed to a much later date. He here treats pretty fully and ably, of progressional and figurate numbers, and in particular of the triangular table, for constructing both them and the coefficients of the terms of all powers of a binomial; which has been so often used since his time for these and other purposes, and which more than a century after was, by Pascal, otherwise called the Arithmetical Triangle, and who only mentioned some additional properties of the table. Stifel shows, that the horizontal lines of the table furnish the coefficients of the terms of the corresponding powers of a binomial; and teaches how to make use of them in the extraction of roots of all powers whatever. Cardan seems to ascribe the invention of that table to Stifelius; but I apprehend that is only to be understood of its application to the extraction of roots.

It is remarkable too, how our author, at pa. 35 &c of the same book, treats of the nature and use of logarithms; not under that name indeed, but under the idea of a series of arithmeticals, adapted to a series of geometricals. He there explains all their uses; such as, that the addition of them answers to the multiplication of their geometricals; subtraction to division; multiplication of exponents to involution; and dividing of exponents to evolution. He also exemplifies the use of them in cases of the Rule-of-three, and in finding mean proportionals between given terms, and such like, exactly as is done in logarithms. So that he seems to have been in the foll possession of the idea of logarithms, and wanted only the necessity of troublesome calculations to induce him to make a table of such numbers.

Stifelius wrote also pretty largely on magic squares.

Stifel was a zealous, though weak disciple of Luther. He took it into his head to become a prophet, and he predicted that the end of the world would happen on a certain day in the year 1553, by which he terrified many people. When the proposed day arrived, he repaired early, with multitudes of his followers, to a particular place in the open air, spending the whole day in the most fervent prayers and praises, in vain looking for the coming of the Lord, and the universal conflagration of the elements, &c.

STILE. See STYLE.

STILYARD. See STEELYARD.

STOFLER (JOHN), a German mathematician, was born at Justingen in Suabia, in 1452, and died in 1531, at 79 years of age. He taught mathematics at Tubinga, where he acquired a great reputation, which however he in a great measure lost again, by intermeddling with the prediction of future events. He announced a great deluge, which he said would happen in the year 1524, a prediction with which he terrified all Germany, where many persons prepared vessels proper to escape with from the floods. But happily the prediction failing, it enraged the astrologer, though it served to convince him of the vanity of his prognostications.—He was author of several works in mathematics and astrology, full of foolish and chimerical ideas; such as,

1. Elucidatio Fabric. Ususque Astrolabii; fol. 1513.
2. Procli Sphæram Comment. fol. 154.
3. Cosmographicæ aliquot Descriptiones; 4to, 1537.

STONE (EDMUND), a respectable mathematician, who was author of several ingenious works. I know not the particular place or date of his birth, but it was probably in the shire of Argyle, and towards the conclusion of the 17th century. Nor have we any memoirs of his life, except what are contained in a letter from the Chevalier de Ramsay, author of the Travels of Cyrus, in a letter to father Castel, a Jesuit at Paris, and published in the Memoires de Trevoux, pa. 109, as follows: "True genius overcomes all the disadvantages of birth, fortune, and education; of which Mr. Stone is a rare example. Born a son of a gardener of the duke of Argyle, he arrived at 8 years of age before he learnt to read.—By chance a servant having taught young Stone the letters of the alphabet, there needed nothing more to discover and expand his genius. He applied himself to study, and he arrived at the knowledge of the most sublime geometry and analysis, without a master, without a conductor, without any other guide but pure genius.

"At 18 years of age he had made these considerable advances without being known, and without knowing himself the prodigies of his acquisitions. The duke of Argyle, who joined to his military talents a general knowledge of every science that adorns the mind of a man of his rank, walking one day in his garden, saw lying on the grass a Latin copy of Sir Isaac Newton's celebrated Principia. He called some one to him to take and carry it back to his library. Our young gardener told him that the book belonged to him. To you? replied the Duke. Do you understand geometry, Latin, Newton? I know a little of them, replied the young man with an air of simplicity arising from a profound ignorance of his own knowledge and talents. The Duke was surprised; and having a taste for the sciences, he entered into conversation with the young mathematician: he asked him several questions, and was astonished at the force, the accuracy, and the candour of his answers. But how, said the Duke, came you by the knowledge of all these things? Stone replied, A servant taught me, ten years since, to read: does one need to know any thing more than the 24 letters in order to learn every thing else that one wishes? The Duke's curiosity redoubled—he sat down upon a bank, and requested a detail of all his proceedings in becoming so learned.

"'I first learned to read, said Stone: the masons were then at work upon your house: I went near them one day, and I saw that the architect used a rule, compasses, and that he made calculations. I inquired what might be the meaning of and use of these things; and I was informed that there was a science called Arithmetic; I purchased a book of arithmetic, and I learned it.—I was told there was another science called Geometry: I bought the books, and I learnt geometry. By reading I found that there were good books in these two sciences in Latin: I bought a dictionary, and I learned Latin. I understood also that there were good books of the same kind in French: I bought a dictionary, and I learned French. And this, my lord, is what I have done: it seems to me that we may learn every thing when we know the 24 letters of the alphabet.'

"This account charmed the Duke. He drew this wonderful genius out of his obscurity; and he provided him with an employment which left him plenty of time to apply himself to the sciences. He discovered in him also the same genius for music, for painting, for architecture, for all the sciences which depend on calculations and proportions.

"I have seen Mr. Stone. He is a man of great simplicity. He is at present sensible of his own knowledge; but he is not puffed up with it. He is possessed with a pure and disinterested love for the mathematics; though he is not solicitous to pass for a mathematician; vanity having no part in the great labour he sustains to excel in that science. He despises fortune also; and he has solicited me twenty times to request the duke to give him less employment, which may not be worth the half of that he now has, in order to be more retired, and less taken off from his favourite studies. He discovers sometimes, by methods of his own, truths which others have discovered before him; and he is charmed to find on these occasions that he is not a first inventor, and that others have made a greater progress than he thought. Far from being a plagiary, he attributes ingenious solutions, which he gives to certain problems, to the hints he has found in others, although the connexion is but very distant," &c.

Mr. Stone was author and translator of several useful works; viz, A New Mathematical Dictionary, in 1 vol. 8vo, first printed in 1726.

2. Fluxions, in 1 vol. 8vo, 1730. The Direct Method is a translation from the French, of Hospital's Analyse des Infiniments Petits; and the Inverse Method was supplied by Stone himself.

3. The Elements of Euclid, in 2 vols. 8vo, 1731. A neat and useful edition of this work, with an account of the life and writings of Euclid, and a defence of his elements against modern objectors.

4. Dr. Barrow's Geometrical Lectures, translated from the Latin, 1 vol. 8vo, 1735.

Besides other smaller works.

Stone was a fellow of the Royal Society, and had inserted in the Philos. Trans. (vol. 41, pa. 218) an "Account of two species of lines of the 3d order, not mentioned by Sir Isaac Newton, or Mr. Stirling."

Stones, *Meteoric*, certain semi-metallic masses which sometimes fall from the atmosphere. See Aerolite

STRABO, a celebrated Greek geographer, philosopher, and historian, was born at Amasia, and was descended from a family settled at Gnossus in Crete. He was the disciple of Xenarchus, a Peripatetic philosopher, but at length attached himself to the Stoics. He contracted a strict friendship with Cornelius Gallus, governor of Egypt; and travelled into several countries, to observe the situation of places, and the customs of nations.

Strabo flourished under Augustus; and died under Tiberius about the year 25, at a very advanced age.—He composed several works; all of which are lost, except his Geography, in 17 books; which are justly esteemed very precious remains of antiquity. The first two books are employed in showing, that the study of geography is not only worthy of a philosopher, but even necessary to him; the 3d describes Spain; the 4th, Gaul and the Britannic isles; the 5th and 6th, Italy and the adjacent isles; the 7th, which is imperfect at the end, Germany, the countries of the Getæ and Illyrii, Taurica, Chersonesus, and Epirus; the 8th, 9th, and 10th, Greece with the neighbouring isles; the four following, Asia within Mount Taurus; the 15th and 16th, Asia without Taurus, India, Persia, Syria, Arabia; and the 17th, Egypt, Ethiopia, Carthage, and other parts of Africa.

Strabo's work was published with a Latin version by Xylander, and notes by Isaac Casaubon, at Paris 1620, in folio; but a better edition is that of Amsterdam in 1707, in 2 volumes folio, by the learned Theodore Janson of Almelooveen, with the entire notes of Xylander, Casaubon, Meursius, Cluver, Holsten, Salmasius, Bochart, Ez. Spanheim, Cellar, and others. To this edition is subjoined the Chrestomathiæ, or Epitome of Strabo; which, according to Mr. Dodswell, who has written a very elaborate and learned dissertation about it, was made by some unknown person, between the years of Christ 676 and 996. It has been found of some use, not only in helping to correct the original, but in supplying in some measure the defect in the 7th book. Mr. Dodswell's dissertation is prefixed to this edition. An edition has lately been published at Oxford.

STRAIT, or Straight, or Streight, in Hydrography, is a narrow channel or arm of the sea, shut up between lands on either side, and usually affording a passage out of one great sea into another. As the Straits of Magellan, of Le Maire, of Gibraltar, &c.

Strait is also sometimes used, in Geography, for an isthmus, or neck of land between two seas, preventing their communication.

STRENGTH, *vis*, force, power. Some authors suppose the strength of animals, of the same kind, to depend on the quantity of blood; but most on the size of the bones, joints, and muscles; though we find by daily experience, that the animal spirits contribute greatly to strength at different times.

Emerson has most particularly treated of the strength of bodies depending on their dimensions and weight. In the general scholium after his propositions on this subject, he adds; If a certain beam of timber be able to support a given weight; another beam, of the same timber, similar to the former, may be taken so great, as to be able but just to bear its own weight: while any larger beam cannot support itself, but must break by its own weight; but any less beam will bear something more. For the strength being as the cube of the depth; and the stress, being as the length and quantity of matter, is as the 4th power of the depth; it is plain, therefore, that the stress increases in a greater ratio than the strength. Whence it follows, that a beam may be taken so large, that the stress may far exceed the strength: and that, of all similar beams, there is but one that will just support itself, and nothing more. And the like holds true in all machines, and in all animal bodies. And hence there is a certain limit, in regard to magnitude, not only in all machines and artificial structures, but also in natural ones, which neither art nor nature can go beyond; supposing them made of the same matter, and in the same proportion of parts.

Hence it is impossible that mechanic engines can be increased to any magnitude at pleasure. For when they arrive at a particular size, their several parts will break and fall asunder by their own weight. Neither can any buildings of vast magnitudes be made to stand, but must fall to pieces by their great weight, and go to ruin.

It is likewise impossible for nature to produce animals of any vast size at pleasure: except some sort of matter can be found, to make the bones of, which may be so much harder and stronger than any hitherto known: or else that the proportion of the parts be so much altered, and the bones and muscles made thicker in proportion; which will make the animal distorted, and of a monstrous figure, and not capable of performing any proper actions. And being made similar and of common matter, they will not be able to stand or move; but, being burthened with their own weight, must fall down. Thus, it is impossible that there can be any animal so large as to carry a castle upon his back; or any man so strong as to remove a mountain, or pull up a large oak by the roots: nature will not admit of these things; and it is impossible that there can be animals of any sort beyond a determinate size.

Fish may indeed be produced to a larger size than land animals; because their weight is supported by the water. But yet even these cannot be increased to immensity, because the internal parts will press upon one another by their weight, and destroy their fabric.

On the contrary, when the size of animals is diminished, their strength is not diminished in the same proportion as the weight. For which reason a small animal will carry far more than a weight equal to its own, while a great one cannot carry so much as its weight. And hence it is that small animals are more active, will run faster, jump farther, or perform any motion quicker, for their weight, than large animals: for the less the animal, the greater the proportion of the strength to the stress. And nature seems to know no bounds as to the smallness of animals, at least in regard to their weight.

Neither can any two unequal and similar machines resist any violence alike, or in the same proportion; but the greater will be more hurt than the less. And the same is true of animals; for large animals by falling break their bones, while lesser ones, falling higher, receive no damage. Thus a cat may fall two or three yards high, and be no worse, and an ant from the top of a tower.

It is likewise impossible in the nature of things, that there can be any trees of immense size; if there were any such, their limbs, boughs, and branches, must break off and fall down by their own weight. Thus it is impossible there can be an oak a quarter of a mile high; such a tree cannot grow or stand, but its branches will drop off by their own weight. And hence also smaller plants can better sustain themselves than large ones.

As to the due proportion of strength in several bodies, according to their particular positions, and the weights they are to bear; he further observes that, if a piece of timber is to be pierced with a mortise-hole, the beam will be stronger when it is taken out of the middle, than when taken out of either side. And in a beam supported at both ends, it is stronger when the hole is made in the upper side than when made in the under, provided a piece of wood is driven hard in to fill up the hole.

If a piece is to be spliced upon the end of a beam, to be supported at both ends; it will be the stronger when spliced on the under side of a beam: but if the piece is supported only at one end, to bear a weight on the other; it is stronger when spliced on the upper side.

When a small lever, &c, is nailed to a body, to move it or suspend it by; the strain is greater upon the nail nearest the hand, or point where the power is applied.

If a beam be supported at both ends; and the two ends reach over the props, and be fixed down immoveable; it will bear twice as much weight, as when the ends only lie loose or free upon the supporters.

When a slender cylinder is to be supported by two pieces; the distance of the pins ought to be nearly $\frac{4}{7}$ of the length of the cylinder, and the pins equidistant from its ends; and then the cylinder will endure the least bending or strain by its weight.

The strength of a beam or bar, to resist a fracture by a force acting laterally, is as a solid, made by a section of the beam in the place where the force is applied, into the distance of its centre of gravity, from the point or line where the breach will end.

In square beams, the lateral strengths are as the cubes of the breadths or depths: and in cylindrical beams, the strengths are as the cubes of the diameters; the same is also true of all beams whose sections are similar figures, that is, the strengths are as the cubes of the corresponding dimensions.

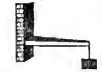
In rectangular beams the lateral strengths are conjointly as the breadths and squares of the depths. Hence the lateral strength of a beam with its narrower face upwards, is to its strength with its broader face upwards, as the breadth of the broader face to the narrower one.

The lateral strengths of prismatic beams of the same materials, are as the areas of the sections and the distances of their centres of gravity, directly, and as their lengths and weights, inversely. This is true whether the beams be both supported at one end or at both; and in the latter case, a beam of any length is equal in strength to another of the same breadth and depth and of only half the length, when supported at one end.

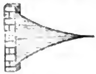
The lateral strengths of two cylinders (of the same matter) of equal weight and length, one of which is hollow and the other solid, are to each other as the diameters of their ends.—The lateral strengths of tubes and solid cylinders of equal length and similar materials, are as the areas of their ends and their diameters conjointly.

The strongest rectangular beam which can be cut out of a given cylinder, is that of which the squares of the breadth and depth, and the square of the cylinder's diameter, are respectively as the numbers 1, 2, and 3.—When a triangular beam is supported at both ends, its strength when the edge of the beam is uppermost, is to the strength when the other side is uppermost, as 2 to 1.

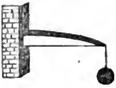
A beam fixed at one end, and bearing a weight at the other; if it be cut in the form of a wedge, and placed with its parallel sides parallel to the horizon; it will be equally strong every where; and no sooner break in one place than another.



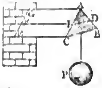
When a beam has all its sides cut in form of a concave parabola, having the vertex at the end, and its absciss perpendicular to the axis of the solid, and the base a square, or a circle, or any regular polygon; such a beam fixed horizontally, at one end, is equally strong throughout for supporting its own weight.



If a beam be placed horizontally with one end fixed to a wall, and a weight be hung at the other, then if its breadth be the same throughout, it will be equally strong in all parts, when the vertical sides are in the form of a parabola.



Moreover, if AE be a beam in form of a triangular prism; and if AD = $\frac{1}{9}$AB, and AI = $\frac{1}{9}$AC, and the edge or small similar prism ADIF be cut away parallel to the base; the remaining beam DIBEF will bear a greater weight P, than the whole ABCFG, or the part will be stronger than the whole; which is a paradox in Mechanics.



Also when a wall faces the wind, and if the vertical section of it be a right-angled triangle; or if the fore part next the wind &c be perpendicular to the horizon, and the back part a sloping plane; such a wall will be equally strong in all its parts to resist the wind, if the parts of the wall cohere strongly together; but when it is built of loose materials, it is better to be convex on the back part in form of a parabola.

When a wall is to support a bank of earth or any fluid body, it ought to be built concave in form of a semicubical parabola, whose vertex is at the top of the wall, provided the parts of the wall adhere firmly together. But if the parts be loose, then a right line or sloping plane ought to be its figure. Such walls will be equally strong throughout.

All spires of churches in the form of cones or pyramids, are equally strong in all parts to resist the wind. But when the parts do not cohere together, then they ought to be parabolic conoids, to be equally strong throughout.

Likewise if there be a pillar erected in form of the logarithmic curve, the asymptote being the axis; it cannot be crushed to pieces in one part sooner than in another, by its own weight. And if such a pillar be turned upside down, and suspended by the thick end, it will not be more liable to separate in one part than another, by its own weight

As to the strength of several sorts of wood, drawn from experiments, Mr. E. says, On a medium, a piece of good oak, an inch square, and a yard long, supported at both ends, will bear in the middle, for a very short time, about 330lb avoirdupois, but will break with more than that weight. But such a piece of wood should not, in practice, be trusted for any length of time, with more than a third or a fourth part of that weight. And the proportion of the strength of several sorts of wood, he found to be as follows:

Box, oak, plumtree, yew - - -	11
Ash, elm - - - - - - - -	$8\frac{1}{2}$
Thorn, walnut - - - - - -	$7\frac{1}{2}$
Apple tree, elder, red fir, holly, plane	7
Beech, cherry, hazle - - - -	$6\frac{2}{3}$
Alder, asp, birch, white-fir, willow	6
Iron - - - - - - - - - -	107
Brass - - - - - - - - -	50
Bone - - - - - - - - - -	22
Lead - - - - - - - - - -	$6\frac{1}{2}$
Fine free stone - - - - - -	1

As to the strength of bodies in direction of the fibres, he observes, A cylindric rod of good clean fir, of an inch circumference, drawn in length, will bear at extremity 400lb; and a spear of fir 2 inches diameter, will bear about 7 ton.—A rod of good iron, of an inch circumference, will bear near 3 ton weight. And a good hempen rope of an inch circumference, will bear 1000lb. at extremity.

All this supposes these bodies to be sound and good throughout; but none of them should be put to bear more than a third or a fourth part of that weight, especially for any length of time. From what has been said; if a spear of fir, or a rope, or a spear of iron, of d inches diameter, were to lift $\frac{1}{4}$ the extreme weight; then

The fir would bear $8\frac{4}{5}dd$ hundred weight.

The rope would bear $22dd$ hundred weight.

The iron would bear $6\frac{3}{4}dd$ ton weight.

See on this subject Gregory's Mechanics, vol. 1, pa. 104, and following: as also Emerson on the same subject in his 4to edition. Also my Course of Mathematics, vol. 2.

As to animals; men may apply their strength several ways, in working a machine. A man of ordinary strength turning a roller by the handle, can act for a whole day against a resistance equal to 30lb. weight; and if he works 10 hours a day, he will raise a weight of 30lb. through $3\frac{1}{2}$ feet in a second of time; or if the weight be greater, he will raise it so much less in proportion. But a man may act, for a small time, against a resistance of 50lb. or more.

If two men work at a windlass, or roller, they can more easily draw up 70lb, than one man can 30lb, provided the elbow of one of the handles be at right angles to that of the other. And with a fly, or heavy wheel, applied to it, a man may do $\frac{1}{2}$ part more work; and for a little while he can act with a force, or overcome a continual resistance, of 80lb; and work a whole day when the resistance is but 40lb.—Men used to bear loads, such as porters, will carry, some 150lb, others 200 or 250lb, according to their strength.—A man can draw but about 70 or 80lb. horizontally; for he can but apply about half his weight.—If the weight of a man be 140lb, he can act with no greater a force in thrusting horizontally, at the height of his shoulders, than 27lb.

As to horses; a horse is, generally speaking, as strong as 5 men. A horse will carry 240 or 270lb. A horse draws to greatest advantage, when the line of direction is a little elevated above the horizon, and the power acts against his breast: and he can draw 200lb. for 8 hours a day, at $2\frac{1}{2}$ miles an hour. If he draw 240lb, he can work but 6 hours, and not go quite so fast. And in both cases, if he carries some weight, he will draw the better for it. And this is the weight a horse is supposed to be able to draw over a pulley out of a well. But in a cart, a horse may draw 1000lb, or even double that weight, or a ton weight, or more.

As the most force a horse can exert, is when he draws a little above the horizontal position: so the worst way of applying the strength of a horse, is to make him carry or draw uphill: And three men in a steep hill, carrying each 100lb, will climb up faster than a horse with 300lb. Also, though a horse may draw in a round walk of 18 feet diameter; yet such a walk should not be less than 25 or 30 feet diameter. Emerson's Mechan. pa. 111 and 177.

For more on this subject, see Girard's treatise on the Resistance of Solids; Gregory's Mechanics, vol. 1; my Course of Mathematics, vol. 3, &c.

STRESS, in Mechanics, a familiar term used to denote the load, weight, or force, which a bar or beam has to sustain; being as the *distress* or oppression which it has to sustain and support; whether arising from its own weight, or from any adventitious load or force whatever. This is commonly treated of in conjunction with the strength, as in the preceding article; or as in the Mechanics of Emerson or of Gregory, or in my Course of Mathematics, &c.

STRIKE, or STRYKE, a measure, containing 4 bushels, or half a quarter.

STRIKING-*wheel*, in a clock, the same as that by some called the pin-wheel, because of the pins which are placed on the round or rim, the number of which is the quotient of the pinion divided by the pinion of the detent-wheel. In sixteen-day clocks, the first or great wheel is usually the pin-wheel; but in such as go 8 days, the second wheel is the pin-wheel, or striking-wheel.

STRING, in Music. See CHORD.—If two strings or chords of a musical instrument only differ in length; their tones, or the number of vibrations they make in the same time, are in the inverse ratio of their lengths. If they differ only in thickness, their tones are in the inverse ratio of their diameters.

As to the tension of strings, to measure it regularly, they must be conceived stretched or drawn by weights; and then, cæteris paribus, the tones of two strings are in a direct ratio of the square roots of the weights that stretch them; that is, ex. gr. the tone of a string stretched by a weight 4, is an octave above the tone of a string stretched by the weight 1.

It is an observation of very old standing, that if a viol or lute-string be touched with the bow, or the hand, another string on the same instrument, or even on another, not far from it, if in unison with it, or in octave, or the like, will at the same time tremble of itself. But it is now found, that it is not the whole of that other string that thus trembles, but only the parts, severally, according as they are unisons to the whole, or the parts, of the string so struck. Thus, supposing AB to be an upper octave to *ab*, and therefore an unison to each half of it, stopped at *c*; if while *ab* is open, AB be struck,

the two halves of this other, that is, *ac*, and *cb*, will both tremble; but the middle point will be at rest; as will be easily perceived, by wrapping a bit of paper lightly about the string *ab*, and moving it successively from one end of the string to the other. In like manner, if AB were an upper 12th to *ab*, and consequently an unison to its three parts *ad*, *de*, *eb*; then, *ab* being open, if AB be struck, the three parts of the other, *ad*, *de*, *eb* will severally tremble; but the points *d* and *e* remain at rest.

This, Dr. Wallis tells us, was first discovered by Mr. William Noble of Merton college; and after him by Mr. T. Pigot of Wadham college, without knowing that Mr. Noble had observed it before. To which may be added, that M. Sauveur, long afterwards, proposed it to the Royal Academy at Paris, as his own discovery, which in reality it might be; but upon his being informed, by some of the members then present, that Dr. Wallis had published it before, he immediately resigned all the honour of it. Philos. Trans.

STURM, or STURMIUS (JOHN CHRISTOPHER), a celebrated mathematician and philosopher, was born at Hippolstein, 1635, where also he died in 1703. He was first minister of a church in Germany during 5 years; and then became professor of mathematics and natural philosophy, at Altdorf in Germany. He exerted himself greatly in the cause of literature, and was very useful, by his lectures and otherwise, in explaining and diffusing the knowledge and discoveries made in that remarkable age, the 17th century; as manifest by all his writings.—He was author of several useful works, on the mathematics and philosophy, the most esteemed of which are, 1, his Mathesis Enucleata, in one vol. 8vo; 2. Mathesis Juvenilis, in 2 large volumes 8vo; 3. A large collection of letters to Dr. Henry More, of Cambridge, on the controversy concerning the weight and spring of the air; 4. Sturm published also a German translation of Archimedes. 5. But his most considerable work was, the Collegium Experimentale sive Curiosum, in quo primaria hujus seculi Inventa et Experimenta Physico-Mathematica, an. 1672, quibusdam naturæ demonstrativa &c, Norimb. an. 1676, in 4to.—In 1684 the author gave a second, and much larger part, of the like collection of discoveries, made till that era; with an appendix of further additions and explanations to the particulars in the first part. Editions of these two parts, and of the letters to Dr. More, were also printed in 1701 and 1715, together with several appendixes, the whole being usually bound in one large volume in 4to.

This is a very curious work, containing a multitude of interesting experiments, neatly illustrated by copper-plate figures printed upon almost every page, by the side of the letter-press. Of these, the 10th experiment is an improvement on father Lana's project for navigating a small vessel suspended in the atmosphere by several globes exhausted of air. But a more particular and satisfactory account of this work may be seen in the Philos. Trans. vol. 10, pa. 505, or in my Abridgment, vol. 2, pa. 265.

STYLE, in Chronology, a particular manner of counting time; as the old style, the new style. See CALENDAR.

Old STYLE, is the Julian manner of computing, as instituted by Julius Cæsar, in which the mean year consists of $365\frac{1}{4}$ days.

New STYLE, is the Gregorian manner of computation, instituted by pope Gregory the 13th, in the year 1582, and is used by most catholic countries, and many other states of Europe. The Gregorian, or new style, agrees with the true solar year, which contains only 365 days 5 hours 49 minutes. In the year of Christ 200, there was no difference of styles. In the year 1582, when the new style was first introduced, there was a difference of 10 days. At present there is 12 days difference. At the diet of Ratisbon, in the year 1700, it was decreed by the body of protestants of the empire, that 11 days should be retrenched from the old style, to accommodate it for the future to the new; and another day having been retrenched in the year 1800, it makes the difference of 12 days, as above stated. The same regulation has since passed into Sweden, Denmark, and into England, where it was established in the year 1752, when it was enacted, that in all dominions belonging to the crown of Great Britain, the supputation, according to which the year of our Lord begins on the 25th day of March, shall not be used from and after the last day of December 1751; and that from thenceforth, the 1st day of January every year shall be reckoned to be the first day of the year: and that the natural day next immediately following the 2d day of September 1752, shall be accounted the 14th day of September, omitting the 11 intermediate nominal days of the common calendar. It is further enacted, that all kinds of writings, &c, shall bear date according to the new method of computation, and that all courts and meetings &c, feasts, fasts, &c, shall be held and observed accordingly. And for preserving the calendar in the same regular course for the future, it is enacted, that the several years of our Lord 1800, 1900, 2100, 2200, 2300, &c, except only every 400th year, of which the year 2000 shall be the first, shall be common years of 365 days, and that the years 2000, 2400, 2800, &c, and every other 400th year from the year 2000 inclusive, shall be leap years, consisting of 366 days. See Bissextile and Calendar.

The following table shows by what number of days the new style differs from the old, from 5900 years before the birth of Christ, to 5900 years after it. The days under the sign − (viz from 6000 years before to 200 years after Christ) are to be subtracted from the old style, to reduce it to the new; and the days under the sign + (viz from 200 to 5900 years after Christ) are to be added to the old style, to reduce it to the new.—All the years mentioned in the table are leap years in the old style; but those only that are marked with an L are leap years in the new.

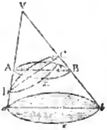
L 0	2	5900	43

The French nation, during the revolution in the year 1792, commenced another new style, or computation of time; according to which, the year commenced usually on our 22d of September. The year is divided into 12 months of 30 days each; and each month into 3 decades of 10 days each. For the names and computations of which, see the article Calendar.—They have lately however returned to the former general way of counting time.

Style, in Dialling, denotes the cock or gnomon, raised above the plane of the dial, to project a shadow.—The edge of the style, which by its shadow marks the hours on the face of the dial, is to be set according to the latitude, always parallel to the axis of the world.

STYLOBATA, or Stylobaton, in Architecture, the same with the pedestal of a column. It is sometimes taken for the trunk of the pedestal, between the cornice and the base, and is then called truncus. It is also otherwise named abacus.

SUBCONTRARY position, in Geometry, is when two equiangular triangles, as VAB and VCD are so placed as to have one common angle V at the vertex, and yet their bases not parallel. Consequently the angles at the bases are equal, but on the contrary sides; viz, the ∠A = ∠C, and the ∠B = ∠D.



If the oblique cone VAB or *vab*, having the circular base AEB, or *aeb*, be so cut by a plane DEC, that the angle D be = the ∠B, or the ∠C = ∠A, then the cone is said to be cut, by this plane, in a subcontrary position to the base AEB, or *aeb*; and in this case the section DEC is always a circle, as well as the base AEB or *aeb*.

SUBDUCTION, in Arith. the same as Subtraction.

SUBDUPLE *Ratio*, is when any number or quantity is the half of another, or contained twice in it. Thus, 3 is said to be subduble of 6, as 3 is the half of 6, or is twice contained in it.

SUBDUPLICATE *Ratio*, of any two quantities, is the ratio of their square roots, being the opposite to duplicate ratio, which is the ratio of the squares. Thus, of the quantities, a and b, the subduplicate ratio is that of $\sqrt{a}$ to $\sqrt{b}$ or $a^{\frac{1}{2}}$ to $b^{\frac{1}{2}}$, as the duplicate ratio is that of a^2 to b^2.

SUBLIME *Geometry*, the higher geometry, or that of curve lines. See GEOMETRY.

SUBLUNARY, is said of all things below the moon; as all things on the earth, or in its atmosphere, &c.

SUBMULTIPLE, the contrary of a multiple, being a number or quantity which is contained exactly a certain number of times in another of the same kind; or it is the same as an aliquot part of it. Thus, 3 is a submultiple of 21, or an aliquot part of it, because 21 is a multiple of 3.

SUBMULTIPLE *Ratio*, is the ratio of a submultiple or aliquot part, to its multiple; as the ratio of 3 to 21.

SUBNORMAL, in Geometry, is the subperpendicular AC, or line under the perpendicular to the curve BC, a term used in curve lines to denote the distance AC in the axis, between the ordinate AB, and the perpendicular BC to the curve or to the tangent.

And the said perpendicular BC is the normal.—In all curves, the subnormal AC is a 3d proportional to the subtangent TA and the ordinate AB; and in the parabola, it is equal to half the parameter of the axis.

SUBSTITUTION, in Algebra, is the putting and using, in an equation, one quantity instead of another which is equal to it, but expressed after another manner. See REDUCTION of Equations.

SUBSTILE, or SUBSTYLE, in Dialling, a right line upon which the stile or gnomon of a dial is erected, being the common section of the face of the dial and a plane perpendicular to it passing through the stile.—The angle included between this line and the stile, is called the elevation or height of the stile.

In polar, horizontal, meridional, and northern dials, the substilar line is the meridional line, or line of 12 o'clock; or the intersection of the plane of the dial with that of the meridian.—In all declining dials, the substile makes an angle with the hour line of 12, and this angle is called the distance of the substile from the meridian.—In easterly and westerly dials, the substilar line is the line of 6 o'clock, or the intersection of the dial plane with the prime vertical.

SUBTANGENT *of a Curve*, is the line TA in the axis below the tangent TB, or limited between the tangent and ordinate to the point of contact. (See the last figure above.)—The tangent, subtangent, and ordinate, make a right-angled triangle.

In all parabolic and hyperbolic figures, the subtangent is equal to the absciss multiplied by the exponent of the power of the ordinate in the equation of the curve. Thus, in the common parabola, whose property or equation is $px = y^2$, the subtangent is equal to $2x$, double the absciss. And if $ax^2 = y^3$, or $px = y^{\frac{3}{2}}$, then the subtangent is $= \frac{3}{2}x$. Also if $a^m x = y^{m+n}$, or $px = y^{\frac{m+n}{n}}$, the subtan. is $\frac{m+n}{n}x$. See *Method of* TANGENTS.

SUBTENSE, in Geometry, of an arc, is the same as the chord of the arc; but of an angle, it is a line drawn across from the one leg of the angle to the other, or between the two extremes of the arc that measures the angle.

SUBTRACTION, or SUBSTRACTION, in Arithmetic, is the taking of one number or quantity from another, to find the remainder, or difference between them; and is usually made the second rule in arithmetic. The greater number or quantity is called the minuend, the less is the subtrahend, and the remainder is the difference. Also the sign of subtraction is −, or minus.

SUBTRACTION *of Whole Numbers*, is performed by setting the less number below the greater, as in addition, units under units, tens under tens, &c; and then, proceeding from the right hand towards the left, subtract or take each lower figure from that above it, and set down the several remainders or differences underneath; and these will compose the whole remainder or difference of the two given numbers. But when any one of the figures of the under number is greater than that of the upper, from which it is to be taken, you must add 10 (in your mind) to that upper figure, then take the under one from this sum, and set the difference underneath, carrying or adding 1 to the next under figure to be subtracted. Thus, for example, to subtract 2904821 from 37409732

Minuend	37409732
Subtrahend	2904821
Difference	34504911
Proof	37409732

To prove Subtraction: Add the remainder or difference to the less number, and the sum will be equal to the greater when the work is right.

SUBTRACTION *of Decimals*, is performed in the same manner as in whole numbers, by observing only to set the figures or places of the same kind under each other. Thus:

From	351·04	·479	27
Take	72·71	·0573	0·936
Rem. Diff.	278·33	·4217	26·064

To Subtract Vulgar Fractions. Reduce the two fractions to a common denominator, if they have different ones; then take the less numerator from the greater, and set the remainder over the common denominator, for the difference sought.—It is best to set the less fraction after the greater, with the sign (−) of subtraction between them, and the mark of equality (=) after them.

Thus, $\frac{7}{9} - \frac{2}{9} = \frac{5}{9}$.

And $\frac{3}{5} - \frac{4}{7} = \frac{21}{35} - \frac{20}{35} = \frac{1}{35}$.

SUBTRACTION, *in Algebra*, is performed by changing the signs of all the terms of the subtrahend, to their contrary signs, viz, + into −, and − into +; and then uniting the terms with those of the minuend after the manner of addition of Algebra.

Ex. From $+ 6a$
Take $+ 2a$
Rem. $6a - 2a = 4a$.

From $+ 6a$
Take $- 2a$
Rem. $6a + 2a = 8a$.

From $- 6a$
Take $+ 2a$
Rem. $- 6a - 2a = - 8a$.

From $- 6a$
Take $- 4a$
Rem. $- 6a + 4a = - 2a$.

From $2a - 3x + 5z - 6$
Take $6a + 4x + 5z + 4$
Rem. $- 4a - 7x \quad 0 - 10$

SUBTRIPLE, is when one quantity is the third part of another; as 2 is subtriple of 6. And SUBTRIPLE *Ratio*, is the ratio of 1 to 3.

SUBTRIPLICATE *Ratio*, is the ratio of the cube roots. So the subtriplicate ratio of a to b, is the ratio of $\sqrt[3]{a}$ to $\sqrt[3]{b}$, or of $a^{\frac{1}{3}}$ to $b^{\frac{1}{3}}$.

SUCCESSION *of Signs*, in Astronomy, is the order in which they are reckoned, or follow one another, and according to which the sun enters them; called also consequentia. As Aries, Taurus, Gemini, Cancer, &c. When a planet goes according to the order and succession of the signs, or in consequentia, it is said to be direct; but retrograde when they move the contrary way, or in antecedentia, as from Gemini to Taurus, then to Aries, &c.

SUCCULA, in Mechanics, a bare axis or cylinder with staves in it to move it round; but without any tympanum, or peritrochium.

SUCKER, in Mechanics, a name by which sometimes is called the piston or bucket, in a sucking pump; and sometimes the pump itself is so called.

SUCKING *Pump*, the common pump, working by two valves opening upwards. See PUMP.

SUISETH (RICARDI or RAYMUNDI), an early writer on Arithmetic. A long account of his book, called the Calculator, is given in Brucker's History of Philosophy.

SUM, the quantity produced by addition, or by adding two or more numbers or quantities together. So the sum of 6 and 4 is 10, and the sum of a and b is $a + b$.

SUMMER, the name of one of the seasons of the year, being one of the quarters when the year is divided into 4 parts, or one half when the year is divided only into two, summer and winter. In the former case, summer is the quarter during which, in northern climates, the sun is passing through the three signs Cancer, Leo, Virgo, or from the time of the greatest declination, till it comes to the equinoctial again, or have no declination; which is from about the 21st of June, to the 22d of September. In the latter case, summer contains the 6 warmer months, while the sun is on one side of the equinoctial; and winter the other 6 months, when the sun is on the other side of it.

SUMMER *Beam*, in carpentry, a large piece of timber which, being supported on two pillars or posts, serves as a lintel to a gate, door, or window, &c.

SUMMER *Solstice*, the time or point when the sun attains his greatest declination, and is nearest the zenith of the place. See SOLSTICE.

SUN, SOL, ☉, in Astronomy, the great luminary that is placed in the centre of our system, and about which all the planets revolve, in different periods, and at different distances. It is the great fountain of light and heat to all those bodies, warming and refreshing both their animal and vegetable inhabitants with the refulgence of his beams; without which, all nature would be involved in impenetrable darkness. The comets also revolve about the sun, but in excentric orbits, being sometimes very near him; and at others, at an incalculable distance from him.

The ancient astronomers conceived the earth to be the centre of the universe, having the sun, and all the other celestial bodies revolving about it; but this absurd doctrine was at last confuted and annihilated by Copernicus; though not without many angry disputes, and malignant persecutions, particularly by the church of Rome, because it seemed to contradict some parts of Scripture. Truth however at length prevailed; and gave to the sun his due place in the centre of our system.

It has since been discovered, that the sun has a motion on its own axis, in about $25\frac{1}{4}$ days, as appears from the maculæ or spots on his disc. For, some of these spots have made their first appearance near the edge or margin of the sun, from thence they have seemed gradually to pass over the sun's face to the opposite edge, then disappear; and hence, after an absence of about 14 days, they have reappeared in their first place, and have taken the same course over again; finishing their entire circuit in 27 days $12^h\ 20^m$; which is hence inferred to be the period of the sun's rotation round his axis: and therefore the periodical time of the sun's revolution to a fixed star is $25^d\ 15^h\ 16^m$; because in $27^d\ 12^h\ 20^m$ of the month of May, when the observations were made, the earth describes an angle about the sun's centre of $26°\ 22'$, and therefore as the angular motion $360° + 26°\ 22' : 360 :: 27^d\ 12^h\ 20^m : 25^d\ 15^h\ 16^m$. This motion of the spots is from west to east: whence we conclude the motion of the sun, to which the other is owing, to be from east to west. The more correct period of the sun's rotation is now stated at 25 days 10 hours.

Besides this motion round his axis, the sun, on account of the various attractions of the surrounding planets, is agitated by a small motion round the centre of gravity of the system.—Whether the sun and stars have any proper motion of their own in the immensity of space, however small, is not absolutely certain; though some very accurate observers have intimated conjectures of this kind, and have shown that such a general motion is not improbable. See STARS.

As for the apparent annual motion of the SUN *round the earth*: it is easily shown, by astronomers, that the real annual motion of the earth, about the sun, will cause such an appearance. A spectator in the sun would see the earth move from west to east, for the same reason as we see the sun move from east to west: and all the phenomena resulting from this annual motion in whichever of the bodies it be, will appear the same from either. And hence arises that apparent motion of the sun, by which he is seen to advance insensibly towards the eastern stars; in so much that, if any star, near the ecliptic, rise at any time with the sun; after a few days the sun will be got more to the east of the star, and the star will rise and set before him.

Nature, Properties, Figure, &c, of the SUN.

Those who have maintained that the substance of the sun is fire, argue in the following manner: The sun shines, and his rays, collected by concave mirrors, or convex lenses, will burn, consume, and melt the most solid bodies, or else convert them into ashes, or glass: therefore, as the force of the solar rays is diminished, by their divergency, in a duplicate ratio of the distances reciprocally taken; it is evident that their force and effect are the same, when collected by a burning lens, or mirror, as if we were at such distance from the sun, where they were equally dense. The sun's rays therefore, in the neighbourhood of the sun, produce the same effects, as might be expected from the most vehement fire: consequently the sun is of a fiery substance.

Hence it follows, that its surface is probably every where fluid; that being the condition of flame. Indeed, whether the whole body of the sun be fluid, as some think; or solid, as others; they do not presume to determine: but as there are no other marks, by which to distinguish fire from other bodies, but light, heat, a power of burning, consuming, melting, calcining, and vitrifying; they do not see what objection should be made to the hypothesis that the sun is a globe of fire, like our fires, invested with flame: and, supposing that the maculæ are formed out of the solar exhalations, they infer that the sun is not pure fire; but that there are heterogeneous parts mixed with it.

Philosophers have been much divided in opinion with respect to the nature of fire, light, and heat, and the causes that produce them: and they have given very different accounts of the agency of the sun, with which, whether we consider them as substances or qualities, they are intimately connected, and on which they seem primarily to depend. Some, among whom we may reckon Sir Isaac Newton, consider the rays of light as composed of small particles, which are emitted from shining bodies, and move with uniform velocities in uniform mediums, but with variable velocities in mediums of variable densities. These particles, say they, act upon the minute constituent parts of bodies, not by impact, but at some indefinitely small distance; they attract and are attracted; and in being reflected or refracted, they excite a vibratory motion in the component particles. This motion increases the distance between the particles, and thus occasions an augmentation of bulk, or an expansion in every dimension, which is the most certain characteristic of fire. This expansion, which is the beginning of a disunion of the parts, being increased by the increasing magnitude of the vibrations proceeding from the continued agency of light, it may easily be apprehended, that the particles will at length vibrate beyond their sphere of mutual attraction, and thus the texture of the body will be altered or destroyed; from solid it may become fluid, as in melted gold; or from being fluid, it may be dispersed in vapour, as in boiling water.

Others, as Boerhaave, represent fire as a substance sui generis, unalterable in its nature, and incapable of being produced or destroyed; naturally existing in equal quantities in all places, imperceptible to our senses, and only discoverable by its effects, when, by various causes, it is collected for a time into a less space than that which it would otherwise occupy. The matter of this fire is not in any wise supposed to be derived from the sun: the solar rays, whether direct or reflected, are of use only as they impel the particles of fire in parallel directions: that parallelism being destroyed, by intercepting the solar rays, the fire instantly assumes its natural state of uniform diffusion. According to this explication, which attributes heat to the matter of fire, when driven in parallel directions, a much greater degree must be given it when the quantity, so collected, is amassed into a focus; and yet the focus of the largest speculum does not heat the air or medium in which it is found, but only bodies of densities different from that medium.

M. Deluc (Lettres Physiques) is of opinion, that the solar rays are the principal cause of heat; but that they heat such bodies only as do not allow them a free passage. In this remark he agrees with Newton: but then he differs totally from him, as well as from Boerhaave, concerning the nature of the rays of the sun. He does not admit the emanation of any luminous corpuscles from the sun, or other self-shining substances, but supposes all space to be filled with an ether of great elasticity and small density, and that light consists in the vibrations of this ether, as sound consists in the vibrations of the air. "Upon Newton's supposition," says an excellent writer, "the cause by which the particles of light and the corpuscles constituting other bodies are mutually attracted and repelled, is uncertain. The reason of the uniform diffusion of fire, of its vibration, and repercussion, as stated in Boerhaave's opinion, is equally inexplicable. And in the last mentioned hypothesis, we may add to the other difficulties attending the supposition of an universal ether, the want of a first mover to make the sun vibrate."

Dr. Herschel has given, in the Philos. Trans. an ingenious paper on the physical construction of the sun. This plausible and ingenious theory is suggested by a variety of observations on the solar phenomena. The sun, he supposes, has an atmosphere resembling that of the earth; and this atmosphere consists of various elastic fluids, some of which exhibit a shining brilliancy, while others are merely transparent. Whenever the lucid fluid is removed, the body of the sun may be seen through those that are transparent. In like manner, an observer placed in the moon, will see the solid body of the earth only in those places where the transparent fluids of our atmosphere will permit him. In others, the opaque vapours will reflect the sun's light, without permitting his view to penetrate to the surface of our globe.

By changes in the atmosphere of Jupiter too, Dr. H. accounts for the phenomena of its belts: and on the same principle he illustrates the various appearances of spots observed in the sun. Such phenomena, he thinks, may be easily and satisfactorily explained, if it be allowed that the real solid body of the sun itself is seen on these occasions, though we seldom see more than its shining atmosphere. He apprehends that there are considerable inequalities in the surface of the sun; and that there may be elevations not less than 5 or 600 miles high. That a very high country, or chain of mountains, may oftener become visible, by the removal of the obstructing fluid, than the lower regions, on account of its not being so deeply covered by it. See *Solar* SPOTS.

All the phenomena of the spots, of the faculæ, and of the livid surface of the sun, concur to establish the existence of a solar atmosphere of very considerable extent, and to evince its composition of various elastic fluids, that are more or less lucid and transparent: but the lucid one is that which furnishes us with light. The generation of this lucid fluid, in the solar atmosphere, is a phenomenon similar to the generation of clouds in our atmosphere, which are produced by the decomposition of its constituent elastic fluids: but with this difference, that the continual and very extensive decompositions of the elastic fluids of the sun, are of a phosphoric nature, and attended with lucid appearances, by giving out light. To the objection that such decompositions, and the consequent emission of light, would exhaust the sun, Dr. H. replies that, in the decomposition of phosphoric fluids, every other ingredient besides light may return to the body of the sun. This waste, however, must be quite insensible, even in a very long period, when the extreme subtilty of light is considered: and besides, it may possibly be supplied by those telescopic comets, many of which are observed, which have no appearance of any solid nucleus, seeming to be mere collections of vapours condensed about a centre.

The sun, contemplated with the assistance of the doctor's theory, "appears to be nothing else than a very large, eminent, lucid planet, evidently the first, or indeed the only primary one of our system; all others being truly secondary to it. Its similarity to the other globes of the solar system, with regard to its solidity, its atmosphere, and its diversified surface; the rotation on its axis, and the fall of heavy bodies, lead us on to suppose that it is most probably also inhabited, like the rest of the planets, by beings whose organs are adapted to the peculiar circumstances of that vast globe."

Should it be objected that the heat of the sun renders it unfit for a habitable world, Dr. H. answers, that heat is produced by the sun's rays only when they act on a calorific medium, and that they are the cause of the production of heat, by uniting with the matter of fire, which is contained in the substances that are heated. Dr. H. suggests other considerations, intended to invalidate the objection. He then deduces from analogy a variety of arguments, in order to confirm the notion of the sun's being habitable; and infers that, if the sun be capable of accommodating inhabitants, the other stars, which are suns may be appropriated to the same use; and thus, says he, we see at once what an extensive field for animation opens itself to our view. Philos. Trans. Abridg. vol. 17, pa. 478. See also Spots.

Dr. Herschel has made many interesting experiments on the nature of the sun's rays, and has thus firmly established a fact which had long been disputed between philosophers, namely, the separate identity of light and heat: that they are both subject to the laws of reflection and refraction; that they are each of different refrangibility, are liable to be stopped in certain proportions when transmitted through diaphanous bodies; and that they are liable to be scattered on rough surfaces. These curious facts were discovered by the doctor in his optical experiments on coloured glass, in which he was led to examine the difference between the coloured rays of the sun with regard to their heating power. He thereby discovered that the most refracted rays of light, the violet, possess the lowest heating power; and the least refracted, the red, the greatest power, and the mean rays of the prismatic spectrum showed an intermediate power. Thus, in the red rays the thermometer, by the average of several experiments, rose 6⅞ degrees; in the green rays 3¼ degrees; and the violet 2 degrees; or in round numbers, the effect of the red rays was to that of the green as 9 to 4, and to that of the violet as 7 to 2.

Pursuing those experiments, the same philosopher found the range of dispersion of the rays of heat by the prism, to differ most essentially from that of light; for on applying thermometers of great sensibility and successively in a line, beginning at the violet rays, proceeding along the prismatic spectrum, he found not only the heat increased by advancing towards the red, or least refracted rays, but that the heat was greatest at a small distance beyond the extreme limits of the spectrum, that is, where no rays of light at all fell; and still continuing to advance the thermometer in the same line, the heat then gradually diminished, till it became too small to be noticed. This most curious and important discovery shows, therefore, both an entire separation of heat from light in the solar ray, and refrangibility of one from the other, which together go near to establish the separate identity of caloric and light, and cause precisely the same arguments used to demonstrate the materiality of light to apply to the materiality of heat.

These experiments of Dr. Herschel have been fully confirmed by sir H. Englefield, whose apparatus were somewhat different, and more accurate. The particulars of which are as follow. The coloured rays of the spectrum were successively and singly thrown on a lens (all the others being excluded by a screen), the thermometer with a blackened ball being placed in its focus, and allowed to remain there some time after it had ceased to rise, that the full effect might be secured. Thus circumstanced,

In the blue ray from	55°	to	56°
green	54	to	58
yellow	56	to	62
red	56	to	72
Quite out of visible light	61	to	79

These experiments were repeated several times, and in all with very closely corresponding results, and the most striking and novel phenomenon was manifest in all, namely, the rise of the thermometer, when passed beyond the extreme point of the luminous spectrum on the red side, and its fall when again carried back into the red light.

As to the Figure of the Sun; this, like the planets, is not perfectly globular, but spheroidical, being higher about the equator than at the poles. The reason of which is this: the sun has a motion about his own axis; and therefore the solar matter will have an endeavour to recede from the axis, and that with the greater force as their distances from it, or the circles they move in, are greater: but the equator is the greatest circle; and the rest, towards the poles, continually decrease; therefore the solar matter, though at first in a spherical form, will endeavour to recede from the centre of the equator further than from the centres of the parallels. Consequently, since the gravity, by which it is retained in its place, is supposed to be uniform throughout the whole sun, it will really recede from the centre more at the equator, than at any of the parallels; and hence the sun's diameter will be greater through the equator, than through the poles; that is, the sun's figure is not perfectly spherical, but spheroidical.

Several particulars of the Sun, related by Newton, in his Principia, are as follow: 1. That the density of the sun's heat, which is proportional to his light, is 7 times as great at Mercury as with us; and therefore our water there would be all carried off in vapour: for he found by experiments of the thermometer, that a heat but 7 times greater than that of the sun beams in summer, will serve to make water boil.

2. That the quantity of matter in the sun is to that in Jupiter, nearly as 1100 to 1; and that the distance of that planet from the sun, is in the same ratio to the sun's semidiameter.

3. That the matter in the sun is to that in Saturn, as 2360 to 1; and the distance of Saturn from the sun is in a ratio but little less than that of the sun's semidiameter. And hence, that the common centre of gravity of the sun and Jupiter is nearly in the superficies of the sun; of the sun and Saturn, a little within it.

4. And by the same mode of calculation it will be found, that the common centre of gravity of all the planets, cannot be more than the length of the solar diameter distant from the centre of the sun. This common centre of gravity he proves is at rest; and therefore though the sun, by reason of the various positions of the planets, may be moved every way, yet it cannot recede far from the common centre of gravity, and this, he thinks, ought to be accounted the centre of our world. Book 3, prop. 12.

5. By means of the solar spots it hath been discovered, that the sun revolves round his own axis, without moving considerably out of his place, in about 25 days, and that the axis of this motion is inclined to the ecliptic in an angle of 87° 30 nearly. The sun's apparent diameter being sensibly longer in December than in June, the sun must be proportionably nearer to the earth in winter than in summer; in the former of which seasons therefore will be the perihelion, in the latter the aphelion: and this is also confirmed by the earth's motion being quicker in December than in June, as it is by about $\frac{1}{15}$ part. For since the earth always describes equal areas in equal times, whenever it moves swifter, it must needs be nearer to the sun: and for this reason there are about 8 days more from the sun's vernal equinox to the autumnal, than from the autumnal to the vernal.

6. That the sun's diameter is equal to 100 diameters of the earth; and therefore the body of the sun must be 1,000,000 times greater than that of the earth.—Mr. Azout assures us, that he observed, by a very exact method, the sun's diameter to be no less than 31′ 45″ in his apogee, and not greater than 32′ 45″ in his perigee.

7. According to Newton, in his theory of the moon, the mean apparent diameter of the sun is 32′ 12″.—The sun's horizontal parallax is now fixed at 8″$\frac{6}{10}$.

8. If you divide 360 degrees (the whole ecliptic) by the quantity of the solar year, it will give 59′ 8″ &c, which therefore is the medium quantity of the sun's daily motion; and if this 59′ 8″ be divided by 24, you have the sun's horary motion equal to 2′ 28″: and if this last be divided by 60, it will give his motion in a minute, &c. And in this way are the tables of the sun's mean motion constructed, as placed in books of astronomical tables and calculations.

SUNDAY, the first day of the week; thus called by our idolatrous ancestors, because set apart for the worship of the sun.—It is sometimes called the Lord's Day, because kept as a feast in memory of our Lord's resurrection on this day: and also Sabbath-day, because substituted under the new law instead of the sabbath in the old law.—It was Constantine the Great who first made a law for the observation of Sunday; and who, according to Eusebius, appointed that it should be regularly celebrated throughout the Roman empire.

SUNDAY *Letter*. See DOMINICAL *Letter*.

SUPERFICIAL, relating to Superficies.

SUPERFICIES, or SURFACE, in Geometry, the outside or exterior face of any body. This is considered as having the two dimensions of length and breadth only, but no thickness; and therefore it makes no part of the substance or solid content or matter of the body. The terms or bounds or extremities of a superficies, are lines; and superficies may be considered as generated by the motions of lines.—Superficies are either rectilinear, curvilinear, plane, concave, or convex.

Rectilinear SUPERFICIES, is bounded by right lines.

Curvilinear SUPERFICIES, is bounded by curve lines.

Plane SUPERFICIES, is that which has no inequality in it, nor risings, nor sinkings, but lies evenly and straight throughout, so that a right line may wholly coincide with it in all parts and directions.

Convex SUPERFICIES, is that which is curved and rises outwards.

Concave SUPERFICIES, is curved and sinks inward.

The measure or quantity of a surface, is called its area. And the finding of this measure or area, is sometimes called the quadrature of it, meaning the reducing it to an equal square, or to a certain number of smaller squares. For all plane figures, and the surfaces of all bodies, are measured by squares; as square inches or square feet, or square yards, &c; that is, squares whose sides are inches, or feet, or yards, &c. Our least superficial measure is the square inch, and other squares are taken from it according to the proportion in the following table of superficial or square measure.

144 square inches	=	1 square foot
9 square feet	=	1 square yard
30¼ square yards	=	1 square pole
16 square poles	=	1 square chain
10 square chains	=	1 acre
640 acres	=	1 square mile.

The superficial measure of all bodies and figures depends entirely on that of a rectangle; and this is found by drawing or multiplying the length by the breadth of it; as is proved from plane geometry only, in my Mensuration, pt. 2, sect. 1, prob. 1. From the area of the rectangle we obtain that of any oblique parallelogram, which, by geometry, is equal to a rectangle of equal base and altitude; thence a triangle, which is the half of such a parallelogram or rectangle; and hence, by composition, we obtain the superficies of all other figures whatever, as these may be considered as made up of triangles only.

Besides this way of deriving the superficies of all figures, which is the most simple and natural, as proceeding on common geometry alone, there are certain other methods; such as the methods of exhaustions, of fluxions, &c. See these articles in their places, as also QUADRATURES.

Line of SUPERFICIES, a line usually found on the sector, and Gunter's scale. The description and use of which, see under SECTOR, and GUNTER'S *Scale*.

SUPPLEMENT, of an arch, or angle, in Geometry or Trigonometry, is what it wants of a semicircle, or of 180 degrees; as the complement is what it wants of a quadrant, or of 90 degrees. So, the supplement of 50° is 130°; as the complement of it is 40°.

SURD, in Arithmetic and Algebra, denotes a number or quantity that is incommensurate to unity; or that is inexpressible in rational numbers by any known way of notation, otherwise than by its radical sign or index.—This is otherwise called an irrational or incommensurable number, as also an imperfect power.

The square roots of all numbers except 1, 4, 9, 16, 25, 36, &c, (which are the squares of the whole numbers 1, 2, 3, 4, 5, 6, &c,) are surds, or incommensurables; after the same manner, the cube roots of all numbers except the cubes of 1, 2, 3, 4, 5, 6, &c, are surds. And it is usual to denote such root by setting before it the proper mark of radicality, which is $\surd$, and placing above this radical sign the number that shows what kind of root is intended. Thus, $\sqrt[2]{2}$ or $\sqrt{2}$ signifies the square root of 2, and $\sqrt[3]{10}$ the cube root of 10; which roots, because it is impossible to express them in numbers exactly, are properly called surd roots.

Another way of notation, by which roots are expressed, is by fractional indices, without the radical sign: thus, as x^2, x^3, x^4, &c, denote the square, cube, 4th power, &c, of x; so $x^{\frac{1}{2}}$, $x^{\frac{1}{3}}$, $x^{\frac{1}{4}}$, &c, denote the square root, cube root, 4th root, &c, of the same quantity x.—The reason of which is evident; for since $\sqrt{x}$ is a geometrical mean proportional between 1 and x, so $\frac{1}{2}$ is an arithmetical mean between 0 and 1; and therefore, as 2 is the index of the square of x, $\frac{1}{2}$ will be the proper index of its square root, &c.

It may be observed that, for convenience, or the sake of brevity, quantities which are not naturally surds, are often expressed in the form of surd roots. Thus $\sqrt{4}$, $\sqrt{\frac{9}{4}}$, $\sqrt[3]{27}$, are the same as 2, $\frac{3}{2}$, 3.

Surds are either *simple* or *compound*.

Simple SURDS, are such as are expressed by one single term; as $\sqrt{2}$, or $\sqrt[3]{a}$, &c.

Compound SURDS, are such as consist of two or more simple surds connected together by the signs + or −; as $\sqrt{3} + \sqrt{2}$, or $\sqrt{3} - \sqrt{2}$, or $\sqrt[3]{(5 + \sqrt{2})}$: which last is called an universal root, and denotes the cubic root of the sum arising by adding 5 and the root of 2 together.

Of certain Operations by Surds.

1. Such surds as $\sqrt{2}$, $\sqrt{3}$, $\sqrt{5}$, &c, though they are themselves incommensurable with unity, according to the definition, are commensurable in power with it, because their powers are integers, which are multiples of unity. They may also be sometimes commensurable with one another; as $\sqrt{8}$ and $\sqrt{2}$, which are to each other as 2 to 1, as is found by dividing them by their greatest common measure, which is $\sqrt{2}$, for then those two become $\sqrt{4} = 2$, and 1 the ratio.

2. *To reduce Rational Quantities to the form of any proposed Surd Roots.*—Involve the rational quantity according to the index of the power of the surd, and then prefix before that power the proposed radical sign.

Thus $a = \sqrt{a^2} = \sqrt[3]{a^3} = \sqrt[4]{a^4} = \sqrt[n]{a^n}$, &c.
and $4 = \sqrt{16} = \sqrt[3]{64} = \sqrt[4]{256} = \sqrt[n]{4^n}$, &c.

And in this way may a simple surd fraction, whose radical sign refers to only one of its terms, be changed into another, which shall include both numerator and denominator. Thus,

$\frac{\sqrt{2}}{5}$ is reduced to $\sqrt{\frac{2}{25}}$, and $\frac{5}{\sqrt[3]{4}}$ to $\sqrt[3]{\frac{125}{4}}$: thus also the quantity a reduced to the form of $x^{\frac{1}{n}}$ or $\sqrt[n]{x}$, is $(a^n)^{\frac{1}{n}}$ or $\sqrt[n]{a^n}$. And thus may roots with rational coefficients be reduced so as to be wholly affected by the radical sign; as $a\sqrt[n]{x} = \sqrt[n]{a^n x}$.

3. *To reduce Simple Surds, having different radical signs (which are called heterogeneal Surds) to others that may have one common radical sign, or which are homogeneal: Or to reduce roots of different names to roots of the same name.*—Involve the powers reciprocally, each according to the index of the other, for new powers; and multiply their indices together, for the common index. Otherwise, as surds may be considered as powers with fractional exponents, reduce these fractional exponents to fractions having the same value and a common denominator.—Thus, by the 1st method,

$\sqrt[n]{a}$ and $\sqrt[m]{x}$ become $\sqrt[mn]{a^m}$ and $\sqrt[mn]{x^n}$;

and, by the 2d method,

$a^{\frac{1}{n}}$ and $x^{\frac{1}{m}}$ become $(a^m)^{\frac{1}{mn}}$ and $(x^n)^{\frac{1}{mn}}$.

Also $\sqrt{3}$ and $\sqrt[3]{2}$ are reduced to $\sqrt[6]{27}$ and $\sqrt[6]{4}$, which are equal to them, and have a common radical sign.

4. *To reduce Surds to their most simple expressions, or to the lowest terms possible.*—Divide the surd by the greatest power, of the same name with that of the root, which is contained in it, and which will measure or divide it without a remainder; then extract the root of that power, and place it before the quotient or surd so divided; this will produce a new surd of the same value with the former, but in more simple terms. Thus, $\sqrt{16a^2x}$, by dividing by $16a^2$, and prefixing its root $4a$, before the quotient $\sqrt{x}$, becomes $4a\sqrt{x}$; in like manner, $\sqrt{12} = \sqrt{(4 \times 3)} = 2\sqrt{3}$;

And $\sqrt[3]{ab^3x}$ reduces to $b\sqrt[3]{ax}$.

Also $\sqrt[3]{81} = \sqrt[3]{27 \times 3} = \sqrt[3]{3^3 \times 3} = 3\sqrt[3]{3}$.

And $\sqrt{288} = \sqrt{144 \times 2} = 12\sqrt{2}$.

5. *To Add and Subtract Surds.*—When they are reduced to their lowest terms, if they have the same irrational part, add or subtract their rational coefficients, and to the sum or difference subjoin the common irrational part.

Thus, $\sqrt{75} + \sqrt{48} = 5\sqrt{3} + 4\sqrt{3} = 9\sqrt{3}$;
and $\sqrt{150} - \sqrt{54} = 5\sqrt{6} - 3\sqrt{6} = 2\sqrt{6}$;
also $\sqrt{a^2x} + \sqrt{c^2x} = a\sqrt{x} + c\sqrt{x} = (a+c)\sqrt{x}$.

Or such surds may be added and subtracted, by first squaring them (by uniting the square of each part with double their product), and then extracting the root universal of the whole. Thus, for the first example above,

$\sqrt{75} + \sqrt{48} = \sqrt{(75 + 48 + 2\sqrt{75 \times 48})} =$
$\sqrt{(123 + 2\sqrt{3600})} = \sqrt{(123 + 120)} =$
$\sqrt{243} = 9\sqrt{3}$, the same as before.

If the quantities cannot be reduced to the same irrational part, they can only be connected by the signs + or −.

6. *To Multiply and Divide Surds.*—If the terms have the same radical, they will be multiplied and divided like powers, viz. by adding their indices for multiplication, and subtracting them for division. Thus,

$\sqrt{a} \times \sqrt[3]{a} = a^{\frac{1}{2}} \times a^{\frac{1}{3}} = a^{\frac{3}{6}} \times a^{\frac{2}{6}} = a^{\frac{5}{6}} = \sqrt[6]{a^5}$;

and $\sqrt{2} \times \sqrt[3]{2} = 2^{\frac{5}{6}} = \sqrt[6]{2^5} = \sqrt[6]{32}$;

also $\sqrt{a} \div \sqrt[3]{a} = a^{\frac{1}{2}} \div a^{\frac{1}{3}} = a^{\frac{1}{6}} = \sqrt[6]{a}$;

and $\sqrt{2} \div \sqrt[3]{2} = 2^{\frac{1}{6}} = \sqrt[6]{2}$.

If the quantities be different, but under the same radical sign; multiply or divide the quantities, and place the radical sign to the product or quotient.

Thus, $\sqrt{2} \times \sqrt{5} = \sqrt{10}$;

and $\sqrt[3]{a^2} \times \sqrt[3]{c} = \sqrt[3]{a^2c}$;

also $\sqrt[3]{54} \div \sqrt[3]{2} = \sqrt[3]{27} = 3$.

But if the surds have not the same radical sign, reduce them to such as shall have the same radical sign, and proceed as before.

Thus, $\sqrt[m]{a} \times \sqrt[n]{b} = \sqrt[mn]{a^n} \times \sqrt[mn]{b^m} = \sqrt[mn]{a^nb^m}$;

and $\sqrt{2} \times \sqrt[3]{4} = \sqrt[6]{2^3} \times \sqrt[6]{4^2} = \sqrt[6]{8 \times 16} = \sqrt[6]{128}$.

If the surds have any rational coefficients, their product or quotient must be prefixed.

Thus, $5\sqrt{6} \times 2\sqrt{3} = 10\sqrt{18} = 30\sqrt{2}$;

and $8\sqrt{5} \div 2\sqrt{6} = 4\sqrt{\frac{5}{6}}$.

7. *Involution and Evolution of Surds.*—Surds are involved, or raised to any power, by multiplying their indices by the index of the power; and they are evolved or extracted, by dividing their indices by the index of the root.

Thus, the square of $\sqrt[3]{2}$ or of $2^{\frac{1}{3}}$, is $2^{\frac{2}{3}} = \sqrt[3]{4}$;

and the cube of $\sqrt{5}$ or of $5^{\frac{1}{2}}$, is $5^{\frac{3}{2}} = \sqrt{125}$;

also the square root of $\sqrt[3]{4}$ or $4^{\frac{1}{3}}$, is $4^{\frac{1}{6}} = 2^{\frac{1}{3}} = \sqrt[3]{2}$.

Or thus: Involve or extract the quantity under the radical sign according to the power or root required, continuing the same radical sign.

So the square of $\sqrt[3]{2}$ is $\sqrt[3]{4}$;

and the square root of $\sqrt[3]{4}$, is $\sqrt[3]{2}$.

Unless the index of the power is the same as the name of the surd, or a multiple of it, for in that case the power of the surd becomes rational. Thus, the square of $\sqrt{3}$ is 3, and the cube of $\sqrt[3]{a^2}$ is a^2.

Simple surds are commensurable in power, and by being multiplied by themselves give, at length, rational quantities: but compound surds, multiplied by themselves, commonly give irrational products. Yet, in this case, when any compound surd is proposed, there is another compound surd, which, multiplied by it, gives a rational product.

Thus, $\sqrt{a} + \sqrt{b}$ multiplied by $\sqrt{a} - \sqrt{b}$ gives $a - b$;

and $\sqrt[3]{a} - \sqrt[3]{b}$ mult. by $\sqrt[3]{a^2} + \sqrt[3]{ab} + \sqrt[3]{b^2}$ gives $a - b$.

The finding of such a surd as multiplying the proposed surd gives a rational product, is made easy by three theorems, delivered by Maclaurin, in his Algebra, pa. 109 &c.

This operation is of use in reducing surd expressions to more simple forms. Thus, suppose a binomial surd divided by another, as $\sqrt{20} + \sqrt{12}$ by $\sqrt{5} - \sqrt{3}$, the quotient might be expressed by

$\frac{\sqrt{20} + \sqrt{12}}{\sqrt{5} - \sqrt{3}} = \frac{2\sqrt{5} + 2\sqrt{3}}{\sqrt{5} - \sqrt{3}}$; but this will be expressed in a more simple form, by multiplying both numerator and denominator by such a surd as makes the product of the denominator become a rational quantity: thus, multiplying them by $\sqrt{5} + \sqrt{3}$, the fraction or quotient becomes

$$2 \times \frac{\sqrt{5} + \sqrt{3}}{\sqrt{5} - \sqrt{3}} \times \frac{\sqrt{5} + \sqrt{3}}{\sqrt{5} + \sqrt{3}} = 2 \times \frac{(\sqrt{5} + \sqrt{3})^2}{5 - 3 = 2} = \sqrt{(5 + \sqrt{3})^2} = 8 + 2\sqrt{15}.$$

To do this generally, see Maclaurin's Alg. p. 113.

When the square root of a surd is required, it may be found nearly, by extracting the root of a rational quantity that approximates to its value. Thus, to find the square root of $3 + 2\sqrt{2}$; first find the $\sqrt{2} = 1\cdot41421$; hence $3 + 2\sqrt{2} = 5\cdot82842$, the root of which is nearly $2\cdot41421 = 1 + \sqrt{2}$.

In like manner we may proceed with any other proposed root. And if the index of the root be very high, a table of logarithms may be used to advantage: thus, to extract the root $\sqrt[7]{(5 + \sqrt[13]{17})}$; take the logarithm of 17, divide it by 13, find the number answering to the quotient, add this number to 5, find the log. of the sum, and divide it by 7, and the number answering to this quotient will be nearly equal to $\sqrt[7]{(5 + \sqrt[13]{17})}$.

But it is sometimes requisite to express the roots of surds exactly by other surds. Thus, in the first example, the square root of $3 + 2\sqrt{2}$ is $1 + \sqrt{2}$, because $(1 + \sqrt{2})^2 = 1 + 2\sqrt{2} + 2 = 3 + \sqrt{2}$. For the method of performing this, the curious reader may consult Maclaurin's Algeb. pa. 115, where also rules for trinomials &c may be found. See also the article Binomial *Roots*, in this Dictionary.

For extracting the higher roots of a binomial, whose two members when squared are commensurable numbers, we have a rule in Newton's Arith. pa. 59, but without demonstration. This is supplied by Maclaurin, in his Alg. pa. 120: as also by Gravesande, in his Matheseos Univers. Elem. pa. 211.

It sometimes happens, in the solution of cubic equations, that binomials of this form $a \pm b\sqrt{-1}$ occur, the cube roots of which must be found; and to these Newton's rule cannot always be applied, because of the impossible or imaginary factor $\sqrt{-1}$; yet if the root be expressible in rational numbers, the rule will often yield to it in a short way, not merely tentative, the trials being confined to known limits. See Maclaurin's Alg. pa. 127. It may be further observed, that such roots, whether expressible in rational numbers or not, may be found by evolving the quantity $a + b\sqrt{-1}$ by Newton's binomial theorem, and summing up the alternate terms. Maclaurin, p. 130.

Those who are desirous of a general and elegant solution of the problem, to extract any root of an impossible binomial $a + b\sqrt{-1}$, or of a possible binomial $a + \sqrt{b}$, may have recourse to the appendix to Saunderson's Algebra, and to the Philos. Trans. No. 451. On the management of surds, see also the numerous authors upon Algebra.

SURFACE, in Geometry. See Superficies.

A *Mathematical* Surface is the mere exterior face of a body, but is not any part of it, being of no thickness, but only the bare figure or termination of the body.

A *Physical* Surface is considered as of some very small thickness.

SURSOLID, in Arithmetic, the 5th power of a number, considered as a root. The number 2, for instance, considered as a root, produces the powers thus:

2	=	2	the root or 1st power,
2 × 2	=	4	the square or 2d power,
2 × 4	=	8	the cube or 3d power,
2 × 8	=	16	the biquadratic or 4th power,
2 × 16	=	32	the sursolid or 5th power.

Sursolid *Problem*, is that which cannot be resolved but by curves of a higher kind than the conic sections.

SURVEYING, the art of measuring land; which comprises the three following parts; viz, taking the dimensions of any tract or piece of ground; the delineating or laying it down in a map or draught; and finding the superficial content or area of the same; besides the dividing and laying out of lands. The first of these is what is properly called Surveying; the second is called plotting, or protracting, or mapping; and the third casting up, or computing the contents.

The first again consists of two parts, the making of observations for the angles, and the taking of lineal measures for the distances. The former of these is performed by some of the following instruments; the theodolite, circumferentor, semicircle, plain-table, or compass, or even by the chain itself: the latter is performed by means either of the chain, or the perambulator. The description and manner of using each of these, see under its respective article.

It is useful in surveying, to take the angles which the bounding lines form with the magnetic needle, in order to check the angles of the figure, and to plot them conveniently afterwards. But, as the difference between the true and magnetic meridian perpetually varies in all places, and at all times; it is impossible to compare two surveys of the same place, taken at distant times, by magnetic instruments, without making due allowance for this variation. See observations on this subject, by Mr. Molineux, Philos. Trans. No. 230, pa 625.

The second branch of surveying is performed by means of the protractor, and plotting scale. The description of which, see under their proper names.

If the lands in the survey are hilly, and not in any one plane, the measured lines cannot be truly laid down on paper, till they are reduced to one plane, which must be the horizontal one, because angles are taken in that plane. And in this case, when observing distant objects, for their elevation or depression, the following table shows the links or parts to be subtracted from each chain in the hypothenusal line, when the angle is the corresponding number of degrees.

A Table *of the links to be subtracted out of every chain in hypothenusal lines, of several degrees of altitude or depression, for reducing them to horizontal.*

		links			links
4°	3′	$\frac{1}{4}$	19°	57′	6
5	44	$\frac{1}{2}$	21	34	7
7	1	$\frac{3}{4}$	23	4	8
8	7	1	24	30	9
11	29	2	25	50	10
14	4	3	27	8	11
16	16	4	28	22	12
18	12	5	29	32	13

For example, if a station line measure 1250 links, or $12\frac{1}{2}$ chains, on an ascent, or a descent, of 11°; here it is after the rate of almost two links per chain, and it will be exact enough to take only the 12 chains at that rate, which make 24 links in all, to be deducted from 1250, which leaves 1226 links, for the length to be laid down. Practical surveyors say, it is best to make this deduction at the end of every chain-length while measuring, by drawing the chain forward every time as much as the deduction is; viz, in the present instance, drawing the chain on 2 links at each chain-length.

The third branch of surveying, namely computing the contents, is performed by reducing the several inclosures and divisions into triangles, trapeziums, and parallelograms, but especially the two former; then finding the areas or contents of these several figures, and adding them together.

The Practice of Surveying.

1. Land is measured with a chain, called Gunter's chain, of 4 poles or 22 yards in length, which consists of 100 equal links, each link being $\frac{22}{100}$ of a yard, or $\frac{66}{100}$ of a foot, or 7·92 inches long, that is nearly 8 inches or $\frac{2}{3}$ of a foot.

An acre of land is equal to 10 square chains, that is, 10 chains in length and 1 chain in breadth.

Or it is 40 × 4 or 160 square poles.
Or it is 220 × 22 or 4840 square yards.
Or it is 1000 × 100 or 100000 square links.

These being all the same quantity.

Also, an acre is divided into 4 parts called roods, and a rood into 40 parts called perches, which are square poles, or the square of a pole of $5\frac{1}{2}$ yards long, or the square of $\frac{1}{4}$ of a chain, or of 25 links, which is 625 square links. So that the divisions of land measure will be thus:

625 sq. links = 1 pole or perch
40 perches = 1 rood
4 roods = 1 acre.

The length of lines, measured with a chain, are set down in links as integers, every chain in length being 100 links; and not in chains and decimals. Therefore, after the content is found, it will be in square links; then cut off five figures on the right hand for decimals, and the rest will be acres. Those decimals are then multiplied by 4 for roods, and the decimals of these again by 40 for perches.

2. Among the various instruments for surveying, the plain-table is the easiest and most generally useful, especially in crooked difficult places, as in a town among houses, &c. Yet there are cases in which this cannot be conveniently used, as different surveys require different instruments, and the surveyor must judge which is the fittest instrument and method, and use it accordingly: nay, sometimes no instrument at all, but barely the chain itself, is the best method, particularly in regular open fields lying together; and even when using the plain-table, it is often of advantage to measure such large open parts with the chain only, and from those measures lay them down upon the table.

The perambulator is used for measuring roads, and other great distances on level ground, and by the sides of rivers. It has a wheel of $8\frac{1}{4}$ feet, or half a pole, in circumference, upon which the machine turns; and the distance measured is pointed out by an index, which is moved round by clock work.

Levels, with telescopic or other sights, are used to find the level between place and place, or how much one place is higher or lower than another.

An offset-staff is a very useful and necessary instrument, for measuring the offsets and other short distances. It is 10 links in length, being divided and marked at each of the 10 links.

Ten small arrows, or rods of iron or wood, are used to mark the end of every chain length, in measuring lines. And sometimes pickets, or staves with flags, are set up as marks or objects of direction.

Various scales are also used in protracting and measuring on the plan or paper; such as plane scales, line of chords, protractor, compasses, reducing scales, parallel and perpendicular rulers, &c. Of plane scales, there should be several sizes, as a chain in 1 inch, a chain in ½ of an inch, a chain in ¼ of an inch, &c. And of these, the best for use are those that are laid on the very edges of the ivory scale, to prick off distances by, without compasses.

3. The Field Book.

In surveying with the plain-table, a field-book is not used, as every thing is drawn on the table immediately when it is measured. But in surveying with the theodolite, or any other instrument, some kind of a field-book must be used, to write down in it a register or account of all that is done and occurs relative to the survey in hand. And this book every one contrives and rules as he thinks fittest for himself.

But a few skilful surveyors now make use of a new method for the field-book, namely, beginning at the bottom of the page and writing upwards; by which they sketch a neat boundary on either hand, as they pass it; an example of which will be given below, with the plan of the ground to accompany it.

In smaller surveys and measurements, a good way of setting down the work, is, to draw, by the eye, on a piece of paper, a figure resembling that which is to be measured; and so write the dimensions, as they are found, against the corresponding parts of the figure. And this method may be practised to a considerable extent, even in the larger surveys.

For all the parts of surveying, and with all the instruments, see my large book on Mensuration; also my Course of Mathematics.

The New Method of Surveying.

Instead of the foregoing method, an ingenious friend (Mr. Abraham Crocker), after mentioning the new and improved method of keeping the field-book by writing from bottom to top of the pages, observes that, "In the former method of measuring a large estate, the accuracy of it depends on the correctness of the instruments used in taking the angles. To avoid the errors incident to such a multitude of angles, other methods have of late years been used by some few skilful surveyors; the most practical, expeditious, and correct, seems to be the following.

"As was advised in former methods, so in this, choose two or more eminences, as grand stations, and measure a principal base line from one station to the other, noting every hedge, brook, or other remarkable object as you pass by it; measuring also such short perpendicular lines to such bends of hedges as may be near at hand. From the extremities of this base line, or from any convenient parts of the same, go off with other lines to some remarkable object situated towards the sides of the estate, without regarding the angles they make with the base line or with one another; still remembering to note every hedge, brook or other object that you pass by. These lines, when laid down by intersections, will with the base line form a grand triangle upon the estate; several of which, if need be, being thus laid down, you may proceed to form other smaller triangles and trapezoids on the sides of the former: and so on, until you finish with the enclosures individually.

"To illustrate this excellent method, let us take AB (in the plan of an estate, fig. 1, pl. 34) for the principal base line. From B go off to the tree at C; noting down, in the field-book, every cross hedge, as you measure on; and from C measure back to the first station at A, noting down every thing as before directed.

"This grand triangle being completed, and laid down on the rough-plan paper, the parts, exterior as well as interior, are to be completed by smaller triangles and trapezoids.

"When the whole plan is laid down on paper, the contents of each field might be calculated by the methods laid down below in mensuration.

"In countries where the lands are enclosed with high hedges, and where many lanes pass through an estate, a theodolite may be used to advantage, in measuring the angles of such lands; by which means, a kind of skeleton of the estate may be obtained, and the lane-lines serve as the bases of such triangles and trapezoids as are necessary to fill up to the interior parts."

The method of measuring the other cross lines, off-sets and interior parts and enclosures, appears in the plan, fig. 1, last referred to.

16. Another ingenious correspondent (Mr. John Rodham of Richmond, Yorkshire) has also communicated the following example of the new method of surveying, accompanied by the field-book, and its corresponding plan. His account of the method is as follows.

The field-book is ruled into three columns. In the middle one are set down the distances on the chain line at which any mark, offset, or other observation is made; and in the right and left hand columns are entered, the offsets and observations made on the right and left hand respectively of the chain line.

It is of great advantage, both for brevity and perspicuity, to begin at the bottom of the leaf and write upwards; denoting the crossing of fences, by lines drawn across the middle column, or only a part of such a line on the right and left opposite the figures, to avoid confusion, and the corners of fields, and other remarkable turns in the fences where offsets are taken to, by lines joining in the manner the fences do, as will be best seen by comparing the book with the plan annexed, fig. 2, pl. 34.

The marks called *a*, *b*, *c*, &c, are best made in the fields, by making a small hole with a spade, and a chip or small bit of wood, with the particular letter upon it, may be put in, to prevent one mark being taken for another, on any return to it. But in general, the name of a mark is very easily had by referring in the book to the line it was made in. After the small alphabet is gone through, the capitals may be next, the print letters afterwards, and so on, which answer the purpose of so many different letters; or the marks may be numbered.

The letter in the left hand corner at the beginning of every line, is the mark or place measured from; and, that at the right hand corner at the end, is the mark measured to. But when it is not convenient to go exactly from a mark, the place measured from, is described such a distance from one mark towards another; and where a mark is not measured to, the exact place is ascertained by saying, turn to the right or left hand, such a distance to such a mark, it being always understood that those distances are taken in the chain line.

The characters used, are ⌐ for turn to the right hand, ¬ for turn to the left hand, and ∧ placed over an offset, to show that it is not taken at angles with the chain line, but in the line with some straight fence; being chiefly used when crossing their directions, and is a better way of obtaining their true places than by offsets at right angles.

When a line is measured whose position is determined, either by former work (as in the case of producing a given line or measuring from one known place or mark to another) or by itself (as in the third side of a triangle) it is called a fast line, and a double line across the book is drawn at the conclusion of it; but if its position is not determined (as in the second side of a triangle) it is called a loose line, and a single line is drawn across the book. When a line becomes determined in position, and is afterwards continued, a double line half through the book is drawn.

When a loose line is measured, it becomes absolutely necessary to measure some other line that will determine its position. Thus, the first line *ah*, being the base of a triangle, is always determined; but the position of the second side *hj*, does not become determined, till the third side *jb* is measured; then the triangle may be constructed, and the position of both is determined.

At the beginning of a line, to fix a loose line to the mark or place measured from, the sign of turning to the right or left hand must be added (as at *j* in the third line); otherwise a stranger, when laying down the work may as easily construct the triangle *hjb* on the wrong side of the line *ah*, as on the right one: but this error cannot be fallen into, if the sign above named be carefully observed.

In choosing a line to fix a loose one, care must be taken that it does not make a very acute or obtuse angle; as in the triangle *pBr*, by the angle at B being very obtuse, a small deviation from truth, even the breadth of a point at *p* or *r*, would make the error at B when constructed very considerable; but by constructing the triangle *pBq*, such a deviation is of no consequence.

Where the words *leave off* are written in the field-book, it is to signify that the taking of offsets is from thence discontinued; and of course something is wanting between that and the next offset.

The field-book above referred to, is engraved on plate 35, in four parts, representing so many pages, each of which is supposed to begin at the bottom, and end at top. And the map or plan belonging to it, in fig. 2, pl. 34.

Surveying of Harbours.

The method of surveying harbours, and of forming maps of them, as also of the adjacent coasts, sands, &c, depends on the same principles, and is chiefly conducted like that of common surveying. The operation is indeed more complicated and laborious; as it is necessary to erect a number of signals, and to mark a variety of objects along the coast, with different bearings from one another, and the several parts of the harbour; and likewise to measure a great number of angles at different stations, whether on the land or the water. For this purpose, the best instrument is Hadley's quadrant, as all these operations may be performed by it, not only with greater ease, but also with much more precision, than can be hoped for by any other means; as it is the only instrument in use, in which neither the exactness of the observations, nor the ease with which they may be made, are sensibly affected by the motion of a vessel: and hence a single observer, in a boat, may generally determine the situation of any place at pleasure, with a sufficient degree of exactness, by taking the angles subtended by several pairs of objects properly chosen upon shores at different places about him; but it will be still better to have two observers, or the same observer at different stations, to take the like angles to the several objects, and also to the stations. By this means, two angles and one side are given, in every triangle, from whence the situation of every part of them will be known. By such observations, when carefully made with good instruments, the situation of places may be easily determined to 20 or 30 feet, or less, upon every 3 or 4 miles. See Philos. Trans. vol. 55, pa. 70; also Mackenzie's Maritime Surveying.

SURVEYING *Cross*. See CROSS.

SURVEYING *Quadrant*. See QUADRANT.

SURVEYING *Scale*, the same with Reducing Scale.

SURVEYING *Wheel*. See PERAMBULATOR.

SURVIVORSHIP, the doctrine of Reversionary payments that depend upon certain contingencies, or contingent circumstances. Payments which are not to be made till some future period, are termed reversions, to distinguish them from payments that are to be made immediately.

Reversions are either certain or contingent. Of the former sort, are all sums or annuities, payable certainly or absolutely at the expiration of any terms, or on the extinction of any lives. And of the latter sort, are all such reversions as depend on any contingency; and particularly the survivorship of any lives beyond or after other lives. An account of the former may be found under the articles Assurance, Annuities, and Life-annuities. But the latter form the most intricate and difficult part of the doctrine of reversions and life-annuities; and the books in which this subject is treated most at large, and at the same time with the most precision, are Mr. Simpson's Select Exercises; Dr. Price's Reversionary Payments; Mr. Morgan's Annuities and Assurances on Lives and Survivorships; and Mr. Bayly's Annuities. The whole likewise of the 3d volume of Dodson's Mathematical Repository is on this subject; but his investigations are founded on Demoivre's false hypothesis, viz, of an equal decrement of life through all its stages, and which is explained under Life-annuities: but as this hypothesis does not agree near enough to fact and experience, the rules deduced from it cannot be sufficiently correct. For this reason, Dr. Price, and also Mr. Maseres, cursitor baron of the exchequer (in two volumes lately published, entitled the Principles of the Doctrine of Life Annuities), have discarded the valuations of lives founded upon it; and the former in particular, in order to obviate all occasion for using them, has substituted in their stead, a great variety of new tables of the probabilities and values of lives, at every age and in every situation; calculated, not upon any hypothesis, but in strict conformity to the best observations. These tables, added to other new tables of the same kind, in Mr. Baron Maseres's work just mentioned, form a complete set of tables, by which all questions relating to annuities on lives and survivorships, may be answered with as much correctness as the nature of the subject admits of.

Rules for calculating correctly, in most cases, the values of reversions depending on survivorships, may be found in the several treatises just mentioned. Mr. Morgan, in particular, has gone a good way towards exhausting this subject, as far as any questions can include in them any survivorships between two or three lives, either for terms, or the whole duration of the lives.

There is, however, one circumstance necessary to be attended to in calculating such values, to which no regard could be paid till lately. This circumstance is the shorter duration of the lives of males than of females; and the consequent advantage in favour of females in all cases of survivorship. In the 4th edition of Dr. Price's Treatise on Reversionary Payments, this fact is not only ascertained, but separate tables of the duration and values of lives are given for males and females.

SUSPENSION, in Mechanics, as in a balance, are those points in the axis or beam where the weights are applied, or from which they are suspended.

SUTTON's *Quadrant*. See QUADRANT.

SWAN, in Astronomy. See CYGNUS.

SWALLOW's-TAIL, in Fortification, is a single tenaille, which is narrower towards the place than towards the country.

SWANPAN, or *Chinese Abacus*, an instrument for performing arithmetical operations, described by Du Halde in his History of China. See ABACUS.

SWING-*Wheel*, in a royal pendulum, is that wheel which drives the pendulum. In a watch, or balance clock, it is called the *crown-wheel*.

SYDEREAL *Day*, or *Year*. See SIDEREAL.

SYMMETRY, the relation of parity, both in respect of length, breadth, and height, of the parts necessary to compose a beautiful whole. Symmetry arises from that proportion which the Greeks call analogy, which is the relation of conformity of all the parts of a building, and of the whole, to some certain measure; upon which depends the nature of symmetry.

According to Vitruvius, symmetry consists in the union and conformity of the several members of a work to their whole, and of the beauty of each of the separate parts to that of the entire work; regard being had to some certain measure: so the body, for instance, is framed with symmetry, by the due relation which the arm, elbow, hand, fingers, &c, have to each other, and to their whole.

SYMPHONY, is a consonance or concert of several sounds agreeable to the ear; whether they be vocal or instrumental, or both; called also harmony. The symphony of the ancients went no farther than to two or more voices or instruments set to unison; for they had no such thing as music in parts; as is very well proved by Perrault: at least, if ever they knew such a thing, it must have been lost very early.

It is to Guido Aretine, about the year 1022, that most writers agree in ascribing the invention of composition: it was he, they say, who first joined in one harmony several distinct melodies; and brought it even to the length of 4 parts, viz, bass, tenor, counter-tenor, and treble.

The term symphony is now applied to instrumental music, both that of pieces designed only for instruments, as sonatas and concertos, and that in which the instruments are accompanied with the voice, as in operas, &c. A piece is said to be in grand symphony, when, besides the bass and treble, it has also two other instrumental parts, viz, tenor and 5th of the violin.

SYNCHRONISM, the being or happening of several things together, at or in the same time. The happening or performing of several things in equal times, as the vibrations of pendulums, &c, is more properly called isochronism; though some authors confound the two.

SYNCOPATION, in Music, is a striking or breaking of the time; by which the distinctness of the several times or parts of the measure is interrupted.

SYNCOPATION, or SYNCOPE, is more particularly used for the connecting the last note of one measure or bar with the first of the following measure; so as to make only one note of both.

SYNCOPATION is also used when a note of one part ends on the middle of a note of the other part. This is otherwise called binding.

SYNODICAL *Month*, is the period or interval of time in which the moon passes from one conjunction with the sun to another. This period is also called a Lunation, since in this period the moon puts on all her phases, or appearances, as to increase and decrease.—Kepler found the quantity of the mean synodical month to be 29 days, 12 hrs. 44 min. 3 sec. 11 thirds.

SYNTHESIS, denotes a method of composition, as opposed to analysis. In the synthesis, or synthetic method, we pursue the truth by reasons drawn from principles before established, or assumed, and propositions formerly proved; thus proceeding by a regular chain till we come to the conclusion; and hence called also the direct method, and composition, in opposition to analysis or resolution. Such is the method in Euclid's Elements, and most demonstrations of the ancient mathematicians, which proceed from definitions and axioms, to prove theorems &c, and from those theorems proved, to demonstrate others. See ANALYSIS.

SYNTHETICAL *Method*, the method by synthesis, or composition, or the direct method. See SYNTHESIS.

SYPHON. See SIPHON.

SYRINGE, in Hydraulics, a small simple machine, serving first to imbibe or suck in a quantity of water, or other fluid, and then to expel the same with violence in a small jet. The syringe is a small single sucking pump, without a valve, the water ascending in it on the same principle. It consists, like the pump, of a small cylinder, with an embolus or sucker, moving up and down in it by means of a handle, and fitting it very close within. At the lower end is either a small hole, or a smaller tube fixed to it than the body of the instrument, through which the fluid or the water is drawn up, and squirted out again.

This ascent of the water the ancients, who supposed a plenum, attributed to nature's abhorrence of a vacuum; but the moderns, more reasonably, as well as more intelligibly, attribute it to the pressure of the atmosphere on the exterior surface of the fluid. For, by drawing up the embolus, the cavity of the cylinder would become a vacuum, or the air left there extremely rarefied; so that being no longer a counterbalance to the air incumbent on the surface of the fluid, this prevails, and forces the water through the little tube, or hole, up into the body of the syringe.

SYSTEM, in a general sense, denotes an assemblage or chain of principles and conclusions; or the whole of any doctrine, the several parts of which are bound together, and follow or depend on each other: as a system of astronomy, a system of planets, a system of philosophy, a system of motion, &c.

SYSTEM, in Astronomy, denotes an hypothesis or a supposition of a certain order and arrangement of the several parts of the universe; by which astronomers explain all the phenomena or appearances of the heavenly bodies, their motions, changes, &c. This is more peculiarly called the System of the world, and sometimes the Solar System.

System and hypothesis have much the same signification; unless perhaps hypothesis be a more particular system, and system a more general hypothesis. Some late authors indeed make another distinction: an hypothesis, say they, is a mere supposition or fiction, founded rather on imagination than reason; while a system is built on the firmest ground, and raised by the severest rules; it is founded on astronomical observations, and physical causes, and confirmed by geometrical demonstrations.

The most celebrated systems of the world, are the Ptolemaic, the Copernican or Pythagorean, and the Tychonic: the economy of each of which is as follows.

Ptolemaic SYSTEM is so called from the celebrated astronomer Ptolemy. In this system, the earth is placed at rest, in the centre of the universe, while the heavens are considered as revolving about it, from east to west, and carrying along with them all the heavenly bodies, the stars and planets, in the space of 24 hours. The principal assertors of this system, are Aristotle, Hipparchus, Ptolemy, and many of the old philosophers; and indeed almost all astronomers, for a great number of ages, supported this system. But the late improvements in philosophy and reasoning, have utterly exploded this erroneous system from the place it so long held in the minds of men.

Copernican SYSTEM, is that system of the world which places the sun at rest, in the centre of the world, and the earth and planets revolving about him, in their several orbits. See this more particularly explained under the article COPERNICAN *System*.

Solar or *Planetary* SYSTEM, is usually confined to narrower bounds; the stars, by their immense distance, and the little relation they seem to bear to us, being accounted no part of it. It is highly probable that each fixed star is itself a sun, and the centre of a particular system, surrounded with a company of planets &c, which, in different periods, and at different distances, perform their courses round their respective sun, which enlightens, warms, and cherishes them. Hence we have a very magnificent idea of the world, and the immensity of it. Hence also arises a kind of system of systems.

The planetary system, described under the article COPERNICAN, is the most ancient in the world. It was first of all, as far as we know, introduced into Greece and Italy by Pythagoras; from whom it was called the Pythagorean System. It was followed by Philolaus, Plato, Archimedes, &c: but it was lost under the reign of the Peripatetic philosophy; till happily retrieved about the year 1500 by Copernicus.

Tychonic SYSTEM, was taught by Tycho, a Dane; who was born an dom. 1546. It supposes that the earth is fixed in the centre of the universe or firmament of stars, and that all the stars and planets revolve round the earth in 24 hours; but it differs from the Ptolemaic system, as it not only allows a menstrual motion to the moon round the earth, and that of the satellites about Jupiter and Saturn, in their proper periods, but it makes the sun to be the centre of the orbits of the primary planets Mercury, Venus, Mars, Jupiter, &c, in which they are carried round the sun in their respective years, as the sun revolves round the earth in a solar year; and all these planets, together with the sun, are supposed to revolve round the earth in 24 hours. This hypothesis was so embarrassed and perplexed, that very few persons embraced it. It was afterwards altered by Longomontanus and others, who allowed the diurnal motion of the earth on its own axis, but denied its annual motion round the sun. This hypothesis, partly true and partly false, is called the semi-Tychonic system. See the figure and economy of these systems, in plates 36 and 37.

SYSTEM, in Music, denotes a compound interval; or an interval composed, or conceived to be composed of several less intervals. Such is the octave, &c.

SYSTYLE, in Architecture, the manner of placing columns, where the space between the two fusts consists of 2 diameters, or 4 modules.

SYZYGY, a term equally used for the conjunction and opposition of a planet with the sun.—On the phenomena and circumstances of the syzygies, a great part of the lunar theory depends. See MOON. For,

1. It is shown in the physical astronomy, that the force which diminishes the gravity of the moon in the syzygies, is double that which increases it in the quadratures; so that, in the syzygies, the gravity of the moon is diminished by a part which is to the whole gravity, as 1 to 89·36; for in the quadratures, the addition of gravity is to the whole gravity, as 1 to 178·73.

2. In the syzygies, the disturbing force is directly as the distance of the moon from the earth, and inversely as the cube of the distance of the earth from the sun. And at the syzygies, the gravity of the moon towards the earth receding from its centre, is more diminished than according to the inverse ratio of the square of the distance from that centre.—Hence, in the moon's motion from the syzygies to the quadratures, the gravity of the moon towards the earth is continually increased, and the moon is continually retarded in her motion; but in the moon's motion from the quadratures to the syzygies, her gravity is continually diminished, and the motion in her orbit is accelerated.

3. Further, in the syzygies, the moon's orbit, or circuit round the earth, is more convex than in the quadratures; for which reason she is less distant from the earth at the former than the latter.—Also, when the moon is in the syzygies, her apses go backward, or are retrograde.—Moreover, when the moon is in the syzygies, the nodes move in antecedentia fastest; then slower and slower, till they become at rest when the moon is in the quadratures.—Lastly, when the nodes are come to the syzygies, the inclination of the plane of the orbit is the least of all.

However, these several irregularities are not equal in each syzygy, being all somewhat greater in the conjunction than in the opposition.

T.

TABLE, in Architecture, a smooth, simple member or ornament, of various forms, but most commonly in that of a parallelogram.

TABLE, in Perspective, is sometimes used for the perspective plane, or the transparent plane on which the objects are formed in their respective appearance.

TABLE *of Pythagoras*, is the same as the MULTIPLICATION table; which see; as also PYTHAGORAS's table.

Tables, in Mathematics, are systems or series of numbers, calculated to be ready at hand for expediting calculations in the various branches of mathematics; as, tables of powers, or roots, of reciprocals, of products, &c.

Astronomical Tables, are computations of the motions, places, and other phenomena of the planets, both primary and secondary. The oldest astronomical tables extant are those of Ptolemy, found in his Almagest. These however are not now of much use, as they no longer agree with the motions of the heavens.

In 1252, Alphonso XI, king of Castile, undertook the correcting of them, chiefly by the assistance of Isaac Hazen, a learned Jew; and spent 400,000 crowns on the business. Thus arose the Alphonsine tables, to which that prince himself prefixed a preface. But the deficiency of these also was soon perceived by Purbach and Muller, or Regiomontanus; on which the latter, and after him Walther Warner, applied themselves to celestial observations, for further improving them; but death, or various difficulties, prevented the effect of these laudable designs.

Copernicus, in his books of the celestial revolutions, gives other tables, calculated by himself, partly from his own observations, and partly from the Alphonsine tables.

From Copernicus's observations and theorems, Erasmus Reinhold afterwards compiled the Prutenic tables, which have been printed several times, and in several places.

Tycho Brahé, even in his youth, became sensible of the deficiency of the Prutenic tables: which determined him to apply himself with so much vigour to celestial observations. From these he adjusted the motions of the sun and moon; and Longomontanus, from the same observations, constructed tables of the motions of the planets, which he added to the theories of the same, published in his Astronomia Danica; those being called the Danish tables. And Kepler also, from the same observations, published in 1627 his Rudolphine tables, which are much esteemed.

These were afterwards, viz, in 1650, changed into another form, by Maria Cunitia, whose astronomical tables, comprehending the effect of Kepler's physical hypothesis, are very easy, satisfying all the phenomena without any mention of logarithms, and with little or no trouble of calculation. So that the Rudolphine calculus is here greatly improved.

Nic. Mercator made a similar attempt in his Astronomical Institution, published in 1676. As did also J. Bap. Morini, whose abridgement of the Rudolphine tables was prefixed to a Latin version of Street's Astronomia Carolina, published in 1705. Lansberg indeed endeavoured to discredit the Rudolphine tables, and framed perpetual tables, as he calls them, of the heavenly motions. But his attempt was never much regarded by the astronomers; and our countryman Horrox warmly attacked him, in his defence of the Keplerian astronomy.

Since the Rudolphine tables, many others have been framed, and published: as the Philolaic tables of Bulliald; the Britannic Tables of Vincent Wing, calculated on Bulliald's hypothesis; the Britannic tables of John Newton; the French ones of the count Pagan; the Caroline tables of Street, all calculated on Ward's hypothesis; and the Novelmajestic tables of Riccioli. Among these, however, the Philolaic and Caroline tables are esteemed the best; insomuch that Mr. Whiston, by the advice of Mr. Flamsteed, thought fit to subjoin the Caroline tables to his astronomical lectures.

The Ludovician tables, published in 1702, by Lahire, were constructed wholly from his own observations, and without the assistance of any hypothesis; which, before the invention of the micrometer telescope and the pendulum clock, was held impossible.

Dr. Halley also long laboured to perfect another set of tables; which were printed in 1719, but not published till 1752.

M. Monnier, in 1746, published, in his Institutions Astronomiques, tables of the motions of the sun and moon, with the satellites; as also of refractions, and the places of the fixed stars. Lahire also published tables of the planets, and Lacaille tables of the sun: Gael Morris published tables of the sun and moon, and Mayer constructed tables of the moon, which were published by the board of longitude. Tables of the same have also been computed by Charles Mason, from the principles of the Newtonian philosophy, which are found to be very accurate, and are employed in computing the Nautical Ephemeris. Many other sets of astronomical tables have also been published by various persons and academies; and divers sets of them may be found in the modern books of astronomy, navigation, &c, of which those are esteemed among the best that are printed in Lalande's Astronomy; in Vince's Astronomy; also Delambre's, Burg's, and Burckhardt's tables, &c. For an account of several, and especially of those published annually under the direction of the commissioners of longitude, see Almanac, Ephemeris, and Longitude.

For Tables *of the Stars*, see Catalogue.

Tables of *Sines*, *Tangents*, and *Secants*, used in trigonometry, &c, are usually called Canons. See Sine.

Tables *of Logarithms, Rhumbs, &c*, used in trigonometry, navigation, &c, see Logarithm, and Rhumb.

Tables, *Loxodromic*, and *of Difference of Latitude and Departure*, are tables used in computing the way and reckoning of a ship on a voyage, and are published in most books of navigation.

TACQUET (Andrew), a Jesuit of Antwerp, who died in 1660. He was a most laborious and voluminous writer in mathematics. His works were collected, and printed at Antwerp in one large volume in folio, 1669. Tacquet was one of those learned Jesuits who chiefly cultivated the liberal sciences in the 16th and 17th centuries. Besides the collection of his works above-mentioned, he had before published very neat editions of the Elements of Geometry, and of Arithmetic, both in 8vo. In matters of astronomy, his fear of the church censures seems to have prevented him from more effectually defending the Copernican system of the world. A very particular and satisfactory account of the collection of his works may be seen in the Philos. Trans. vol. 3, pa. 868, or in my Abridgment, vol. 1, pa. 314.

TACTION, in Geometry, the same as tangency, or touching. See Tangent.

TALUS, or Talud, in Architecture, the inclination or slope of a work; as of the outside of a wall, when its thickness is diminished by degrees, as it rises in height, to make it the firmer.

Talus, in Fortification, means also the slope of a work, whether of earth or masonry.

The *Exterior Talus* of a work, is its slope on the side outwards or towards the country; which is always made as small as possible, to prevent the enemy's escalade, unless the earth be bad, for then it is necessary to allow a considerable talus for its parapet, and sometimes to support the earth with a slight wall, called a revetement.

The *Interior Talus* of a work, is its slope on the inside, towards the place. This is larger than the former, and it has, at the angles of the gorge, and sometimes in the middle of the curtains, ramps, or sloping roads for mounting upon the terreplain of the rampart.

Superior TALUS *of the Parapet*, is a slope on the top of the parapet, that allows of the soldiers defending the covert-way with small-shot, which they could not do if it were level.

TAMBOUR, in Architecture, a term applied to the Corinthian and Composite capitals, as bearing some resemblance to a tambour or drum.

TAMUZ, in Chronology, the 4th month of the Jewish ecclesiastical year, answering to part of our June and July. The 17th day of this month is observed by the Jews as a fast, in memory of the destruction of Jerusalem by Nebuchadnezzar, in the 11th year of Zedekiah, and the 588th before Christ.

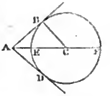
TANGENCIES (Problem of). This general problem in Geometry furnishes the subject of one of the 12 treatises described by Pappus in the preface to the 7th book of his Mathematical Collections. The general problem is this: Of points, right-lines, and circles, any three being given; to describe a circle that shall pass through the given points, and also touch the given lines.

This naturally divides into 10 distinct propositions; which, if the three things be thus denoted, viz, a point by the mark (·), a line by (1), and a circle by (0), may be stated very briefly according to the several data, in the following order: viz, (··1), (·11), (110), (·10), (100), (··0), (·00), (000), (···), (111).

The original treatise on this subject, by Apollonius, having been lost, the restoration of it has lately been attempted by several persons; viz, by Vieta, under the title of Apollonius Gallus; and many of the deficiencies were supplied by Ghetaldus. Afterwards the tactions were restored by various other mathematicians, both geometrically and algebraically. A treatise on them by G. Camerar was published at Gotha and Amsterd. in 1795; but it contains only an edition of Vieta's treatise, with notes and additions, and a curious history of the problem. The history is interesting, from the accounts it contains of the labours of some foreign mathematicians on this problem, which are little known in this country. He gives the preface and lemmata of the tactions in Greek, with some various readings of several manuscripts of Pappus. Though Vieta's solutions are elegant, yet they are in several respects deficient: there is not a full distinction either of the cases, or of the necessary determinations: no analysis is given, and no attempt to restore the Apollonian solutions by the use of the lemmata in Pappus, which had been assumed in the work of Apollonius.

In the remaining papers of Dr. Rob. Simson, it seems, are found solutions of some of the cases of this problem. Also the treatises of Vieta and Ghetaldus have been translated into English, with the addition of a supplement, by the Rev. John Lawson, and a further addition of Fermat's Treatise on Spherical Tangencies. And Mr. Leslie has given, in his Geometry, as examples of the geometrical analysis, solutions to many of the cases of this problem. Also Mr. John Lawson published a neat edition, in English, of the two books on Tangencies, 1771, in 4to.

TANGENT, in Geometry, is a line that touches a curve, &c, that is, which meets it in a point without cutting it, though it be produced both ways; as the tangent AB of the circle BD. The point B, where the tangent touches the curve, is called the point of contact.



The direction of a curve at the point of contact, is the same as that of the tangent. It is demonstrated in Geometry,

1. That a tangent to a circle, as AB, is perpendicular to the radius BC drawn to the point of contact.

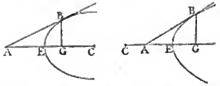
2. The tangent AB is a mean proportional between AF and AE, the whole secant and the external part of it; and the same for any other secant drawn from the same point A.

3. The two tangents AB and AD, drawn from the same point A, are always equal to each other. And therefore also, if a number of tangents be drawn to different points of the curve quite around, and an equal length BA be set off upon each of them from the points of contact, the locus of all the points A will be a circle having the same centre C.

4. The angle of contact ABE, formed at the point of contact, between the tangent AB and the arc BE, is less than any rectilineal angle whatever.

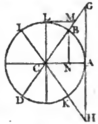
5. The tangent of an arc is the right line that limits the position of all the secants that can pass through the point of contact; though strictly speaking it is not one of the secants, but only the limit of them.

6. As a right line is the tangent of a circle, when it touches the circle so closely, that no right line can be drawn through the point of contact between it and the arc, or within the angle of contact that is formed by them; so, in general, when any right line touches an arc of any curve, in such a manner, that no right line can be drawn through the point of contact, between the right line and the arc, or within the angle of contact that is formed by them, then is that line the tangent of the curve at the said point; as AB in the figures below.



7. In all the conic sections; if C be the centre of the figure, and BG an ordinate drawn from the point of contact and perpendicular to the axis; then is CG : CE : : CE : CA, or the semiaxis CE is a mean proportional between CG and CA.

TANGENT, in Trigonometry. A TANGENT *of an arc*, is a right line touching one extremity of the arc, and limited by a secant or line drawn through the centre and the other extremity of the arc.



So, AG is the tangent of the arc AB, or of the arc ABD; and AH is the tangent of the arc AI, or of the arc AIDK.

The same are also the tangents of the angles that are subtended or measured by the arcs.

Hence, 1. The tangents in the 1st and 3d quadrants are positive, in the 2d and 4th negative, or drawn the contrary way. But of 0 or 180° the semicircle, the tangent is 0 or nothing; while those of 90° or a quadrant, and 270° or 3 quadrants, are both infinite; the former infinitely positive, and the latter infinitely negative. That is,

Between 0 and 90°, or between 180° and 270°, the tangents are positive.

Between 90° and 180°, or between 270° and 360°, the tangents are negative.

2. The tangent of an arc and the tangent of its supplement, are equal, but of contrary affections, the one being positive, and the other negative;

as of a and $180° - a$, where a is any arc.

Also $180° + a$ and a } have the same tangent, and are of the same affection.

Or $180° + a$ and $180° - a$ } have the same tangent, but of different affections.

3. The tangent of an arc is a 4th proportional to the cosine, the sine, and the radius; that is, CN : NB : : CA : AG. Hence, a canon of sines being made or given, the canon of tangents is easily constructed from them.

Co-Tangent, contracted from complement-tangent, is the tangent of the complement of the arc or angle, or of what it wants of a quadrant or 90°. So LM is the cotangent of the arc AB, being the tangent of its complement BL.

The tangent is reciprocally as the cotangent; or the tangent and cotangent are reciprocally proportional with the radius. That is tang. is as $\frac{1}{\text{cotan.}}$, or tang. : radius : : radius : cotan. And the rectangle of the tangent and cotangent is equal to the square of the radius; that is, tan. × cot. = radius ^{2}.

If a denote any arc, and t its tangent, radius 1: then is $a = t - \frac{1}{3}t^3 + \frac{1}{5}t^5 - \frac{1}{7}t^7 + \text{\&c.}$ Whence, since tan. 45° = 1, we have arc $45° = 1 - \frac{1}{3} + \frac{1}{5} - \frac{1}{7} + \frac{1}{9} - \text{\&c.}$ And conversely $t = a + \frac{1}{3}a^3 + \frac{2}{15}a^5 + \frac{17}{315}a^7 + \text{\&c.}$

Further, $t = \frac{\sin a}{\cos a} = \frac{1}{\cot a} = \sqrt{(\frac{1}{\cos^2 a} - 1)} = \frac{\sin a}{\sqrt{(1-\sin^2 a)}} = \frac{\sqrt{(1-\cos^2 a)}}{\cos a} = \frac{2 \tan \frac{1}{2}a}{1 - \tan^2 \frac{1}{2}a} = \frac{2}{\cot \frac{1}{2}a - \tan \frac{1}{2}a} = \cot a - 2\cot 2a = \frac{1 - \cos 2a}{\sin 2a} = \frac{\sin 2a}{1 + \cos 2a} = \sqrt{\frac{1 - \cos 2a}{1 + \cos 2a}} = \frac{\tan(45 + \frac{1}{2}a) - \tan(45 - \frac{1}{2}a)}{2}.$

$$\text{Also, } \tan(a+b) = \frac{\tan a + \tan b}{1 - \tan a \cdot \tan b}.$$

$$\tan(a-b) = \frac{\tan a - \tan b}{1 + \tan a \cdot \tan b}.$$

$$\tan a + \tan b = \frac{\sin(a+b)}{\cos a \cdot \cos b}.$$

$$\cot a + \cot b = \frac{\sin(a+b)}{\sin a \cdot \sin b}.$$

See the treatises on trigonometry by Emerson, Cagnoli, Mauduit, and several others.

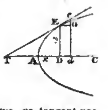
Artificial Tangents, or *Logarithmic* Tangents, are the logarithms of the tangents of arcs; so called, in contradistinction from the natural tangents, or the tangents expressed by the natural numbers.

Line of Tangents, is a line usually placed on the sector, and Gunter's scale; the description and uses of which see under the article Sector.

Sub-Tangent, a line lying beneath the tangent, being the part of the axis intercepted by the tangent and the ordinate to the point of contact: as the line AG in the 2d and 3d figures above.

Method of Tangents, is a method of determining the quantity of the tangent and subtangent of any algebraic curve; the equation of the curve being given. This method is one of the great results of the doctrine of fluxions. It is of great use in geometry; because that in determining the tangents of curves, we determine at the same time the quadrature of the curvilinear spaces: on which account it deserves to be here particularly treated on.

To Draw the Tangent, or to find the Subtangent, of a curve.



If AE be any curve, and E any point in it, to which it is required to draw a tangent TE. Draw the ordinate DE: then if we can determine the subtangent TD, by joining the points T and E, the line TE will be the tangent sought.

Let *dae* be another ordinate indefinitely near to DE, meeting the curve, or tangent produced, in e: and let Ea be parallel to the axis AD. Then is the elementary triangle Eae similar to the triangle TDE;

and therefore - ea : aE : : ED : DT;

but - - - - ea : aE : : flux. ED : flux. AD;

therefore - - flux. ED : flux. AD : : DE : DT;

that is - - - $\dot{y} : \dot{x} : : y : \frac{y\dot{x}}{\dot{y}}$ = DT,

which is therefore the value of the subtangent sought; where x is the absciss AD, and y the ordinate DE.

Hence comes this general rule: By the given equation of the curve, find the value either of $\dot{x}$ or $\dot{y}$, or of $\frac{\dot{x}}{\dot{y}}$, which substitute for it in the expression DT $= \frac{y\dot{x}}{\dot{y}}$, and, when reduced to its simplest terms, it will be the value of the subtangent sought. This we may illustrate in the following examples.

Ex. 1. The equation defining a circle is $2ax - xx = y^2$, where a is the radius; and the fluxion of this is $2a\dot{x} - 2x\dot{x} = 2y\dot{y}$; hence $\frac{\dot{x}}{\dot{y}} = \frac{y}{a-x}$; this multiplied by y, gives $\frac{y\dot{x}}{\dot{y}} = \frac{y^2}{a-x} = \frac{\text{DE}^2}{\text{CD}}$ = the subtangent TD, or CD : DE : : DE : TD, which is a property of the circle also known from common geometry.

Ex. 2. The equation defining the common parabola is $ax = y^2$, a being the parameter, and x and y the absciss and ordinate in all cases. The fluxion of this is $a\dot{x} = 2y\dot{y}$; hence $\frac{\dot{x}}{\dot{y}} = \frac{2y}{a}$; consequently $\frac{y\dot{x}}{\dot{y}} = \frac{2y^2}{a} = \frac{2ax}{a} = 2x$ = TD; that is, the subtangent TD is double the absciss AD, or TA is = AD, which is a well-known property of the parabola.

Ex. 3. The equation defining an ellipsis is $c^2(2ax - x^2) = a^2y^2$, where a and c are the semiaxes. The fluxion of it is $c^2(2a\dot{x} - 2x\dot{x}) = 2a^2y\dot{y}$; hence $\frac{y\dot{x}}{\dot{y}} = \frac{a^2y^2}{c^2(a-x)} = \frac{c^2(2ax-x^2)}{c^2(a-x)} = \frac{2a-x}{a-x}x$ = TD the subtangent; or by adding CD which is $= a - x$, it becomes

$CT = \frac{2ax - x^2}{a - x} + a - x = \frac{a^2}{a - x} = \frac{CA^2}{CD}$, or CD : CA : : CA : CT, a well-known property of the ellipse.

Ex. 4. The equation defining the hyperbola is $c^2 (2ax + x^2) = a^2y^2$, which is similar to that for the ellipse, having only $+ x^2$ for $- x^2$; hence the conclusion is exactly similar also, viz,

$\frac{2a + x}{a + x}x$ or $\frac{2ax + xx}{a + x} =$ TD, which taken from CD or $a + x$, gives $CT = \frac{CA^2}{CD}$, or CD : CA : : CA : CT.

And so on, for the tangents to other curves.

The Inverse Method of TANGENTS. This is the reverse of the foregoing, and consists in finding the nature of the curve that has a given subtangent. The method of solution is to put the given subtangent equal to the general expression $\frac{y\dot{x}}{\dot{y}}$, which serves for all kinds of curves; then the equation reduced, and the fluents taken, will give the fluential equation of the curve sought.

Ex. 1. To find the curve line whose subtangent is $= \frac{2y^2}{a}$. Here $\frac{2y^2}{a} = \frac{y\dot{x}}{\dot{y}}$; hence $2y\dot{y} = a\dot{x}$, and the fluents of this give $y^2 = ax$, the equation to a parabola, which therefore is the curve sought.

Ex. 2. To find the curve whose subtangent is $= \frac{yy}{2a - x}$, or a third proportional to $2a-x$ and y. Here $\frac{yy}{2a - x} = \frac{y\dot{x}}{\dot{y}}$; hence $y\dot{y} = 2a\dot{x} - x\dot{x}$, the fluents of which give $y^2 = ax - x^2$, the equation to a circle, which therefore is the curve sought.

Or, in a more general sense, this is the same thing as finding the fluents of such forms as involve several variable quantities. See INVERSE, &c. Also the Fluxional Treatises by Maclaurin, Simpson, Emerson, Dealtry, Bossu, Lacroix, Lagrange, &c.

TANTALUS's *Cup*, in Hydraulics, is a cup, as A, with a hole in the bottom, and the longer leg of a syphon BCED cemented into the hole; so that the end D of the shorter leg DE may always touch the bottom of the cup within. Then, if water be poured into this cup, it will rise in the shorter leg by its upward pressure, extruding the air before it through the longer leg, and when the cup is filled above the bend of the syphon at E, the pressure of the water in the cup will force it over the bend; from whence it will descend in the longer leg EB, and through the bottom at G, till the cup be quite emptied. The legs of this syphon are almost close together, and it is sometimes concealed by a small hollow statue, or figure of a man placed over it; the bend E being within the neck of the figure as high as the chin. So that poor thirsty Tantalus stands up to the chin in water, according to the fable, imagining it will rise a little higher, as more water is poured in, and he may drink; but instead of that, when the water comes up to his chin, it immediately begins to descend, and therefore, as he cannot stoop to follow it, he is left in the same distressful state of thirst as before. Ferguson's Lect. pa. 72, 4to.

TARRANTIUS (LUCIUS), surnamed *Firmanus*, because he was a native of Firmum, a town in Italy, flourished at the same time with Cicero, and was one of his friends. He was a mathematical philosopher, and therefore was thought to have great skill in judicial astrology. He was particularly famous by two horoscopes which he drew, the one the horoscope of Romulus, and the other of Rome. Plutarch says, "Varro, who was the most learned of the Romans in history, had a particular friend named Tarrantius, who, out of curiosity, applied himself to draw horoscopes, by means of astronomical tables, and was esteemed the most eminent in his time." Historians controvert some particular circumstances of his calculations; but all agree in conferring on him the honorary title *Prince of astrologers.*

TARTAGLIA, or TARTALEA (NICHOLAS), a noted mathematician, was born at Brescia in Italy, in 1479, of a very poor family; and was in that town when the French plundered it on their return from Naples. On this occasion he received many wounds, several of them on the head, which affected his speech, causing him to stutter. It is not known how he learned to read; but, to acquire writing, he was obliged to steal from a teacher a set of the letters of the alphabet. Hence, it is easy to imagine what difficulties he must have surmounted in acquiring his knowledge. Yet we find he was a considerable master or preceptor in mathematics in the year 1521, when the first of his collection of questions and answers was written, which he afterwards published in the year 1546, under the title of Quesiti et Inventioni diverse, at Venice, where he then resided as a public lecturer on mathematics, having removed to this place about the year 1534. This work consists of 9 chapters, containing solutions to a number of questions on all the different branches of mathematics and philosophy then in vogue. The last or 9th of these contains the questions in algebra, among which are those celebrated letters and communications between Tartalea and Cardan, by which our author put the latter in possession of the rules for cubic equations, which he first discovered in the year 1530.

But the first work of Tartalea's that was published, was his Nova Scientia inventa, in 4to, at Venice in 1537. This is a treatise on the theory and practice of gunnery, and the first of the kind, he being the first writer on the flight and path of balls and shells. This work was translated into English, by Lucar, and printed at London in 1588, in folio, with many notes and additions by the translator. Tartalea published at Venice, in folio, 1543, the whole books of Euclid, accompanied with many curious notes and commentaries. But the last and chief work of Tartalea, was his Trattato di Numeri et Misure, in folio, 1556 and 1560. This is a universal treatise on arithmetic, algebra, geometry, mensuration, &c. It contains also many other curious particulars of the disputes between our author and Cardan, which ended only with the death of Tartalea, in 1557, before the last part of this work was published in the year 1558. One of the ingenious inventions of Tartalea was the method of finding the area of a triangle from having the three sides given.

For many other circumstances concerning Tartalea and his writings, see the article ALGEBRA, vol. 1.

TAURUS, *the Bull*, in Astronomy, one of the 12 signs in the zodiac, and the second in order. The Greeks fabled that this was the bull which carried Europa safely across the seas to Crete; and that Jupiter, in reward for so signal a service, placed the creature, whose form he had assumed on that occasion, among the stars, and that this is the constellation formed of it. But it is probable that the Egyptians, or Babylonians, or whoever invented the constellations of the zodiac, placed this figure in that part of it which the sun entered about the time of the bringing forth of calves; like as they placed the ram in the first part of spring, as the lambs appear before them, and the two kids (for that was the original figure of the sign Gemini), afterwards, to denote the time of the goats bringing forth their young.

In the constellation Taurus there are some remarkable stars that have names; as Aldebaran in the south or right eye of the bull, the cluster called the Pleiades in the neck, and the cluster called Hyades in the face. The stars in the constellation Taurus, in Ptolemy's catalogue are 44, in Tycho's catalogue 43, in Hevelius's catalogue 51, and in the Britannic catalogue 141.

TAYLOR (Dr. Brook), a very able mathematician and secretary of the Royal Society, was born at Edmonton, in Middlesex, 1685. In 1701 he entered St. John's College, Cambridge; and in 1708 wrote his tract on the centre of oscillation. In 1712 he was elected into the Royal Society, of which he was chosen secretary two years after. Dr. Taylor had many excellent papers, on philosophy and mathematics, inserted in the Philos. Trans. from vol. 27 to vol. 32, inclusively; besides which, he published some other excellent works, viz, Methodus Incrementorum, in 4to, 1715, containing many excellent tracts, particularly a curious and general theorem, on the manner of expressing a variable quantity by all the orders of its differentials or fluxions; also the problem of the vibrations of a tense cord, of which he gave the first solution. The same year also came out his Principles of Linear Perspective, first establishing the true practice of that art, on principles which have been ever since followed by all other authors. Dr. Taylor was a profound and elegant mathematician of the old school of Newton, Jones, Cotes, &c, and one of the chief writers in the disputes with the Bernoullis and other eminent writers on the continent. Dr. Brook died at an early age, 46, in the year 1731.

Taylor's *Theorem*, in the higher mathematics, is a very elegant and fertile formula, given by Dr. Brook Taylor, in cor. 2, pr. 7, pa. 23, of his Method of Increments. The purport of it is as follows:—If x and z be any two variable quantities, having any given relation; then, while x by flowing uniformly, is increased by $\dot{x}$, z will be increased by $\dot{z} + \frac{1}{1.2}\ddot{z} + \frac{1}{1.2.3}\dddot{z} + \&c$; in which the values of $\dot{z}$, $\ddot{z}$, &c, are to be determined from the given equation.

The demonstration of this theorem has been given by several eminent writers; as Frisi; Lacroix, pa. 25, Calcul. Differential.; Francœur, Mathematiques Pures, tom. 2, pa. 243, &c; and by Dr. Brinkley, vol. 7, Transactions of the Irish Acad. with applications of the use of the theorem, in finding fluxions *per saltum*, and in approximating to the roots of equations, &c.

TEBET, or Thevet, the 4th month of the civil year of the Hebrews, and the 10th of their ecclesiastical year. It answered to part of our December and January, and had only 29 days.

TEETH, of various kinds of machines, as of mill wheels, &c. These are often called cogs by the workmen; and by working in the pinions, rounds, or trundles, the wheels are made to turn one another. Mr. Emerson (in his Mechanics, prop. 25), treats of the theory of teeth, and shows that they ought to have the figure of epicycloids, for properly working in one another. Camus (in his Cours de Mathematique, tom. 2, pa. 349, &c, edit. 1767) treats more fully on the same subject; and demonstrates that the teeth of the two wheels should have the figures of epicycloids, but that the generating circles of these epicycloids should have their diameters only the half of what Mr. Emerson makes them.

Mr. Emerson observes, that the teeth ought not to act upon one another before they arrive at the line which joins their centres. And though the inner or under sides of the teeth may be of any form; yet it is better to make them both sides alike, which will serve to make the wheels turn backwards. Also a part may be cut away on the back of every tooth, to make way for those of the other wheel. And the more teeth that work together, the better; at least one tooth should always begin before the other has done working. The teeth ought to be disposed in such manner as not to disturb or hinder one another, before they begin to work; and there should be a convenient length, depth, and thickness given to them, as well for strength, as that they may more easily disengage themselves.

TELEGRAPH, a machine brought into use by the French nation, in the year 1793, contrived to communicate words or signals from one person to another at a great distance, in a very small space of time.

The telegraph, though it has been generally known and used by the moderns only for a few years, is by no means an entirely modern invention; some kind of signals for distant communication having probably existed in all ages, and in all nations. There is reason to believe that among the Greeks something of this kind was in use; as the burning of Troy was certainly known in Greece very soon after it happened, and before any person had returned from thence.—The Chinese, when they send couriers on the great canal, or when any great man travels there, make signals by fire from one day's journey to another, to have every thing prepared. And most of the barbarous nations used formerly, and often do still, to give the alarm of war, or the approach of an enemy, by fires lighted on the hills or rising grounds.

The object proposed is, to obtain an intelligible figurative language, which may be distinguished at a distance, and by which the obvious delay in the dispatch of orders or information by messenger may be avoided. On first reflection we find the practical modes of such distant communication must be confined to sound and vision. Each of which is in a great degree subject to the state of the atmosphere; as, independent of the wind's direction, it is known that the air is sometimes so far deprived of its elasticity, or whatever other quality the conveyance of sound depends on, that the heaviest ordnance is scarce heard farther than the shot flies; it is also well known, that in thick hazy weather the largest objects become totally obscured at a short distance. No instrument therefore designed for the purpose can be perfect. We can only endeavour to diminish these defects as much as may be.

Polybius names the different instruments used by the ancients, for communicating information, *πυρσειαι*, *pyrsiæ*, because the signals were always made by means of fire or lights. At first they communicated information of events, in an imperfect manner, merely by torches. A new method was invented by Cleoxenus, or as others say by Democlitus, which was much improved by Polybius, as he himself informs us; and which he describes as follows: Take the letters of the (Greek) alphabet, and divide them into 5 parts, each of which will consist of 5 letters, except the last division, which will have only 4. Let these be fixed on a board in five columns. The man who is to give the signals is then to begin by holding up 2 torches, which he is to keep aloft till the other person has also shown two; which is only to ascertain that both sides are ready; these two torches being then withdrawn. Both parties are provided with boards, on which the letters are disposed as before described. The person then, who gives the signal, is to hold up torches on the left, to point out to the other party from which column he shall take the letters, as they are pointed out to him. If it is to be from the first column, he holds up one torch; it from the second, 2; and so on for the others. He is then to hold up torches on the right, to denote the particular letter of the column that is to be taken, according to their place in the column. The man who gives the signals has an instrument consisting of two tubes, so placed as that, by looking through one of them, he can see only the right side, and through the other only the left, of him who is to answer. The board is set up near this instrument; and the station on the right and left surrounded with a wall, 10 feet broad, and about the height of a man, that the torches raised above it may be clearly seen, and to conceal them when taken down. Thus, then, it is easy to conceive how the letters of a short sentence, one after another, are communicated from station to station, as far as required.—And this is the pytsia or telegraph recommended by Polybius.

It seems the Romans had a method in their walled cities, either by a hollow formed in the masonry, or by tubes affixed to it, so to confine and augment sound, as to convey information to any part they wished; and in lofty houses it is now sometimes the custom to have a pipe, by way of speaking trumpet, to give orders from the upper apartments to the lower: by this mode of confining sound its volume may be carried to a very great distance; but beyond a certain extent the sound, losing articulation, would only convey alarm, not give directions.

Every city among the ancients had its watch-towers; and the castra stativa of the Romans, had always some spot, elevated either by nature or art, from whence signals were given to the troops cantoned or foraging in the neighbourhood. But I believe they had not arrived to greater refinement than that on seeing a certain signal they were immediately to repair to their appointed stations.

A beacon or bonfire made of the first inflammable materials that offered, as the most obvious, is perhaps the most ancient mode of general alarm; and by being previously concerted, the number or point where the fires appeared might have its particular intelligence affixed. The same observations may be referred to the throwing up of rockets, whose number or point from whence thrown may have its affixed signification.

Flags or ensigns with their various devices are of the earliest invention, especially at sea; where, from the first idea, which most probably was that of a vane to show the direction of the wind, they have been long adopted as the distinguishing mark of nations, and are now so neatly combined by the ingenuity of a great naval commander, that by his system every requisite order and question is received and answered by the most distant ships of a fleet.

To the adopting this or a similar mode in land service, the following are objections: That in the latter case, the variety of matter necessary to be conveyed, is so infinitely greater, that the combinations would become too complicated. And if the person for whom the information is intended should be in the direction of the wind, the flag would then present a straight line only, and at a little distance be scarce visible. The Romans were so well aware of this inconvenience of flags, that many of their standards were solid, and the name manipulus denotes the rudest of their modes, which was a truss of hay fixed on a pole.

But it does not seem that the moderns had thought of such a thing as a telegraph till the year 1663, when the marquis of Worcester, in his Century of Inventions, affirmed that he had discovered "a method by which, at a window, as far as eye can discover black from white, a man may hold discourse with his correspondent, without noise made or notice taken; being according to occasion given, or means afforded, *ex re nata*, and no need of provision beforehand; though much better if foreseen, and course taken by mutual consent of parties." This could be done only by means of a telegraph, which, in the next sentence, is declared to have been rendered so perfect, that by means of it the correspondence could be carried on "by night as well as by day, though as dark as pitch is black."

Dr. Hooke, whose genius as a mechanical inventor was perhaps never surpassed, delivered a "Discourse to the Royal Society, May 21st, 1684, showing a way how to communicate one's mind at great distances." In this discourse he asserts the possibility of conveying intelligence from one place to another, at the distance of 30, 40, 100, 120, &c, miles, "in as short a time as a man can write what he would have sent." He takes to his aid the then recent invention of the telescope, and explains the method by which characters exposed at one station, may be rendered visible at the others. He directs, "first, for the stations; if they be far distant, it will be necessary that they should be high, and lie exposed to the sky, that there be no higher hill or part of the earth beyond them, that may hinder the distinctness of the characters, that are to appear dark, the sky beyond them appearing white: by which means also the thick and vaporous air near the ground will be passed over and avoided." "Next, the height of the stations is advantageous, upon the account of the refractions or inflections of the air." "Next, in choosing of these stations, care must be taken, as near as may be, that there be no hill that interposes between them, that is almost high enough to touch the visual ray; because in such cases, the refraction of the air of that hill will be very apt to disturb the clear appearance of the object." "The next thing to be considered is, what telescopes will be necessary for such stations." "One of these telescopes must be fixed at each extreme station, and two of them in each intermediate; so that a man for each glass sitting and looking through them, may plainly discover what is done in the next adjoining station, and with his pen write down on paper the characters there exposed in their due order; so that there ought to be two persons at each extreme station, and three at each intermediate; so that, at the same time, intelligence may be conveyed forwards and backwards. Next, there must be certain times agreed on, when the correspondents are to expect; or else there must be set at the top of the pole, in the morning, the hour appointed by either of the correspondents, for acting that day; if the hour be appointed, pendulum clocks may adjust the moment of expectation and observing." "Next, there must be a convenient apparatus of characters, whereby to communicate any thing with great ease, distinctness, and secrecy. And there must be either day characters, or night characters." The day characters "may all be made of three slit deals:" the night characters "may be made with links, or other lights, disposed in a certain order." The Doctor invented 24 simple characters, each formed of right lines, for the letters of the alphabet; and several single characters, made up of semicircles, for whole sentences. He recommended that three very long masts or poles should be placed vertically, and joined at top by one strong horizontal beam; that a large screen should be placed at one of the upper corners of this frame, behind which all the deal-board characters should hang, and by the help of proper chords should quickly be drawn forwards to be exposed, and then drawn back again behind the screen. "By these means," says the Doctor, "all things may be made so convenient, that the same character may be seen at Paris within a minute after it has been exposed at London, and the like in proportion for greater distances; and that the characters may be exposed so quick after one another, that a composer shall not much exceed the exposer in swiftness." Among the cases of this contrivance, the inventor mentions these: "The first is for cities or towns besieged; and the second for ships upon the sea; in both which cases it may be practised with great certainty, security, and expedition."

The whole of Dr. Hooke's paper was published in Derham's collection of his Experiments and Observations; from which it appears that he had brought the telegraph to a state of far greater maturity and perfection than M. Amonton's, who attempted the same thing about the year 1702; and indeed to a state but little inferior to several which have been proposed during the last 20 years.

It was not however till the French revolution that the telegraph was applied to useful purposes. Whether M. Chappe, who is said to have invented the telegraph, first used by the French about the end of 1793, knew any thing of Hooke's or Amonton's invention or not, it is impossible to say; but his telegraph was constructed on principles nearly similar, the description of which here follows:

The following account of this curious instrument is copied from Barrere's report in the sitting of the French Convention of August 15, 1794.—"The new-invented telegraphic language of signals is an artful contrivance to transmit thoughts, in a peculiar way, from one distance to another, by means of machines, which are placed at different distances, of from 12 to 15 miles from one another, so that the expression reaches a very distant place in the space of a few minutes. Last year an experiment of this invention was tried in the presence of several Commissioners of the Convention. From the favourable report which the latter made of the efficacy of the contrivance, the Committee of Public Welfare tried every effort to establish, by this means, a correspondence between Paris and the frontier places, beginning with Lisle. Almost a whole twelvemonth has been spent in collecting the necessary instruments for the machines, and to teach the people employed how to use them. At present, the telegraphic language of signals is prepared in such a manner, that a correspondence may be conducted with Lisle upon every subject, and that every thing, nay even proper names, may be expressed; an answer may be received, and the correspondence thus be renewed several times a day. The machines are the invention of Citizen Chappe, and were constructed under his own eye; he also directs their establishment at Paris. They have the advantage of resisting the changes in the atmosphere, and the inclemencies of the seasons. The only thing which can interrupt their effect is, if the weather is so very bad and turbid that the objects and signals cannot be distinguished. By this invention, remoteness and distance almost disappear; and all the communications of correspondence are effected with the rapidity of the twinkling of an eye. The operations of government can be very much facilitated by this contrivance, and the unity of the republic can be the more consolidated by the speedy communication with all its parts. The greatest advantage which can be derived from this correspondence is, that, if one chooses, its object shall only be known to certain individuals, or to one individual alone, or to the extremities of any distance; so that the Committee of Public Welfare may now correspond with the representative of the people at Lisle without any other persons getting acquainted with the object of the correspondence. Hence it follows that, were Lisle even besieged, we should know every thing at Paris that might happen in that place, and could send thither the decrees of the Convention without the enemy's being able to discover or to prevent it."—The figure of the French machine, as given in some English prints, is represented in fig. 3, pl. 34.

Such is the account given of the French invention. Various improved contrivances have been since made in England, and a pamphlet has lately been published, giving an account of some of them, by the Rev. J. Gamble, under the title of Observations and Telegraphic Experiments.

As to the French machine, it is evident that to every angular change of the greater beam or of the lesser end arms, a different letter or figure may be annexed. But where the whole difference consists in the variation of the angle of the greater or lesser pieces, much error may be expected, from the inaccuracy either of the operator or the observer: besides other inconveniences arising from the great magnitude of the machinery.

Another idea is perfectly numerical; which is to raise and depress a flag or curtain a certain number of times for each letter, according to a previously concerted system: as, suppose one elevation to mean A, two to mean B, and so on through the alphabet. But in this case, the least inaccuracy in giving or noting the number changes the letter; and besides, the last letters of the alphabet would be a tedious operation.

Another method that has been proposed, is an ingenious combination of the magnetical experiment of Comus, and the telescopic micrometer. But as this is only an imperfect idea of Mr. Garnet's very ingenious machine, described in the latter part of this article, no farther notice need be taken of it here.

Mr. Gamble proposes one on a new idea of his own. The principle of it is simply that of a Venetian blind, or rather what are called the lever boards of a brewhouse, which, when horizontal, present so small a surface to the distant observer, as to be lost to his view, but are capable of being in an instant converted into a screen of a magnitude adapted to the required distance of vision.—Let AB and CD (fig. 4, pl. 34), two upright posts fixed in the ground, and joined by the braces BD and EF, be considered as the frame work for 9 lever boards working upon centres in EB and DF, and opening in three divisions by iron rods connected with each three of the lever boards.

Let *abcd* and *efgh* be two lesser frames fixed to the great one, having also three lever boards in each, and moving by iron rods, in the same manner as the others. If all these rods be brought so near the ground as to be in the management of the operator, he will then have five, of what may be called, keys to play on. Now as each of the bundles *iklmn* commands three lever boards, by raising any one of them, and fixing it in its place by a catch or hook, it will give a different appearance to the machine; and by the proper variation of these five movements, there will be more than 25 of what may be called mutations, in each of which the machine exhibits a different appearance, and to which any letter or figure may be annexed at pleasure.

Should it be required to give intelligence in more than one direction, the whole machine may be easily made to turn to different points on a strong centre, after the manner of a single-post windmill.—To use this machine by night, another frame must be connected with the back part of the telegraph, for raising five lamps, of different colours, behind the openings of the lever boards; these lamps by night answer for the openings by day. M. Gamble gives also particular directions for placing and using the machine, and for writing down the several figures or movements.

Mr. John Garnet's most simple and ingenious contrivance, is as follows. This is merely a bar or plank turning upon a centre, like the sail of a windmill, and being moved into any position, the distant observer turns the tube of a telescope into the same position, by bringing a fixed wire within it to coincide with or parallel to the bar, which is a thing extremely easy to do. The centre of motion of the bar has a small circle about it, with letters and figures around the circumference, and an index moving round with the bar, pointing to any letter or mark that the operator wishes to set the bar to, or to communicate to the observer. The eye end of the telescope without has a like index and circle, with the corresponding letters or other marks. The consequence is obvious: the telescope being turned about till its wire cover or become parallel to the bar, the index of the former necessarily points out the same letter or mark in its circle, as that of the latter; and the communication of sentiment is immediate and perfect. The use of this machine is so easy, that I have seen it put into the hands of two common labouring men, who had never seen it before, and they have immediately held a quick and distant conversation together.

The more particular description and figure of this machine, is as follows. ABDE (fig. 5, pl. 34), is the telegraph, on whose centre of gravity C, about which it revolves, is a fixed pin, which goes through a hole or socket in the firm upright post O, and on the opposite side of which is fixed an index CI. Concentric to C, on the same post, is fixed a wooden or brass circle, of 6 or 8 inches diameter, divided into 48 equal parts, 24 of which represent the letters of the alphabet, and between the letters, are numbers. So that the index, by means of the arm AB, may be moved to any letter or number. The length of the arm should be 2½ or 3 feet for every mile of distance. Two revolving lamps of different colours suspended occasionally at A and B, the ends of the arm, would serve equally at night.

Let *ss* (fig. 6, pl. 34) represent the transverse section of the outward tube of a telescope to its axis, and *xx* the like section of the sliding or adjusting tube, on which is fixed an index II. On the part of the outward tube next to the observer, there is fixed a circle of letters and numbers, similarly divided and situated to the circle in figure 5; then the index II, by means of the sliding or adjusting tube, may be turned to any letter or number.—Now there being a hair, or fine silver wire *fg*, fixed in the focus of the eye-glass, in the same direction as the index II; so that when the arm AB (fig. 5) of the telegraph is viewed at a distance through the telescope, the hair may be turned, by means of the sliding tube, to the same direction of the arm AB; then the index II (fig. 6) will point to the same letter or number on its own circle, as the index I (fig. 5) points to on the telegraphic circle.—If, instead of using the letters and numbers to form words at length, they be employed as signals, three motions of the arm will give above a hundred thousand different signals.

Two ingenious telegraphs have also been invented by Captain Pasley, of the Royal Engineers; descriptions of which are given in the Philosophical Magazine, Nos. 115 and 116.

It seems there are now in use in England, four grand lines of telegraphs, communicating with London: viz, to Portsmouth, to Plymouth, to Deal, and to Yarmouth. "There are 12 stations between London and Portsmouth, and 31 between London and Plymouth, of which 8 are part of the Portsmouth line, till they separate in the New Forest. The other chains extend from London to Yarmouth, formed by 19 stations, and from London to Deal, formed by 10 stations, making in the whole 64 separate telegraphs. Their distances average about 8 miles, yet some of them 12 or 14 miles; the distances being often increased by the want of commanding heights: in the Yarmouth line particularly they make a considerable detour northward.

After about 20 years' experience, they calculate on about 200 days in a year, on which signals can be transmitted throughout the day; about 60 others on which they pass only part of the day, or at particular stations; and about 100 days on which few of the stations can see the others. The powers of the stations in this respect are exceedingly various. Dead flats are found to be universally unfavourable. On the contrary, stations between hill and hill, looking across a valley, or series of valleys, are mostly clear; and water surfaces are found to produce fewer obscure days than land in any situation. The stillness of the morning and evening are found to be the most favourable times for observations. The least favourable period of the day is an hour or two before and after noon, particularly on dead levels, where the play of the sun's rays on the rising exhalations renders distant vision very obscure.

The transmission of a message from London to Portsmouth usually occupies about 15 minutes; but, by an experiment tried for the purpose, a single signal has been transmitted to Plymouth and back again in 3 minutes, which by the telegraph route was at least 500 miles. In this instance however notice had been given to make ready, and every captain was at his post to receive and return the signals. The speed was at the rate of 170 miles in a minute, or 3 miles per second, or 3 seconds at each station; a facility truly wonderful! The number of signals produced by the English telegraph is 63—by which they represent the ten digits, and the letters of the alphabet, with many generic words, and all the numbers expressed by the combination of the digits 63 ways. The signals are sufficiently various to express any 3 or 4 words in twice as many changes of the shutters.

The telescopes used are Dollond's achromatics; though a simple Galilean might serve equally well, or better. The field of this telescope is quite large enough; and, having but two lenses, one of which is a thin concave, it gives the object with more brighiness. It may seem strange too, that, to ease the operator, it was never contrived to exhibit the fixed spectrum on the principle of a portable camera, so that, without wearying the eye, the motion of the distant telegraph might have been exhibited on a plain surface, and seen with both eyes like as on the leaf of a book." Mo. Mag. vol. 39, pa. 202.

TELESCOPE, an optical instrument which serves for discovering and viewing distant objects, either directly by glasses, or by reflection, by means of specula, or mirrors. Accordingly,

Telescopes are either refracting or reflecting; the former consisting of different lenses, through which the objects are seen by rays refracted through them to the eye; and the latter of specula, from which the rays are reflected and passed to the eye. The lens or glass turned towards the object, is called the object-glass; and that next the eye, the eye-glass; and when the telescope consists of more than two lenses, all but that next the object are called eye-glasses. The latter consisting of different metallic speculums, finely polished and figured, so as to magnify the objects by reflection.

The invention of the telescope is one of the noblest and most useful these ages have to boast of: by means of it, the wonders of the heavens are discovered to us, and astronomy is brought to a degree of perfection which former ages could have no idea of. The discovery indeed was owing rather to chance than design; so that it is the good fortune of the discoverer, rather than his skill or ability, we are indebted to: on this account it concerns us the less to know, who it was that first hit upon this admirable invention. Be that as it may, it is certain it must have been casual, since the theory it depends upon was not then known.

John Baptista Porta, a Neapolitan, according to Wolfius, first made a telescope, which he infers from this passage in the Magia Naturalis of that author, printed in 1560: "If you do but know how to join the two (viz, the concave and convex glasses) rightly together, you will see both remote and near objects, much larger than they otherwise appear, and withal very distinct. In this we have been of good help to many of our friends, who either saw remote things dimly, or near ones confusedly; and have made them see every thing perfectly." But it is certain, that Porta did not understand his own invention, and therefore neither troubled himself to bring it to greater perfection, nor ever applied it to celestial observation. Besides, the account given by Porta of his concave and convex lenses, is so dark and indistinct, that Kepler, who examined it by desire of the emperor Rudolph, declared to that prince, that it was perfectly unintelligible.

Thirty years afterwards, or in 1590, a telescope 16 inches long was made, and presented to prince Maurice of Nassau, by a spectacle maker of Middleburg: but authors are divided about his name. Sirturus, in a treatise on the telescope, printed in 1618, will have it to be John Lippersheim: and Peter Borelli, in a volume expressly on the inventor of the telescope, published in 1655, states that it was Zacharias Jansen, or, as Wolfius writes it, Hansell. Now the invention of Lippersheim is fixed by some in the year 1609, and by others in 1605: Fontana, in his Novæ Observationes Cælestium et Terrestrium Rerum, printed at Naples in 1646, claims the invention in the year 1608. But Borelli's account of the discovery of telescopes is so circumstantial, and so well authenticated, as to render it very probable that Jansen was the original inventor.

In 1620, James Metius of Alcmaer, brother of Adrian Metius who was professor of mathematics at Franeker, came with Drebel to Middleburg, and there bought telescopes of Jansen's children, who had made them public; and yet this Adr. Metius has given his brother the honour of the invention, in which he is mistakenly followed by Descartes.

But none of these artificers made telescopes of above a foot and a half: Simon Marius in Germany, and Galileo in Italy, it is said, first made long ones fit for celestial observations; though, from the recently discovered astronomical papers of the celebrated Harriot, author of the Algebra, it appears that he must have employed telescopes in viewing the solar maculæ, which he did quite as early as they were observed by Galileo. Whether Harriot made his own telescopes, or whether he had them from Holland, does not appear; it seems however that Galileo's were made by himself; for Le Rossi relates, that Galileo, being then at Venice, was told of a kind of optic glass made in Holland, which brought objects nearer: upon which, setting himself to think how it should be, he ground two pieces of glass into form as well as he could, and fitted them to the two ends of an organ-pipe; and with these he showed at once all the wonders of the invention to the Venetians, on the top of the tower of St. Mark. The same author adds, that from this time Galileo devoted himself wholly to the improving and perfecting the telescope; and that he hence almost deserved all the honour usually done him, of being reputed the inventor of the instrument, and of its being from him called Galileo's tube. Galileo himself, in his Nuncius Sidereus, published in 1610, acknowledges that he first heard of the instrument from a German; and that, being merely informed of its effects, first by common report, and a few days after by letter from a French gentleman, James Badovere, at Paris, he himself discovered the construction by considering the nature of refraction. He adds, in his Sagiatore, that he was at Venice when he heard of the effects of prince Maurice's instrument, but nothing of its construction; that the first night after his return to Padua, he solved the problem, and made his instrument the next day, and soon after presented it to the Doge of Venice, who, in honour of his grand invention, gave him the ducal letters, which settled him for life in his lectureship, at Padua, and doubled his salary, which then became treble of what any of his predecessors had enjoyed before. And thus Galileo may be considered as an inventor of the telescope, though not the first inventor.

F. Mabillon indeed relates, in his travels through Italy, that in a monastery of his own order, he saw a manuscript copy of the works of Commestor, written by one Conradus, who lived in the 13th century; in the 3d page of which was seen a portrait of Ptolemy, viewing the stars through a tube of 4 joints or draws: but Mabillon does not say that the tube had glasses in it. Indeed it is more than probable, that such tubes were then used for no other purpose but to defend and direct the sight, or to render it more distinct, by singling out the particular object looked at, and shutting out all the foreign rays reflected from others, whose proximity might have rendered the image less precise. And this conjecture is verified by experience; for we have often observed that without a tube, by only looking through the hand, or even the fingers, or a pin-hole in a paper, the objects appear more clear and distinct than otherwise. Be this as it may, it is certain that the optical principles, on which telescopes are founded, are contained in Euclid, and were well known to the ancient geometricians; and it has been for want of attention to them, that the world was so long without that admirable invention; as doubtless there are many others lying hid in the same principles, only waiting for reflection or accident to bring them forth.

To the foregoing abstract of the history of the invention of the telescope, it may be proper to add some particulars relating to the claims of our own celebrated countryman, friar Bacon, who died in 1294. Mr. W. Molyneux, in his Dioptrica Nova, pa. 256, declares his opinion, that Bacon did perfectly well understand all kinds of optic glasses, and knew likewise the method of combining them, so as to compose some such instrument as our telescope: and his son, Samuel Molyneux, asserts more positively, that the invention of telescopes, in its first original, was certainly put in practice by an Englishman, friar Bacon; though its first application to astronomical purposes may probably be ascribed to Galileo. The passages to which Mr. Molyneux refers, in support of Bacon's claims, occur in his Opus Majus, pa. 348 and 357 of Jebb's edit. 1773. The first is as follows: Si vero non sint corpora plana, per quæ visus videt, sed sphæria, tunc est magna diversitas; nam vel concavitas corporis est versus oculum vel convexitas: whence it is inferred, that he knew what a concave and a convex glass was. The second is comprised in a whole chapter, where he says, De visione fracta majora sunt; nam de facili patet per canones supra dictos, quod maxima possunt apparere minima, et e contra, et longe distantia videbuntur propinquissime, et e converso. Nam possumus sic figurare perspicua, et taliter ea ordinare respectu nostri visus et rerum, quod frangentur radii, et flectentur quorsumcunque voluerimus, ut sub quocunque angulo voluerimus, videbimus rem prope vel longe, &c. Sic etiam faceremus solem et lunam et stellas descendere secundum apparentiam hic inferius, &c: that is, Greater things than these may be performed by refracted vision; for it is easy to understand by the canons above mentioned, that the greatest objects may appear exceeding small, and the contrary; also that the most remote objects may appear just at hand, and the converse; for we can give such figures to transparent bodies, and dispose them in such order with respect to the eye and the objects, that the rays shall be refracted and bent towards any place we please; so that we shall see the object near at hand or at a distance, under any angle we please, &c. So that thus the sun, moon, and stars may be made to descend hither in appearance, &c. Mr. Molyneux has also cited another passage out of Bacon's Epistle ad Parisiensem, of the Secrets of Art and Nature, cap. 5, to this purpose, Possunt etiam sic figurari perspicua, ut longissime posita appareant propinqua, et è contrario; ita quod ex incredibili distantia legeremus literas minutissimas, et numeraremus res quantumquo parvas, et stellas faceremus apparere quo vellemus: that is, Glasses, or diaphanous bodies may be so formed, that the most remote objects may appear just at hand, and the contrary; so that we may read the smallest letters at an incredible distance, and may number things though never so small, and may make the stars also appear as near as we please.

Moreover, Doctor Jebb, in the dedication of his edition of the Opus Majus, produces a passage from a manuscript, to show that Bacon actually applied telescopes to astronomical purposes: Sed longe magis quam hæc, says he, oporteret homines haberi, qui bene, immo optime, scirent perspectivam et instrumenta ejus—quia instrumenta astronomia non vadunt nisi per visionem secundum leges istius scientiæ.

From these passages, it is not unreasonable to conclude, that Bacon had actually combined glasses so as to have produced the effects which he mentions, though he did not complete the construction of telescopes. Dr. Smith, however, to whose judgment particular deference is due, is of opinion that the celebrated friar wrote hypothetically, without having made any actual trial of the things he mentions: to which purpose he observes, that this author does not assert one single trial or observation upon the sun or moon, or any thing else, though he mentions them both: on the other hand, he imagines some effects of telescopes that cannot possibly be performed by them. He adds, that persons unexperienced in looking through telescopes expect, in viewing any object, as for instance the face of a man, at the distance of one hundred yards, through a telescope that magnifies one hundred times, that it will appear much larger than when they are close to it: this he is satisfied was Bacon's notion of the matter; and hence he concludes that he had never looked through a telescope.

It is remarkable that there is a passage in Thomas Digge's Stratioticos, pa. 359, where he affirms that his father, Leonard Digges, among other curious practices, had a method of discovering, by perspective glasses set at due angles, all objects pretty far distant that the sun shone upon, which lay in the country round about; and that this was by the help of a manuscript book of Roger Bacon of Oxford, who he conceived was the only man besides his father (since Archimedes) who knew it. This is the more remarkable, because the Stratioticos was first printed in 1579, more than 30 years before Metius or Galileo made their discovery of those glasses; and therefore it has hence been thought that Roger Bacon was the first inventor of telescopes, and Leonard Digges the next reviser of them. But from what Thomas Digges says of this matter, it would seem that the instrument of Bacon, and of his father, was something of the nature of a camera obscura, or, if it were a telescope, that it was of the reflecting kind; though the term perspective glass seems to favour a contrary opinion.

There is also another passage to the same effect in the preface to the Pantometria of Leonard Digges, but published by his son Thomas Digges, some time before the Stratioticos, and a second time in the year 1591. The passage runs thus: "My father by his continuall painfull practises, assisted with demonstrations mathematical, was able, and sundrie times hath by Proportional Glasses duely situate in convenient angles, not only discovered things farre off, read letters, numbered peeces of money with the very coyne and superscription thereof, cast by some of his freends of purpose upon downes in open fields, but also seven myles off declared what hath beene doone at that instant in private places: He hath also sundrie times by the sunne beames fixed (should be fired) powder, and dischargde ordinance halfe a mile and more distante," &c.

But to whomsoever we ascribe the honour of first inventing the telescope, the rationale of this admirable instrument, depending on the refraction of light in passing through mediums of different forms, was first explained by the celebrated Kepler, who also pointed out methods of constructing others, of superior powers, and more commodious application, than that first used: though something of the same kind, it is said, was also done by Maurolycus, whose treatise De Lumine et Umbra was published in 1575.

The Principal Effects of TELESCOPES, depend upon this plain maxim, viz, that objects appear larger in proportion to the angles which they subtend at the eye; and the effect is the same, whether the pencils of rays, by which objects are made visible to us, come directly from the objects themselves, or from any place nearer to the eye, where they may have been united, so as to form an image of the object; because they issue again from those points in certain directions, in the same manner as they did from the corresponding points in the objects themselves. In fact therefore, all that is effected by a telescope, is first to make such an image of a distant object, by means of a lens or mirror, and then to give the eye some assistance for viewing that image as near as possible; so that the angle, which it shall subtend at the eye, may be very large, compared with the angle which the object itself would subtend in the same situation. This is done by means of an eye-glass, which so refracts the pencils of rays, as that they may afterwards be brought to their several foci, by the natural humours of the eye. But if the eye had been so formed as to be able to see the image, with sufficient distinctness, at the same distance, without an eye-glass, it would appear to him as much magnified, as it does to another person who makes use of a glass for that purpose, though he would not in all cases have so large a field of view.

Though no image be actually formed by the foci of the pencil without the eye, yet if, by the help of an eye-glass, the pencils of rays shall enter the pupil, just as they would have done from any place without the eye, the visual angle will be the same as if an image had been actually formed in that place. Priestley's History of Light &c, pa. 69, &c.

As to the Grinding of Telescopic Glasses, the first persons who distinguished themselves in that way, were two Italians, Eustachio Divini at Rome, and Campani at Bologna, whose fame was much superior to that of Divini, or that of any other person of his time; though Divini himself pretended, that in all the trials that were made with their glasses, his of a great focal distance performed better than those of Campani, and that his rival was not willing to try them fairly, viz, with equal eye-glasses. It is however generally supposed, that Campani really excelled Divini, both in the goodness and focal length of his object-glasses.

It was with Campani's Telescopes that Cassini discovered the nearest satellites of Saturn. They were made at the express desire of Lewis XIV, and were of 86, 100, and 136, Paris feet focal length.

Campani's laboratory was purchased, after his death, by pope Benedict XIV, who made a present of it to the academy at Bologna called the Institute; and by the account which Fougeroux has given, we learn that (except a machine which Campani constructed, to work the basons on which he ground his glasses) the goodness of his lenses depended on the clearness of his glass, his Venetian tripoli, the paper with which he polished his glasses, and his great skill and address as a workman. It does not appear that he made many lenses of a very great focal distance. Accordingly Dr. Hooke, who probably speaks with the partiality of an Englishman, says that some glasses, made by Divini and Campani, of 36 and 50 feet focal distance, did not excel Telescopes of 12 or 15 feet made in England. He adds, that sir Paul Neile made telescopes of 36 feet, pretty good; and one of 50, but not of proportionable goodness.

Afterwards, Mr. Reive first, and then Mr. Cox, who were the most celebrated in England, as grinders of optic glasses, made some good telescopes of 50 and 60 feet focal distance; and Mr. Cox made one of 100, but how good Dr. Hooke could not assert. Borelli also in Italy made object-glasses of a great focal length, one of which he presented to the Royal Society. But, with respect to the focal length of telescopes, these and all others were far exceeded by those of Auzout, who made one object-glass of 600 feet focus; but he was never able to manage it, so as to make it useful. And Hartsoeker, it is said, made some of a still greater focal length. Philos. Trans. Abr. vol. i, pa. 666. Hooke's Exper. by Derham, pa. 261. Priestley, pa. 211. See GRINDING.

Telescopes are of several kinds, distinguished by the number and form of their lenses, or glasses, and denominated from their particular uses &c: such are the Terrestrial or land Telescope, the Celestial or astronomical Telescope; to which may be added, the Galilean or Dutch Telescope, the Reflecting Telescope, the Refracting Telescope, the Aërial Telescope, Achromatic Telescope, &c.

Galileo's, or the Dutch telescope, is one consisting of a convex object-glass, and a concave eye-glass.

This is the most ancient form of any, being the only kind made by the inventors, Galileo, &c, or known, before Huygens. The first telescope, constructed by Galileo, magnified only 3 times; but he soon made another, which magnified 18 times: and afterwards, with great trouble and expence, he constructed one that magnified 33 times; with which he discovered the satellites of Jupiter, and the spots of the sun. The construction, properties, &c, of it, are as follow:

Construction of Galileo's, or the *Dutch* TELESCOPE.—In a tube prepared for the purpose, at one end is fitted a convex object lens, either a plain convex, or convex on both sides, but a segment of a very large sphere: at the other end is fitted an eye-glass, concave on both sides, and the segment of a less sphere, so disposed as to be at the distance of the virtual focus before the image of the convex lens.

Let AB (fig. 10, pl. 28) be a distant object, from every point of which pencils of rays issue, and falling on the convex glass DE, tend to their foci at FSG. But a concave lens HI (the focus of which is at FG) being interposed, the converging rays of each pencil are made parallel when they reach the pupil; so that by the refractive humours of the eye, they can easily be brought to a focus on the retina at PRQ. Also the pencils themselves diverging, as if they came from X, MXO is the angle under which the image will appear, which is much larger than the angle under which the object itself would have appeared. Such then is the telescope that was at first discovered and used by philosophers: the great inconvenience of which is, that the field of view, which depends, not on the breadth of the eye-glass, as in the astronomical telescope, but on the breadth of the pupil of the eye, is exceedingly small: for since the pencils of the rays enter the eye very much diverging from one another, but few of them can be intercepted by the pupil; and this inconvenience increases with the magnifying power of the telescope, so that philosophers may now well wonder at the patience and address with which Galileo and others, with such an instrument, made the discoveries they did. And yet no other telescope was thought of for many years after the discovery. Descartes, who wrote 30 years after, mentions no other as actually constructed, though Kepler had suggested some. Hence,

1. In an instrument thus framed, all people, except myopes, or short-sighted persons, must see objects distinctly in an erect situation, and increased in the ratio of the distance of the virtual focus of the eye-glass, to the distance of the focus of the object-glass.

2. But for myopes to see objects distinctly through such an instrument, the eye-glass must be set nearer the object-glass, so that the rays of each pencil may not emerge parallel, but may fall diverging upon the eye; in which case the apparent magnitude will be altered a little, though scarce sensibly.

3. Since the focus of a plano-convex object lens, and the virtual focus of a plano-concave eye-lens, are at the distance of the diameter; and the focus of an object-glass convex on both sides, and the virtual focus of an eye-glass concave on both sides, are at the distance of a semi-diameter; if the object-glass be plano-convex, and the eye-glass plano-concave, the telescope will increase the diameter of the object, in the ratio of the diameter of the concavity to that of the convexity: if the object-glass be convex on both sides, and the eye-glass concave on both sides, it will magnify in the ratio of the semidiameter of the concavity to that of the convexity: if the object-glass be plano-convex, and the eye-glass concave on both sides, the semidiameter of the object will be increased in the ratio of the diameter of the convexity to the semidiameter of the concavity: and lastly, if the object-glass be convex on both sides, and the eye-glass plano-concave, the increase will be in the ratio of the diameter of the concavity to the semidiameter of the convexity.

4. Since the ratio of the semidiameters is the same as that of the diameters, telescopes magnify the object in the same manner, whether the object-glass be plano-convex, and the eye-glass plano-concave; or whether the one be convex on both sides, and the other concave on both.

5. Since the semidiameter of the concavity has a less ratio to the diameter of the convexity than its diameter has, a telescope magnifies more if the object-glass be plano-convex, than if it be convex on both sides. The case is the same if the eye-glass be concave on both sides, and not plano-concave.

6. The greater the diameter of the object-glass, and the less that of the eye-glass, the less ratio has the diameter of the object, viewed with the naked eye, to its semidiameter when viewed with a telescope, and consequently the more is the object magnified by it.

7. Since a telescope exhibits so much a less part of the object, as it increases its diameter more, for this reason, mathematicians were determined to look out for another telescope, after having clearly found the imperfection of the first, which was discovered by chance. Nor were their endeavours vain, as appears from the astronomical telescope described below.

If the semidiameter of the eye-glass have too small a ratio to that of the object-glass, an object through the telescope will not appear sufficiently clear, because the great divergency of the rays will occasion the several pencils representing the several points of the object on the retina, to consist of too few rays.

It is also found that equal object-lenses will not bear the same eye-lenses, if they be differently transparent, or if there be a difference in their polish; a less transparent object-glass, or one less accurately ground, requiring a more spherical eye-glass than another more transparent, &c.

Hevelius recommends an object-glass convex on both sides, whose diameter is 4 feet; and an eye-glass concave on both sides, whose diameter is 4½ tenths of a foot. An object-glass, equally convex on both sides, whose diameter is 5 feet, he observes, will require an eye-glass of 5½ tenths; and adds, that the same eye-glass will also serve an object-glass of 8 or 10 feet.

Hence, as the distance between the object-glass and eye-glass is the difference between the distance of the virtual focus of the eye-glass, and the distance of the focus of the object-glass; the length of the telescope is had by subtracting that from this. That is, the length of the telescope is the difference between the diameters of the object-glass and eye-glass, if the former be plano-convex, and the latter plano-concave; or the difference between the semidiameters of the object-glass and eye-glass, if the former be convex on both sides, and the latter concave on both; or the difference between the semidiameter of the object-glass and the diameter of the eye-glass, if the former be convex on both sides, and the latter plano-concave; or lastly the difference between the diameter of the object-glass and the semidiameter of the eye-glass, if the former be plano-convex, and the latter concave on both sides. Thus, for instance, if the diameter of an object-glass, convex on both sides, be 4 feet, and that of an eye-glass, concave on both sides, be 4½ tenths of a foot; then the length of the telescope will be 1 foot and 7¾ tenths.

Astronomical TELESCOPE; this is one that consists of an object-glass, and an eye-glass, both convex. It is so called from being wholly used in astronomical observations.

It was Kepler who first suggested the idea of this telescope: having explained the rationale, and pointed out the advantages of it in his Catoptrics, in 1611. But the first person who actually made an instrument of this construction, was father Scheiner, who has given a description of it in his Rosa Ursina, published in 1630. To this purpose he says, if you insert two similar convex lenses in a tube, and place your eye at a convenient distance, you will see all terrestrial objects, inverted indeed, but magnified and very distinct, with a considerable extent of view. He afterwards subjoined an account of a telescope of a different construction, with two convex eye-glasses, which again reverses the images, and makes them appear in their natural position. Father Reita however soon after proposed a better construction, using three eye-glasses instead of two.

Construction of the Astronomical TELESCOPE. The tube being prepared, an object-glass, either plano-convex, or convex on both sides, but a segment of a large sphere, is fitted in at one end; and an eye-glass, convex on both sides, which is the segment of a small sphere, is fitted to the other end; at the common distance of the foci.

Thus the rays of each pencil issuing from every point of the object ABC, (fig. 3, pl. 36) passing through the object-glass DEF, become converging, and meet in their foci at IHG, where an image of the object will be formed. If then another convex lens KM, of a shorter focal length, be so placed, as that its focus shall be in IHG, the rays of each pencil, after passing through it, will become nearly parallel, so as to meet upon the retina, and form an enlarged image of the object at RST. If the process of the rays be traced, it will presently be perceived that this image must be inverted. For the pencil that issues from A, has its focus in G, and again in R, on the same side with A. But as there is always one inversion in simple vision, this want of inversion produces just the reverse of the natural appearance. The field of view in this telescope will be large, because all the pencils that can be received on the surface of the lens KM, being converging after passing through it, are thrown into the pupil of the eye, placed in the common intersection of the pencils at P.

Theory of the Astronomical TELESCOPE.—An eye placed near the focus of the eye-glass, of such a telescope, will see objects distinctly, but inverted, and magnified in the ratio of the distance of the focus of the eye-glass to the distance of the focus of the object-glass.

If the sphere of concavity in the eye-glass of the Galilean telescope, be equal to the sphere of convexity in the eye-glass of another telescope, their magnifying power will be the same. The concave glass however being placed between the object-glass and its focus, the Galilean telescope will be shorter than the other, by twice the focal length of the eye-glass. Consequently, if the length of the telescopes be the same, the Galilean will have the greater magnifying power. Vision is also more distinct in these telescopes, owing in part perhaps to there being no intermediate image between the eye and the object. Besides, the eye-glass being very thin in the centre, the rays will be less liable to be distorted by irregularities in the substance of the glass. Whatever be the cause, we can sometimes see Jupiter's satellites very clearly in a Galilean telescope, of 20 inches or 2 feet long, when one of 4 or 5 feet, of the common sort, will hardly make them visible.

As the astronomical telescope exhibits objects inverted, it serves commodiously enough for observing the stars, as it is not material whether they be seen erect or inverted; but for terrestrial objects it is much less proper, as the inverting often prevents them from being known. But if a plane well-polished metal speculum, of an oval figure, and about an inch long, and inclined to the axis in an angle of 45°, be placed behind the eye-glass; then the eye, conveniently placed, will see the image, hence reflected, in the same magnitude as before, but in an erect situation; and therefore, by the addition of such a speculum, the astronomical telescope is thus rendered fit to observe terrestrial objects.

Since the focus of the glass, convex on both sides, is distant from the glass itself a semidiameter, and that of a plano-convex glass, a diameter; if the object-glass be convex on both sides, the telescope will magnify the semidiameter of the object, in the ratio of the diameter of the eye-glass to the diameter of the object-glass; but if the object-glass be a plano-convex, in the ratio of the semidiameter of the eye-glass to the diameter of the object-glass. And therefore a telescope magnifies more if the object-glass be a plano-convex, than if convex on both sides. And for the same reason, a telescope magnifies more when the eye-glass is convex on both sides, than when it is plano-convex.

A telescope magnifies the more, as the object-glass is a segment of a great sphere, and the eye-glass of a less one. And yet the eye-glass must not be too small in respect of the object-glass; for if it be, it will not refract rays enough to the eye from each point of the object; nor will it separate sufficiently those that come from different points; by which means the vision will be rendered obscure and confused.—Dechales observes, that an object-lens of 2½ feet will require an eye-glass of 1½ tenth of a foot; and an object-glass of 8 or 10 feet, an eye-glass of 4 tenths; in which he is confirmed by Eustachio Divini.

To shorten the Astronomical TELESCOPE; that is, to construct a telescope so, as that, though shorter than the common one, it shall magnify as much.

Having provided a drawing tube, fit in it an object-lens EO which is a segment of a moderate sphere; let the first

eye-glass BD be concave on both sides, and so placed in the tube, as that the focus of the object-glass A may be behind it, but nearer to the centre of the concavity G: then will the image be thrown in Q, so as that GA : GI : : AB : QI. Lastly, fit in another object-glass, convex on both sides, and a segment of a smaller sphere, so as that its focus may be in Q.

This telescope will magnify the diameter of the object more than if the object-glass were to represent its image at the same distance EQ; and consequently a shorter telescope, constructed this way, is equivalent to a longer in the common way. See Wolfius Elem. Math. vol. 3, pa. 245.

Sir Isaac Newton furnishes us with another method of constructing the telescope, in his catoptrical or reflecting telescope, the construction of which is given below. See *Achromatic* TELESCOPE.

Aërial TELESCOPE, a kind of astronomical telescope, the lenses of which are used without a tube. In strictness however, the aërial telescope is rather a particular manner of mounting and managing long telescopes for celestial observation in the night-time, by which the trouble of long unwieldy tubes is saved, than a particular kind of telescope; and the contrivance was one of Huygens's. This invention was successfully practised by the inventor himself and others, particularly with us by Mr. Pound and Dr. Bradley, with an object-glass of 123 feet focal distance, and an apparatus belonging to it, made and presented by Huygens to the Royal Society, and described in his Astroscopia Compendiaria Tubi Optici Molimine Liberata, printed at the Hague in 1684.

The principal parts of this telescope may be comprehended from a view of fig. 4, pl. 36, where AB is a long pole, or a mast, or a high tree, &c, in a groove of which slides a piece that carries a small tube LK in which is fixed an object-glass; which tube is connected by a fine line, with another small tube oq, which contains the eye-glass, &c.

Lahire contrived a little machine for managing the object-glass, which is described Mem. de l'Acad. 1715. See Smith's Optics, book 3, chap. 10.

Hartsoeker, who made telescopes of a very considerable focal length, contrived a method of using them without a tube, by fixing them to the top of a tree, a high wall, or the roof of a house. Miscel. Berol. vol. 1, pa. 261.

Huygens's great telescope, with which Saturn's true face, and one of his satellites were first discovered, consists of an object-glass of 12 feet, and an eye-glass of a little more than 3 inches; though he frequently used a telescope of 23 feet long, with two eye-glasses joined together, each 1½ inch diameter; so that the two were equal to one of 3 inches.

The same author observes, that an object-glass of 30 feet requires an eye-glass of $3\frac{3}{10}$ inches; and has given a table of proportions for constructing astronomical telescopes, an abridgement of which is as follows:

Distance of Focus of Object-Glasses.	Diameter of Aperture.	Distance of Focus of Eye-Glass.	Power or Magnitude of Diameter.
Feet.	Inches and Decim.	Inches and Decim.	
1	0·55	0·61	20
2	0·77	0·85	28
3	0·95	1·05	34
4	1·09	1·20	40
5	1·23	1·35	44
6	1·34	1·47	49
7	1·45	1·60	53
8	1·55	1·71	56
9	1·64	1·80	60
10	1·73	1·90	63
15	2·12	2·33	77
20	2·45	2·70	89
25	2·74	3·01	100
30	3·00	3·30	109
40	3·46	3·81	120
50	3·87	4·26	141
60	4·24	4·66	154
70	4·58	5·04	166
80	4·90	5·39	178
90	5·20	5·72	189
100	5·49	6·03	200
120	6·00	6·60	218
140	6·48	7·12	235
160	6·93	7·62	252
180	7·35	8·09	267
200	7·75	8·53	281
220	8·12	8·93	295
240	8·48	9·33	308
260	8·83	9·71	321
280	9·16	10·08	333
300	9·49	10·44	345
400	10·95	12·05	400
500	12·25	13·47	445
600	13·42	14·76	488

Dr. Smith (Rem. pa. 78) observes, that the magnifying powers of this table are not so great as Huygens himself intended, or as the best object-glasses now made will admit of. For the author, in his Astroscopia Compendiaria, mentions an object-glass of 34 feet focal distance, which, in astronomical observations, bore an eye-glass of 2¼ inches focal distance, and consequently magnified 163 times. According to this standard, a telescope of 35 feet ought to magnify 166 times, and of 1 foot 28 times; whereas the table allows but 118 times to the former, and but 20 to the latter. Now $\frac{166}{118}$ or $\frac{28}{20}$ = 1·4; by which if we multiply the numbers in the given column of magnifying powers, we shall gain a new column, showing how much those object-glasses ought to magnify if wrought up to the perfection of this standard.

The new apertures and eye-glasses must also be taken in the same proportions to each other, as the old ones have in the table; or the eye-glasses may be found by dividing the length of each telescope by its magnifying power. And thus a new table may be easily made for this or any other more perfect standard when offered.

The rule for computing this table depends on the following theorem, viz, that in refracting telescopes of different lengths, a given object will appear equally bright and equally distinct, when their linear apertures and the focal distances of their eye-glasses are severally in a subduplicate ratio of their lengths, or focal distances of their object-glasses; and then also the breadth of their apertures will be in the subduplicate ratio of their lengths.

The rule is this: Multiply the number of feet in the focal distance of any proposed object-glass by 3000, and the square-root of the product will give the breadth of its aperture in centesms, or 100th parts of an inch; that is, $\sqrt{3000F}$ is the breadth of the aperture in centesms of an inch, where F is the focal distance of the object-glass in feet. Also, the same breadth of the aperture increased by the 10th part of itself, gives the focal distance of the eye-glass in centesms of an inch. And the magnifying powers are as the breadths of the apertures.

If, in different telescopes, the ratio between the object-glass and eye-glass be the same, the object will be magnified the same in both. Hence some may conclude the making of large telescopes a needless trouble. But it must be remembered, that an eye-glass may be in a less ratio to a greater object-glass than to a smaller: thus, for example, in Huygens's telescope of 25 feet, the eye-glass is 3 inches: now, keeping this proportion in a telescope of 50 feet, the eye-glass should be 6 inches; but the table shows that 4¼ are sufficient. Hence, from the same table it appears, that a telescope of 50 feet magnifies in the ratio of 1 to 141; whereas that of 25 feet only magnifies in the ratio of 1 to 100.

Since the distance of the lens is equal to the aggregate of the distances of the foci of the object and eye-glasses; and since the focus of a glass convex on each side is a semidiameter's distance from the lens, and that of a plano-convex at a diameter's distance from the same; the length of a telescope is equal to the aggregate of the semidiameters of the lenses, if the object-glass be convex on both sides; and to the sum of the semidiameter of the eye-glass and the whole diameter of the object-glass, if the object-glass be a plano-convex.

But as the diameter of the eye-glass is very small in respect of that of the object-glass, the length of the telescope is usually estimated from the distance of the object-glass; i. e. from its semidiameter if it be convex on both sides, or its whole diameter if plano-convex. Thus, a telescope is said to be 12 feet, if the semidiameter of the object-glass, convex on both sides, be 12 feet, &c.

Since myopes see near objects best; for them, the eye-glass is to be removed nearer to the object-glass, that the rays refracted through it may be the more diverging.

To take in the larger field at one view, some make use of two eye-glasses, the foremost of which is a segment of a larger sphere than that behind; to this it must be added, that if two lenses be joined immediately together, so as the one may touch the other, the focus is removed to double the distance which that of one of them would be at.

Land TELESCOPE, or *Day* TELESCOPE, is one adapted for viewing objects in the day-time, on or about the earth. This contains more than two lenses, usually it has a convex object-glass, and three convex eye-glasses; exhibiting objects erect, yet different from that of Galileo.

In this telescope, after the rays have passed the first eye-glass HI (fig. 3, pl. 38), as in the former construction, instead of being there received by the eye, they pass on to another equally convex lens, situated at twice its focal distance from the other, so that the rays of each pencil, being parallel in that whole interval, those pencils cross one another in the common focus, and the rays constituting them are transmitted parallel to the second eye-glass LM; after which, the rays of each pencil converge to other foci at NO, where a second image of the object is formed, but inverted with respect to the former image in EF. This image then being viewed by a third eye-glass QR, is painted upon the retina at XYZ, exactly as before, only in a contrary position.

Father Reita was the author of this construction; which is effected by fitting in at one end of a tube an object-glass, which is either convex on both sides, or plano-convex, and a segment of a large sphere; to this add three eye-glasses, all convex on both sides, and segments of equal spheres; disposing them in such a manner as that the distance between any two may be the aggregate of the distances of their foci. Then will an eye applied to the last lens, at the distance of its focus, see objects very distinctly, erect, and magnified in the ratio of the distance of the focus of one eye-glass, to the distance of the focus of the object-glass.

Hence, 1. An astronomical telescope is easily converted into a land telescope, by using three eye-glasses for one; and the land telescope, on the contrary, into an astronomical one, by taking away two eye-glasses, the faculty of magnifying still remaining the same.

2. Since the distance of the eye-glasses is very small, the length of the telescope is much the same as if you only used one.

3. The length of the telescope is found by adding five times the semidiameter of the eye-glasses, to the diameter of the object-glass when this is a plano-convex, or to its semidiameter when convex on both sides.

Huygens first observed, both in the astronomical and land telescope, that it contributes considerably to the perfection of the instrument, to have a ring of wood or metal, with an aperture, a little less than the breadth of the eye-glass, fixed in the place where the image is found to radiate upon the lens next the eye; by means of which, the colours, which are apt to disturb the clearness and distinctness of the object, are prevented, and the whole compass taken in at one view, perfectly defined.

Some make land telescopes of three lenses, which yet represent objects erect, and magnified as much as the former. But such telescopes are subject to very great inconveniences, both as the objects in them are tinged with false colours, and as they are distorted about the margin.

Others again use five lenses, and even more; but as some parts of the rays are intercepted in passing every lens, objects are thus exhibited very dimly.

Telescopes of this kind, longer than 20 feet, will be of hardly any use in observing terrestrial objects, on account of the continual motion of the particles of the atmosphere, which these powerful telescopes render visible, and give a tremulous motion to the objects themselves.

The great length of dioptric telescopes, adapted to any important astronomical purpose, rendered them extremely inconvenient for use; as it was necessary to increase their length in no less a proportion than the duplicate of the increase of their magnifying power: so that, in order to magnify twice as much as before, with the same light and distinctness, the telescope required to be lengthened 4 times; and to magnify thrice as much, 9 times the length, and so on. This unwieldiness of refracting telescopes, possessing any considerable magnifying power, was one cause, why the attention of astronomers, &c, was directed to the discovery and construction of reflecting telescopes. And indeed a refracting telescope, even of 1000 feet focus, supposing it possible to make use of such an instrument, could not be made to magnify with distinctness more than 1000 times; whereas a reflecting telescope, of 9 or 10 feet, will magnify 12 hundred times. The perfection of refracting telescopes, it is well known, is very much limited by the aberration of the rays of light from the geometrical focus: and this arises from two different causes, viz, from the different degrees of refrangibility of light, and from the sphericity, which is not of a proper curvature for collecting the rays in a single point. Till the time of Newton, no optician had imagined that the object-glasses of telescopes were subject to any other error besides that which arose from their spherical figure, and therefore all their efforts were directed to the construction of them, with other kinds of curvature: but that author had no sooner demonstrated the different refrangibility of the rays of light, than he discovered in this circumstance a new and a much greater cause of error in telescopes. Thus, since the pencils of each kind of light have their foci in different places, some nearer and some farther from the lens, it is evident that the whole beam cannot be brought into any one point, but that it will be drawn the nearest to a point in the middle place between the focus of the most and least refrangible rays; so that the focus will be a circular space of a considerable diameter. Newton shows that this space is about the 55th part of the aperture of the telescope, and that the focus of the most refrangible rays is nearer to the object-glass than the focus of the least refrangible ones, by about the 27½ part of the distance between the object-glass, and the focus of the mean refrangible rays. But he says, that if the rays flow from a lucid point, as far from the lens on one side as their foci are on the other, the focus of the most refrangible rays will be nearer to the lens than that of the least refrangible, by more than the 14th part of the whole distance. Hence, he concludes, that if all the rays of light were equally refrangible, the error in telescopes, arising from the sphericity of the glass, would be many hundred times less than it now is; because the error arising from the spherical form of the glass, is to that arising from the different refrangibility of the rays of light, as 1 to 5449. See ABERRATION.

Upon the whole he observes, that it is a wonder that telescopes represent objects so distinctly as they do. The reason of which is, that the dispersed rays are not scattered uniformly over all the circular space above-mentioned, but are infinitely more dense in the centre than in any other part of the circle; and that in the way from the centre to the circumference they grow continually rarer and rarer, till at the circumference they become infinitely rare: for which reason, these dispersed rays are not copious enough to be visible, except about the centre of the circle. He also mentions another argument, to prove, that the different refrangibility of the rays of light is the true cause of the imperfection of telescopes. For the dispersions of the rays arising from the spherical figures of object-glasses, are as the cubes of their apertures; and therefore, to cause telescopes of different lengths to magnify with equal distinctness, the apertures of the object-glasses, and the charges or magnifying powers ought to be as the cubes of the square roots of their lengths, which does not answer to experience. But the errors of the rays, arising from the different refrangibility, are as the apertures of the object-glasses; and thence, to make telescopes of different lengths to magnify with equal distinctness, their apertures and charges ought to be as the square roots of their lengths; and this answers to experience.

Were it not for this different refrangibility of the rays, telescopes might be brought to a sufficient degree of perfection, by composing the object-glass of two glasses with water between them. For by this means, the refractions on the concave sides of the glasses will very much correct the errors of the refractions on the convex sides, so far as they arise from their spherical figure; but on account of the different refrangibility of different kinds of rays, Newton did not see any other means of improving telescopes by refraction only, except by increasing their length. Newton's Optics, pa 73, 83, 89, 3d edition.

This important desideratum in the construction of dioptric telescopes, has been since discovered by the ingenious Mr. Dollond; an account of which is given below.

Achromatic TELESCOPE, is a name given to the refracting telescope, invented by Mr. John Dollond, and so contrived as to remedy the aberration arising from colours, or the different refrangibility of the rays of light. See ACHROMATIC.

The principles of Mr. Dollond's discovery and construction, have been already explained under the articles ABERRATION, and ACHROMATIC. The improvement made by Mr. Dollond in his telescopes, by making two object-glasses of crown-glass, and one of flint, which was tried with success when concave eye-glasses were used, was completed by his son Peter Dollond; who, conceiving that the same method might be practised with success with convex eye-glasses, found, after a few trials, that it might be done. Accordingly he finished an object-glass of 5 feet focal length, with an aperture of 3¾ inches, composed of two convex lenses of crown-glass, and one concave of white flint glass. But apprehending afterward that the apertures might be admitted still larger, he completed one of 3½ feet focal length, with the same aperture of 3¾ inches. Philos. Trans. vol. 55, pa. 56.

But besides the obligation we are under to Mr. Dollond, for correcting the aberration of the rays of light in the focus of object-glasses, arising from their different refrangibility, he made another considerable improvement in telescopes, viz, by correcting, in a great measure, both this kind of aberration, and also that which arises from the spherical form of lenses, by an expedient of a very different nature, viz, increasing the number of eye-glasses. If any person, says he, would have the visual angle of a telescope to contain 20 degrees, the extreme pencils of the field must be bent or refracted in an angle of 10 degrees; which, if it be performed by one eye-glass, will cause an aberration from the figure, in proportion to the cube of that angle: but if two glasses be so proportioned and situated, as that the refraction may be equally divided between them, they will each of them produce a refraction equal to half the required angle; and therefore, the aberration being in this case proportional to double the cube of half the angle, will be but a 4th part of that which is in proportion to the cube of the whole angle; because twice the cube of 1 is but ¼ of the cube of 2: so that the aberration from the figure, where two eye-glasses are rightly proportioned, is but a 4th part of what it must unavoidably be, where the whole is performed by a single eye-glass. By the same way of reasoning, when the refraction is divided among three glasses, the aberration will be found to be but the 9th part of what would be produced from a single glass; because 3 times the cube of 1 is but the 9th part of the cube of 3. Whence it appears, that by increasing the number of eye-glasses, the indistinctness, near the borders of the field of a telescope, may be very much diminished, though not entirely taken away.

The method of correcting the errors arising from the different refrangibility of light, is of a different consideration from the former: for, whereas the errors from the figure can only be diminished in a certain proportion to the number of glasses, in this they may be entirely corrected, by the addition of only one glass; as we find in the astronomical telescope, that two eye-glasses, rightly proportioned, will cause the edges of objects to appear free from colours quite to the borders of the field. Also, in the day telescope, where no more than two eye glasses are absolutely necessary for erecting the object, we find, by the addition of a third rightly situated, that the colours, which would otherwise confuse the image, are entirely removed: but this must be understood with some limitation; for though the different colours, which the extreme pencils must necessarily be divided into by the edges of the eye-glasses, may in this manner be brought to the eye in a direction parallel to each other, so as, by its humours, to be converged to a point in the retina, yet if the glasses exceed a certain length, the colours may be spread too wide to be capable of being admitted through the pupil or aperture of the eye; which is the reason that, in long telescopes, constructed in the common way, with three eye-glasses, the field is always very much contracted.

These considerations first set Mr. Dollond on contriving how to enlarge the field, by increasing the number of eye-glasses, without lessening the distinctness or brightness of the image: and though others had laboured at the same work before, yet observing that the five-glass telescopes, sold in the shops, would admit of further improvement, he endeavoured to construct one with the same number of glasses in a better manner; which so far answered his expectations, as to be allowed by the best judges to be a considerable improvement on the former. Encouraged by this success, he resolved to try if he could not make some further enlargement of the field, by the addition of another glass, and by placing and proportioning the glasses in such a manner, as to correct the aberrations as much as possible, without any detriment to the distinctness: and at last he obtained as large a field as is convenient or necessary, and that even in the longest telescopes that can be made. These telescopes, with 6 glasses, having been well received both at home and abroad, the author has settled the date of the invention in a letter addressed to Mr. Short, and read at the Royal Society, March 1, 1753. Philos. Trans. vol. 48, art. 14.

Of the achromatic telescopes, invented by Mr. Dollond, there are several different sizes, from one foot to 8 feet in length, made and sold by his sons P. and J. Dollond. In the 17-inch improved achromatic telescope, the object-glass is composed of three glasses, viz, two convex of crown-glass, and one concave of white flint glass: the focal distance of this combined object-glass is about 17 inches, and the diameter of the aperture 2 inches. There are 4 eye-glasses contained in the tube, to be used for land objects; the magnifying power with these is near 50 times; and they are adjusted to different sights, and to different distances of the object, by turning a finger screw at the end of the outer tube. There is another tube, containing two eye-glasses that magnify about 70 times, for astronomical purposes. The telescope may be directed to any object by turning two screws in the stand on which it is fixed, the one giving a vertical motion, and the other a horizontal one. The stand may be inclosed in the inside of the brass tube.

The object-glass of the 2½ and 3½ feet telescopes is composed of two glasses, one convex of crown glass, and the other concave of white flint glass; and the diameters of their apertures are 2 inches and 2¾ inches. Each of them is furnished with two tubes; one for land objects, containing four eye-glasses, and another with two eye-glasses for astronomical uses. They are adjusted by buttons on the outside of the wooden tube; and the vertical and horizontal motions are given by joints in the stands. The magnifying power of the least of these telescopes, with the eye-glass for land objects, is near 50 times, and with those for astronomical purposes, 80 times; and that of the greatest for land objects is near 70 times, but for astronomical observations 80 and 130 times; for this has two tubes, either of which may be used as occasion requires. This telescope is also moved by a screw and rackwork, and the screw is turned by means of a Hook's joint.

These opticians also construct an achromatic pocket perspective glass, or Galilean telescope; so contrived, that all the different parts are put together and contained in one piece 4¾ inches long. This small telescope is furnished with 4 concave eye-glasses, the magnifying powers of which are 6, 12, 18, and 28 times. With the greatest power of this telescope, the satellites of Jupiter and the ring of Saturn may be easily seen. They have also contrived an achromatic telescope, the sliding tubes of which are made of very thin brass, which pass through springs or tubes; the outside tube being either of mahogany or brass. These telescopes, which from their convenience for gentlemen in the army are called military telescopes, have 4 convex eye-glasses, whose surfaces and focal lengths are so proportioned, as to render the field of view very large. They are of 4 different lengths and sizes, usually called one foot, 2, 3, and 4 feet: the first is 14 inches when in use, and 5 inches when shut up, having the aperture of the object-glass $1\frac{1}{10}$ inch, and magnifying 22 times: the second 28 inches for use, 9 inches shut up, the aperture $1\frac{6}{10}$ inch, and magnifying 35 times; the third 40 inches, and 10 inches shut, with the aperture 2 inches, and magnifying 45 times; and the fourth 52 inches, and 14 inches shut, with the aperture 2½ inches, and magnifying 55 times.

Euler, who, in a memoir of the Academy of Berlin for the year 1757, pa. 323, had calculated the effects of all possible combinations of lenses in telescopes and microscopes, published another long memoir on the subject of these telescopes, showing with precision of what advantages they are naturally capable. See Miscel. Taurin. vol. 3, part 2, pa. 92.

Mr. Caleb Smith, having paid much attention to the subject of shortening and improving telescopes, thought he had found it possible to rectify the errors which arise from the different degrees of refrangibility, on the principle that the sines of refraction of rays differently refrangible, are to one another in a given proportion, when their sines of incidence are equal; and the method he proposed for this purpose, was to make the specula of glass, instead of metal, the two surfaces having different degrees of concavity. But it does not appear that this scheme was ever carried into practice. See Philos. Trans. No. 456, pa. 326.

The ingenious Mr. Ramsden has lately described a new construction of eye-glasses for such telescopes as may be applied to mathematical instruments. The construction which he proposes, is that of two plano-convex lenses, both of them placed between the eye and the observed image formed by the object-glass of the instrument, and thus correcting not only the aberration arising from the spherical figure of the lenses, but also that arising from the different refrangibility of light. For a more particular account of this construction, its principle, and its effects, see Philos. Trans. vol. 73, art. 5.

A construction, similar at least in its principle to that above, is ascribed, in the Synopsis Optica Honorati Fabri, to Eustachio Divini, who placed two equal narrow plano-convex lenses, instead of one eye lens, to his telescopes, which touched at their vertices; the focus of the object-glass coinciding with the centre of the plano-convex lens next it. And this, it is said, was done at once both to make the rays that come parallel from the object fall parallel upon the eye, to exclude the colours of the rainbow from it, to augment the angle of sight, the field of view, the brightness of the object, &c. This was also known to Huygens, who sometimes made use of the same construction, and gives the theory of it in his Dioptrics. See Hugenii Opera Varia, vol. 4, ed. 1728.

TELESCOPE, *Reflecting*, or *Catoptric*, or *Catadioptric*, is a telescope which, instead of lenses, consists chiefly of mirrors, and exhibits remote objects by reflection instead of refraction.

A brief account of the history of the invention of this important and useful telescope, is as follows. The ingenious Mr. James Gregory, of Aberdeen, has been commonly considered as the first inventor of this telescope.—But it seems the first thought of a reflector had been suggested by Mersenne, about 20 years before the date of Gregory's invention: a hint to this purpose occurs in the 7th proposition of his Catoptrics, which was printed in 1651: and it appears from the 3d and 29th letters of Descartes, in vol. 2 of his Letters, which it is said were written in 1639, though they were not published till the year 1666, that Mersenne proposed a telescope with specula to Descartes in that correspondence; though indeed in a manner so very unsatisfactory, that Descartes, who had given particular attention to the improvement of the telescope, was so far from approving the proposal, that he endeavoured to convince Mersenne of its fallacy. This point has been largely discussed by Le Roi in the Encyclopedia, art. Telescope, and by Montucla in his Hist. des Mathem. tom. 2, pa. 643.

Whether Gregory had seen Mersenne's treatise on optics and catoptrics, and whether he availed himself of the hint there suggested, or not, perhaps cannot now be determined. He was led however to the invention by seeking to correct two imperfections in the common telescope: the first of these was its too great length, which made it troublesome to manage; and the second was the incorrectness of the image. It had been already demonstrated, that a pencil of rays could not be collected in a single point by a spherical lens; and also, that the image transmitted by such a lens would be in some degree incurvated. These inconveniencies he thought might be obviated by substituting for the object-glass a metallic speculum, of a parabolical figure, to receive the image, and to reflect it towards a small speculum of the same metal; this again was to return the image to an eye-glass placed behind the great speculum, which was, for that purpose, to be perforated in its centre. This construction he published in 1663, in his Optica Promota. But as Gregory, according to his own account, possessed no mechanical skill, and could not find a workman capable of realizing his invention, after some fruitless trials, he was obliged to give up the thoughts of bringing telescopes of this kind into use.

Sir Isaac Newton however interposed, to save this excellent invention from perishing, and to bring it forward to maturity. Having applied himself to the improvement of the telescope, and imagining that Gregory's specula were neither very necessary, nor likely to be executed, he began with prosecuting the views of Descartes, who aimed at making a more perfect image of an object, by grinding lenses, not to the figure of a sphere, but to that formed from one of the conic sections. But, in the year 1666, having discovered the different refrangibility of the rays of light, and finding that the errors of telescopes, arising from that cause alone, were much more considerable than such as were occasioned by the spherical figure of lenses, he was constrained to turn his thoughts to reflectors. The plague however interrupted his progress in this business; so that it was towards the end of 1668, or in the beginning of 1669, when, despairing of perfecting telescopes by means of refracted light, and recurring to the construction of reflectors, he set about making his own specula, and early in the year 1672 completed two small reflecting telescopes. In these he ground the large speculum into a spherical concave, being unable to accomplish the parabolic form proposed by Gregory; but though he then despaired of performing that work by geometrical rules, yet (as he writes in a letter that accompanied one of these instruments, which he presented to the Royal Society) he doubted not but that the thing might in some measure be accomplished by mechanical devices. With a perseverance equal to his ingenuity, he, in a great measure, overcame another difficulty, which was to find a metallic substance that would be of a proper hardness, have the fewest pores, and receive the smoothest polish: this difficulty he deemed almost insurmountable, when he considered that every irregularity in a reflecting surface would make the rays of light deviate 5 or 6 times more out of their due course, than the like irregularities in a refracting surface. After repeated trials, he at last found a composition that answered in some degree, leaving it to those who should come after him to find a better. These difficulties have accordingly been since obviated by other artists, particularly by Dr. Mudge, the rev. Mr. Edwards, and Dr. Herschel, &c. Newton having succeeded so far, he communicated to the Royal Society a full and satisfactory account of the construction and performance of his telescope. The Society, by their secretary Mr. Oldenburg, transmitted an account of the discovery to Mr. Huygens, celebrated as a distinguished improver of the refractor; who not only replied to the Society in terms expressing his high approbation of the invention, but drew up a favourable account of the new telescope, which he caused to be published in the Journal des Sçavans of the year 1672, and by this mode of communication it was soon known over Europe. See Huygenii Opera Varia, tom. 4.

Notwithstanding the excellence and utility of this contrivance, and the honourable manner in which it was announced to the world, it seems to have been greatly neglected for nearly half a century. Indeed when Newton had published an account of his telescopes in the Philos. Trans. M. Cassegrain, a Frenchman, in the Journal des Sçavans of 1672, claimed the honour of a similar invention, and said, that, before he heard of Newton's improvement, he had hit upon a better construction, by using a small convex mirror instead of the reflecting prism. This telescope, which was the Gregorian one disguised, the large mirror being perforated, and which it is said was never executed by the author, is much shorter than the Newtonian; and the convex mirror, by dispersing the rays, serves greatly to increase the image made by the large concave mirror.

Newton made many objections to Cassegrain's construction, but several of them equally affect that of Gregory, which has been found to answer remarkably well in the hands of good artists.

Dr. Smith took the pains to make many calculations of the magnifying power, both of Newton's and Cassegrain's telescopes, in order to their further improvement, which may be seen in his Optics, Rem. p. 97.

Mr. Short, it is also said, made several telescopes on the plan of Cassegrain.

Dr. Hooke constructed a reflecting telescope (mentioned by Dr. Birch in his Hist. of the Royal Soc. vol. 3, pa. 122) in which the great mirror was perforated, so that the spectator looked directly towards the object, and it was produced before the Royal Society in 1674. On this occasion it was said that this construction was first proposed by Mersenne, and afterwards repeated by Gregory, but that it had never been actually executed before it was done by Hooke. A description of this instrument may be seen in Hooke's Experiments, by Derham, pa. 269.

The Society also made an unsuccessful attempt, by employing an artificer to imitate the Newtonian construction; however, about half a century after the invention of Newton, a reflecting telescope was produced to the world, of the Newtonian construction, which the venerable author, ere yet he had finished his very distinguished course, had the satisfaction to find executed in such a manner, as left no room to fear that the invention would longer continue in obscurity. This effectual service to science was accomplished by Mr. John Hadley, who, in the year 1723, presented to the Royal Society a telescope, which he had constructed on Newton's plan. The two telescopes which Newton had made, were but 6 inches long, were held in the hand for viewing objects, and in power were compared to a 6-feet refractor: but the radius of the sphere, to which the principal speculum of Hadley's was ground, was 10 feet 5½ inches, and consequently its focal length was 62⅝ inches. In the Philos. Trans. Abr. vol. 6, pa. 646, 664, may be seen a drawing and description of this telescope, and also of a very ingenious but complex apparatus, by which it was managed. One of these telescopes, in which the focal length of the large mirror was not quite 5¼ feet, was compared with the celebrated Huygenian telescope, which had the focal length of its object-glass 123 feet; and it was found that the former would bear such a charge, as to make it magnify the object as many times as the latter with its due charge; and that it represented objects as distinctly, though not altogether so clear and bright. With this reflecting telescope might be seen whatever had been hitherto discovered by that of Huygens, particularly the transits of Jupiter's satellites, and their shades over the disk of Jupiter, the black list in Saturn's ring, and the edge of the shade of Saturn cast upon his ring. Five satellites of Saturn were also observed with this telescope, and it afforded other observations on Jupiter and Saturn, which confirmed the good opinion which had been conceived of it by Pound and Bradley.

Mr. Hadley, after finishing two telescopes of the Newtonian construction, applied himself to make them in the Gregorian form, in which the large mirror is perforated. This scheme he completed in the year 1726.

Dr. Smith prefers the Newtonian construction to that of Gregory; but if long experience be admitted as a final judge in such matters, the superiority must be adjudged to the latter; as it is now, and has been for many years past, the only instrument in request.

Mr. Hadley spared no pains, after having completed his construction, to instruct Mr. Molyneux and Dr. Bradley; and when these gentlemen had made a good proficiency in the art, being desirous that these telescopes should become more public, they liberally communicated to some of the chief instrument-makers of London, the knowledge they had acquired from him: and thus, as it is reasonable to imagine, reflectors were completed by other and better methods than even those in which they had been instructed. Mr. James Short in particular signalized himself as early as the year 1734, by performances of this kind. He at first made his specula of glass; but finding that the light reflected from the best glass specula was much less than the light reflected from metallic ones, and that glass was very liable to change its form by its own weight, he applied himself to improve metallic specula; and, by giving particular attention to their curvature, he was able to give them greater apertures than other workmen could do; and by a more accurate adjustment of the specula, &c, he greatly improved the whole instrument. By some which he made, in which the larger mirror was 15 inches focal distance, he and some other persons were able to read in the Philos. Trans. at the distance of 500 feet; and they several times saw the five satellites of Saturn together, which greatly surprised Mr. Maclaurin, who gave this account of it, till he found that Cassini had sometimes seen them all with a 17 feet refractor. Short's telescopes were all of the Gregorian construction. It is supposed that he discovered a method of giving the parabolic figure to his great speculum; a degree of perfection which Gregory and Newton despaired of attaining, and which Hadley it seems had never attempted in either of his telescopes. However, the secret of working that configuration, whatever it was, it seems died with that ingenious artist; though lately in some degree discovered by Dr. Mudge and others.

On the history of reflecting telescopes, see Dr. David Gregory's Elem. of Catopt. and Dioptr. Appendix by Desaguliers: Smith's Optics, book 3, c. 2, Rem. on art. 469: and Sir John Pringle's excellent Discourse on the Invention &c of the Reflecting Telescope.

Construction of the Reflecting Telescope of the Newtonian form.—Let ABCD (fig. 1, pl. 38) be a large tube, open at AD, and closed at BC, and its length at least equal to the distance of the focus from the metallic spherical concave speculum GH placed at the end BC. The rays EG, FH, &c, proceeding from a remote object PR, intersect one another somewhere before they enter the tube, so that EG and *eg* are those that come from the lower part of the object, and *fh* FH from its upper part: these rays, after falling on the speculum GH, will be reflected so as to converge and meet in *mn*, where they will form a perfect image of the object. But as this image cannot be seen by the spectator, they are intercepted by a small plane metallic speculum KK, intersecting the axis at an angle of 45°, by which the rays tending to *mn*, will be reflected towards a hole LL in the side of the tube, and the image of the object will be thus formed in *qs*; which image will be less distinct, because some of the rays which would otherwise fall on the concave speculum GH, are intercepted by the plane speculum: it will nevertheless appear pretty distinct, because the aperture AD of the tube, and the speculum GH, are large. In the lateral hole LL is fixed a convex lens, whose focus is at *sq*; and therefore this lens will refract the rays that proceed from any point of the image, so as at their emergence they will appear parallel, and those that proceed from the extreme points *sq*, will converge after refraction, and form an angle at O, where the eye is placed; which will see the image *sq*, as if it were an object, through the lens LL: consequently the object will appear enlarged, inverted, bright, and distinct. In LL may be placed lenses of different convexities, which, by being moved nearer to the image and farther from it, will represent the object more or less magnified, if the surface of the speculum GH be of a figure truly spherical. If, instead of one lens LL, three lenses be disposed in the same manner with the three eye-glasses of the refracting telescope, the object will appear erect, but less distinct than when it is observed with one lens. On account of the position of the eye in this telescope, it is extremely difficult to direct the instrument towards any object: Huygens therefore first thought of adding to it a small refracting telescope, having its axis parallel to that of the reflector: this is called a finder or director. The Newtonian telescope is also furnished with a suitable apparatus for the commodious use of it.

To determine the magnifying power of this telescope, it is to be considered that the plane speculum KK is of no use in this respect: let us then suppose that one ray proceeding from the object coincides with the axis GLIA of

the lens and speculum: let *bb* be another ray proceeding from the lower extremity of the object, and passing through the focus I of the speculum KH; this will be reflected in the direction *bid*, parallel to the axis GLA, and falling on the lens *dLd*, will be refracted to G, so that GL will be equal to LI, and *do* = *di*. To the naked eye the object would appear under the angle I*bi* = *b*IA; but by means of the telescope it appears under the angle *d*GL = *d*IL = I*di*; and the angle I*di* is to the angle I*bi* as *b*I to I*d*; consequently the apparent magnitude by the telescope, is to that with the naked eye, as the distance of the focus of the speculum from the speculum, to the distance of the focus of the lens from the lens.

Construction of the Gregorian Reflecting Telescope.—Let TYYT (fig. 2, pl. 38) be a brass tube, in which L*ld*D is a metallic concave speculum, perforated in the middle at X; and EF a less concave mirror, so fixed by the arm or strong wire RT, which is moveable by means of a long screw on the outside of the tube, as to be moved nearer to, or farther from the larger speculum L*ld*D; its axis being kept in the same line with that of the great one. Let AB represent a very remote object, from each part of which issue pencils of rays, as *cd*, CD, from A the upper extremity of the object, and IL, *il*, from the lower part B; the rays IL, CD, from the extremities, crossing each other before they enter the tube. These rays, falling upon the larger mirror LD, are reflected from it into the focus KH, where they form an inverted image of the object AB, as in the Newtonian telescope. From this image the rays, issuing as from an object, fall upon the small mirror EF, the centre of which is at *e*, so that after reflection they would meet in their foci at QQ, and there form an erect image. But since an eye at that place could see but a small part of an object, in order to bring rays from more distant parts of it into the pupil, they are intercepted by the plano-convex lens MN, by which means a smaller erect image is formed at PV, which is viewed through the meniscus SS, by an eye at O. This meniscus both makes the rays of each pencil parallel, and magnifies the image PV. At the place of this image all the foreign rays are intercepted by the perforated partition ZZ. For the same reason the hole near the eye O is very narrow. When nearer objects are viewed by this telescope, the small speculum EF is removed to a greater distance from the larger LD, so that the second image may be always formed in PV: and this distance is to be adjusted (by means of the screw on the outside of the great tube) according to the form of the eye of the spectator. It is also necessary that the axis of the telescope should pass through the middle of the speculum EF, and its centre, the centre of the speculum LL, and the middle of the hole X, the centres of the lenses MN, SS, and the hole near O. As the hole X in the speculum LL can reflect none of the rays issuing from the object, that part of the image which corresponds to the middle of the object, must appear to the observer more dark and confused than the extreme parts of it. Besides, the speculum EF will also intercept many rays proceeding from the object; and therefore, unless the aperture TT be large, the object must appear in some degree obscure.

The magnifying power of this telescope is estimated in the following manner. Let LD be the larger mirror (fig. 4, pl. 38), having its focus at O, and aperture in A; and FF the small mirror with the focus of parallel rays in I, and the axis of both the specula and lenses MN, SS, be in the right line DIOAOK. Let *bb* be a ray of light coming from the lower extremity of a very distant visible object, passing through the focus G, and failing upon the point *b* of the speculum LD; which, after being reflected from *b* to F in a direction parallel to the axis of the mirror DAK, is reflected by the speculum F so as to pass through the focus I in the direction FIN to N, at the extremity of the lens MN, by which it would have been refracted to K; but by the interposition of another lens SS is brought to O, so that the eye in O sees half the object under the angle TOS. The angle G*b*F, or AG*b*, under which the object is viewed by the naked eye, is to SOT under which it is viewed by the telescope, in the ratio of G*b*F to IF*i* = *n*IN, of *n*IN to NK*n*, and of NK*n* to SOT.

But G*b*F : IF*i* :: DI : GA,
and *n*IN : *n*KN :: *n*K : *n*I,
and *n*KN : SOT :: TO : TK;
theref. G*b*F : SOT :: DI × *n*K × TO : GA × *n*I × TK.
Musschenbroek's Introd. vol. 2. p. 819.

In reflecting telescopes of different lengths, a given object will appear equally bright and equally distinct, when their linear apertures, and also their linear breadths, are as the 4th roots of the cubes of their lengths; and consequently when the focal distances of their eye-glasses are also as the 4th roots of their lengths. See the demonstration of this proposition in Smith's Optics, art. 361.

Hence he has deduced a rule, by which he has computed the following table for telescopes of different lengths, taking, for a standard, the middle eye-glass and aperture of Hadley's Reflecting telescope, described in Philos. Trans. No. 376 and 378: the focal distances and linear apertures being given in 1000th parts of an inch.

Table for Telescopes of different Lengths.

Length of the Telescope, or Focal Distance of the Concave.	Focal Distance of the Eye-Glass.	Linear amplifying or magnifying Power.	Linear Aperture of the Concave Metal.

Mr. Hadley's telescope, above-mentioned, magnified 228 or 230 times; but we are informed that an object-metal of 3¼ feet focal distance was wrought by Mr. Hauksbee to so great a perfection, as to magnify 226 times, and therefore it was scarcely inferior to Hadley's of 5¼ feet. If Hauksbee's telescope be taken for a new standard, it follows that a speculum of one foot focal distance ought to magnify 93 times, whereas the above table allows it but 60. Now $\frac{93}{60} = 1{\cdot}55$, and the given column of magnifying powers multiplied by this number, gives a new column, showing how much the object-metals ought to magnify if wrought up to the perfection of Hauksbee's. And thus a new table may be easily made for this or any other more perfect standard, taking also the new eye-glasses and apertures in the same ratio to one another as the old ones have in this table. Smith's Optics, Rem. pa. 79.

The magnifying power of any telescope may be easily found by experiment, viz, by looking with one eye through the telescope upon an object of known dimensions, and at a given distance, and throwing the image upon another object seen with the naked eye. Dr. Smith has given a particular account of the process, Rem. pa. 79.

But the easiest method of all, is to measure the diameter of the aperture of the object-glass, and that of the little image of it, which is formed at the place of the eye. For the proportion between these gives the ratio of the magnifying power, provided no part of the original pencil be intercepted by the bad construction of the telescope. For in all cases the magnifying power of telescopes, or microscopes, is measured by the proportion of the diameter of the original pencil, to that of the pencil which enters the eye. Priestley's Hist. of Light, pa. 747.

The most considerable, and indeed truly astonishing magnifying powers, that have ever been used, are those of Dr. Herschel's reflecting telescopes. Some account of these, and of the discoveries made by them, has been already introduced under the article Star; for his method of ascertaining them, see Philos. Trans. vol. 72, pa. 173 &c. See also several of the other late volumes of the Philos. Trans. Likewise vol. 17, pa. 593, of my Abridg. of the Philos. Trans. for a description of Herschel's 40-foot reflecting telescope, with an engraved representation of all its machinery; see also plate xv of this Dictionary.

Dr. Herschel observes, that though opticians have proved, that two eye-glasses will give a more correct image than one, he has always (from experience) persisted in refusing the assistance of a second glass, which is sure to introduce errors greater than those he would correct. "Let us resign," says he, "the double eye-glass to those who view objects merely for entertainment, and who must have an exorbitant field of view. To a philosopher, this is an unpardonable indulgence. I have tried both the single and double eye-glass of equal powers, and always found that the single eye-glass had much the superiority in point of light and distinctness. With the double eye-glass I could not see the belts in Saturn, which I very plainly saw with the single one. I would however except all those cases where a large field is absolutely necessary, and where power joined to distinctness is not the sole object of our view." Philos. Trans. vol. 72, pa. 95.

Meridian TELESCOPE, is one that is fixed at right angles to an axis, and turned about it in the plane of the meridian; and is otherwise called a Transit Instrument.—The common use of this is to correct the motion of a clock or watch, by daily observing the exact time when the sun or a star comes to the meridian. It serves also for a variety of other uses. The transverse axis is placed horizontal by a spirit level. For the farther description and method of fixing this instrument by means of its levels &c, see Smith's Optics, pa. 321. See also TRANSIT *Instrument*.

TELESCOPICAL *Stars*, are such as are not visible to the naked eye, being only discernible by means of a telescope.—All stars less than those of the 6th magnitude, are telescopic to an ordinary eye.

TEMPERAMENT, in Music, is defined by Rousseau to be an operation which, by means of a slight alteration in the intervals, causes the difference between two contiguous sounds to disappear, makes each of these sounds seem identical with the other, which, without offending the ear, may still preserve their respective intervals or distances one from the other. By this operation the scale is rendered more simple, and the number of sounds which would otherwise be necessary retrenched. Had not the scale been thus modified, instead of 12 sounds alone which are contained in the octave, more than 60 would be indispensably required to form what is properly called Modulation in every tone.

It is proved by computation, that on the organ, the harpsichord, and every other instrument with keys, there is not, and there scarcely can be, any chords properly in tune, save the octave alone. The cause is this, that though 3 thirds major, or 4 thirds minor, ought to form a just octave, those are found to surpass, and these not to reach it.

TEMPERATURE, the degree or quantity of heat in any substance or place; as, in the atmosphere, in a climate, in the earth, in the ocean, &c. In all these cases, the heat is greater in the lower latitudes, than in the higher: being greatest at the equator, and gradually less all the way to each pole, where it is least.

TEMPERATURE *of the Atmosphere*, is greatest at the bottom, next the earth's surface, where it is warmed by the contact of the earth, and by the reflection of the sun's heat from it. From hence, gradually in ascending up in the atmosphere, the heat is always the less, till, in the upper regions, there is perpetual cold or frost, and that more or less, at equal elevations, in all latitudes. In so much that, at a certain elevation above the sea, peculiar to each latitude, the mountains exhibit perpetual frost or snow, if not higher than where vapours ascend in the atmosphere; which appearance of ice or snow terminates, however cold, at the highest point of the ascent of vapours. This latter point may be termed the upper altitude termination, as the former is the lower. And the heights of these two terms, for the different latitudes, have been observed as they are here exhibited in the following table; the latitude for every 5° being placed in the first column, and the altitude, in feet, of the lower and upper terms, in the 2d and 3d columns.

Latitude.	Alt. lower Termin.	Alt. upper Termin.	Latitude.	Alt. lower Termin.	Alt. upper Termin.
0°	15573	28000	45°	7658	13730
5	15457	27784	50	6260	11253
10	15067	27084	55	4912	8830
15	14498	26061	60	3684	6546
20	13719	24661	65	2516	4676
25	13020	23423	70	1557	2803
30	11592	20838	75	748	1346
35	10664	19169	80	120	207
40	9016	16207			

By dividing each number in the 2d column, by its corresponding number in the 3d, the quotients generally come out $\cdot 556$, or nearly $\frac{5}{9}$, excepting some very few irregular numbers, which must have been errors in the observations. I find also that the numbers in both these columns are very nearly proportional to the squares of the cosines of the latitudes, excepting a few of the numbers belonging to the very high latitudes; and indeed that those in the 3d column ought to be expressed by this formula $28000c^2$, where c denotes the cosine of the latitude, to radius 1. Hence $\frac{5}{9}$ of $28000c^2$, or $\frac{140000}{9}c^2$ will give the proper numbers for the 2d column. And hence the irregular numbers, in both the columns, may be corrected.

Temperature *of the Climate*, is that of the air which we breathe, at the earth's surface, or the bottom of the atmosphere. This temperature is higher as the place is nearer the equator, and as the time or the season is nearer the warmest part of the year, near the summer equinox.

At London, by a mean of the observations, for each month, made at the Royal Society, from the year 1772 to 1780, it appears that the mean annual temperature there, is 51°·9, or in whole numbers 52°; and the monthly temperature is as follows:

January - -	35°·9	July - - - -	65°·3
February - -	42 ·3	August - - -	65 ·8
March - - -	46 ·4	September - -	59 ·6
April - - -	49 ·9	October - -	52 ·8
May - - - -	56 ·6	November - -	44 ·4
June - - -	63 ·2	December - -	41 ·0

The greatest usual cold is 20°, and happens in January; the greatest usual heat is 81°, and happens generally in July.

At Petersburg, lat. 59° 56′, the mean annual temperature is 38°·8. The greatest cold observed was that at which mercury freezes, that is, − 39°, or 39 below 0; but the greatest mean degree of cold for several years was − 25°; and the greatest summer heat, on a mean, is 79°, though once it amounted to 94°.

With respect to different latitudes, from theory it would seem that the heat must vary with some function of the square of the sine or of the cosine of the latitude. Accordingly, the rule given by Tobias Mayer of Gottingen, for the mean annual temperature, is $84-53s^2$, where s is the sine of the latitude; or which may be otherwise expressed by $31+53c^2$, where c denotes the cosine of the latitude, to the radius 1. And by this rule is computed the following table.

Lat.	Temp.	Lat.	Temp.	Lat.	Temp.
0°	84·0	35°	66·6	70°	37·2
5	83·6	40	62·0	75	34·5
10	82·3	45	57·5	80	32·6
15	80·4	50	52·9	85	31·4
20	77·8	55	48·4	90	31·0
25	74·5	60	44·3		
30	70·7	65	40·4		

Temperature *of the Earth*, is various at different depths below the surface, to a certain depth or limit, where it is stationary, being at about 80 or 90 feet deep. It is found by observation, that the same degree of heat occurs in all subterraneous places at the same depth, varying a little at different depths, but is never less than 36° of Fahrenheit's thermometer. At 80 or 90 feet, and sometimes much less, the temperature varies very little, and generally approaches to the mean annual heat. Thus, the temperature of springs is nearly the same as the mean annual heat, and varies very little in different seasons. The temperature of the cave at the observatory of Paris, of about 90 feet deep, is about 53½ degrees: varying only about half a degree in very cold years. The internal heat of the earth in our climate is always above 40°, and therefore the snow generally begins to melt first at the bottom. Mr. Boyle kept a thermometer for a year, in a cave 80 feet deep, and found the liquid remain stationary all the time. Dr. Withering made a similar experiment on a well 84 feet deep, at Edgbaston, near Birmingham, the temperature of which was found to be 49° in every month of the year 1798. A remarkable circumstance however is observable in experiments made on pits or wells of a moderate depth. Mr. Gough kept a monthly account of the temperature of a well, for the years 1795 and 1798, of only 20 feet deep, and he found the annual variation was under 4°. And it is remarkable that the temperature of the earth, at the depth of 20 feet from the surface, is at the highest in October, when a thermometer in the atmosphere makes the monthly mean coincide with that of the year: on the contrary, the subterranean temperature does not arrive at a minimum before the end of March, 2 or 3 months later than the coldest weather above ground.

Temperature *of the Sea*, like that of the land, is also different at different depths, but at great depths is found to be nearly constant. In winter, when the surface of water is much cooled by contact with the colder air, the deeper and warmer water at the bottom, being specifically lighter, rises and tempers the top; and as the colder water constantly descends during the winter, in the following summer the surface is generally warmer than at any depths; whereas in winter it is colder. As the water in the high latitudes is, by cold, rendered heavier than that in lower warm latitudes; hence occurs a continual current from the poles to the equator, which sometimes carries down large masses of ice, which cool the air to a great extent. The temperatures of land and water differ more in winter than in summer.

The following table exhibits the results of several observations on the temperature of the air, and of the sea at different depths, in several latitudes, and at different seasons of the year.

Latitude.		Time.		Heat of the Air.	Depth of the Sea.	Heat of the Sea.	Heat of the Surface.

TENACITY, in Natural Philosophy, is that quality of bodies by which they sustain a considerable pressure or force without breaking; and is the opposite quality to fragility or brittleneness. Mem. Acad. Berlin, 1745, pa. 47.

TENAILLE, in Fortification, a kind of outwork, consisting of two parallel sides, with a front, having a re-entering angle. In fact, that angle, and the faces which compose it, are the tenaille. The tenaille is of two kinds, simple and double.

Simple or *Single* TENAILLE, is a large outwork, consisting of two faces or sides, including a re-entering angle.

Double, or *Flanked* TENAILLE, is a large outwork, consisting of two simple tenailles, or three saliant and two re-entering angles.

The great defects of tenailles are, that they take up too much room, and on that account are advantageous to the enemy; that the re-entering angle is not defended; the height of the parapet preventing the seeing down into it, so that the enemy can lodge there under cover; and the sides are not sufficiently flanked. For these reasons, tenailles are now mostly excluded out of fortification by the best engineers, and never made but where time does not serve to form a hornwork.

TENAILLE *of the Place*, is the front of the place, comprehended between the points of two neighbouring bastions; including the curtain, the two flanks raised on the curtain, and the two sides of the bastions which face each other. So that the tenaille, in this sense, is the same with what is otherwise called the Face of a fortress.

TENAILLE *of the Ditch*, is a low work raised before the curtain, in the middle of the foss or ditch; the parapet of which is only 2 or 3 feet higher than the level ground of the ravelin.

The use of tenailles in general, is to defend the bottom of the ditch by a grazing fire, and likewise the level ground of the ravelin, which cannot be so conveniently defended from any other place. The first sort do not defend the ditch so well as the others, because they are too oblique a defence; but as they are not subject to be enfiladed, Vauban has generally preferred them in the fortifying of places. Those of the second kind defend the ditch much better than the first, and add a low flank to those of the bastions; but as these flanks are liable to be enfiladed, they have not been much used This defect however might be remedied, by making them so as to be covered by the extremities of the parapets of the opposite ravelins, or by some other work. And the same thing may be said of the third sort as of the second.

The *Ram's-horn* is a curved tenaille, raised in the foss before the flanks, and presenting its convexity to the covered way. This work seems preferable to either of the other tenailles, both on account of its simplicity, and the defence for which it is constructed.

TENAILLONS, in Fortification, are works constructed on each side of the ravelin, much like the lunettes. They differ, as one of the faces of a tenaillon is in the direction of the ravelin, whereas that of the lunette is perpendicular to it.

TENOR, in Music, the first mean or middle part, or that which is the ordinary pitch, or tenor, of the voice, when not either raised to the treble, or lowered to the bass.

TENSION, the state of a thing tight, or stretched. Thus, animals sustain and move themselves by the tension of their muscles and nerves. A chord, or string, gives an acuter or deeper sound, as it is in a greater or less degree of tension, that is, more or less stretched or tightened.

The *Tension* of a cord in *Mechanics*, is the force which acts at one end thereof when the other is fixed, or it is equivalent to that force. Thus, in the case of an equilibrium of forces applied to a physical point; if we consider that point as fixed, the tension of each cord is precisely the force applied at each cord to move the point; but if there be not an equilibrium, as will happen, for example, when two unequal powers act at its extremities; the tension is in this case the least of the two forces; for the tension will evidently be the same, as if one of the extremities were fixed, and the least of the two forces acted solely at the other end.

TERM, in Geometry, is the extreme of any magnitude, or that which bounds and limits its extent. So the terms of a line, are points; of a superficies, lines; of a solid, superficies.

TERMS, of an equation, or of any quantity, in Algebra, are the several names or members of which it is composed, separated from each other by the signs + or −. So, the quantity $ax + 2bc - 3ax^2$, consists of the three terms ax and $2bc$ and $3ax^2$.

In an equation, the terms are the parts which contain the several powers of the same unknown letter or quantity: for if the same unknown quantity be found in several members in the same degree or power, they shall pass but for one term, which is called a compound one, in distinction from a simple or single term. Thus, in the equation $x^3 + \overline{a - 3b} \,.\, x^2 - acx = b^3$, the four terms are x^3 and $(a - 3b)x^2$ and acx and b^3; of which the second term $(a - 3b)x^2$ is compound, and the other three are simple terms.

TERMS, of a Product, or of a Fraction, or of a Ratio, or of a Proportion, &c, are the several quantities employed in forming or composing them. Thus, the terms

of the product ab, are a and b;
of the fraction $\frac{5}{8}$, are 5 and 8;
of the ratio 6 to 7; are 6 and 7;
of the proportion $a : b :: 5 : 9$, are a, b, 5, 9.

TERMS are also used for the several times or seasons of the year in which the public colleges or universities, or courts of law, are open, or sit. Such are the Oxford and Cambridge terms: also the terms for the courts of King's-Bench, Common Pleas, and the Exchequer, which are the high courts of common law. But the high court of Parliament, the Chancery, and inferior courts, do not observe the terms.—The rest of the year, out of term-time, is called *vacation*.

There are four law terms in the year; viz,

Hilary-Term, which, at London, begins the 23d day of January, and ends the 12th of February.

Easter-Term, which begins the 3d Wednesday after Easter-day, and ends on the Monday next after Ascension-day.

Trinity-Term, which begins the Friday next after Trinity-Sunday, and ends the 4th Wednesday after Trinity-Sunday.

Michaelmas-Term, which begins the 6th of November, and ends the 28th of November.

All these terms have also their returns, the days of which are expressed in the following table or synopsis.

Table of the Law Terms, and their Returns.

Term	Begin.	1st Return	2d Return	3d Return	4th Return	5th Return	End
Hilary	January 23	January 20	January 27	February 3	February 9	- - - -	February 12
Easter	3 Wed. af. Eas.	2 Wks. af. East.	3 Wks. af. East.	4 Wks. af. East.	5 Wks. af. East.	Ascension day	Mon. af. Ascens.
Trinity	Fri. af. Trin. S.	Trinity Mond.	1 Wk. af. Trin.	2 Wks. af. Trin.	3 Wks. af. Trin.	- - - -	4th We. af. Tri. S.
Mich.	November 6	November 3	November 12	November 18	November 25	- - - -	November 28

When the beginning or ending of any of these terms happens on a Sunday, it is held on the Monday following.

Oxford TERMS. These are four; which begin and end as below:

Terms	Begin.	End
Lent Term	January 14	Sat. bef. Palm-Sun.
Easter Term	Wed. af. Low-Sun.	Sat. bef. Whitsun.
Trinity Term	Wed. af. Whitsun.	Sat. after the Act
Michaelmas T	October 10	December 17.

The act is 1st Monday after the 6th of July.—When the day of the beginning or ending happens on a Sunday, the terms begin or end the day after.

Cambridge-TERMS. These are three, as below:

Terms	Begin.	End
Lent Term	January 13	Frid. bef. Palm-Sun.
Easter Term	Wed. aft. Low-Sun	Frid. aft. Commence.
Michaelmas	October 10	December 16.

The commencement is the 1st Tuesday in July.—There is no difference on account of the beginning or ending being Sunday.

Scottish TERMS. In Scotland, Candlemas term begins January 23d, and ends February the 12th. Whitsuntide-term begins May 25th, and ends June 15th. Lammas-term begins July the 20th, and ends August the 8th. Martinmas term begins November the 3d, and ends November the 29th.

Irish TERMS. In Ireland the terms are the same as at London, except Michaelmas-term which begins October the 13th, and adjourns to November the 3d, and thence to the 6th.

TERMINATOR, in Astronomy, a name sometimes given to the circle of illumination, from its property of terminating the boundaries of light and darkness.

TERRA, in Geography. See EARTH.

TERRA-*firma*, in Geography, is sometimes used for a continent, in contradistinction to islands. Thus, Asia, the Indies, and South America, are usually distinguished into terra-firmas and islands.

TERRAQUEOUS, in Geography, an epithet given to our globe or earth, considered as consisting of land and water, which together constitute one mass.

TERRE-PLEIN, or TERRE-PLAIN, in Fortification, the top, platform, or horizontal surface of the rampart, upon which the cannon are placed, and where the defenders perform their office. It is so called, because it lies level, having only a little slope outwardly to counteract the recoil of the cannon. Its breadth is from 24 to 30 feet; being terminated by the parapet on the outer side, and inwardly by the inner talus.

TERRELLA, or little earth, is a magnet turned of a spherical figure, and placed so as that its poles, equator, &c, do exactly correspond with those of the world. It was so first called by Gilbert, as being a just representation of the great magnetic globe we inhabit. Such a terrella, it was supposed, if nicely poised, and hung in a meridian like a globe, would be turned round like the earth in 24 hours by the magnetic particles pervading it; but experience has shown that this is a mistake.

TERRESTRIAL, something relating to the earth. As terrestrial globe, terrestrial line, &c.

TERTIAN; denotes an old measure, containing 84 gallons, so called because it is the 3d part of a tun.

TERTIATE, in Gunnery. To tertiate a great gun, is to examine the thickness of the metal at the muzzle, by which to judge of the strength of the piece, and whether it be sufficiently fortified or not.

TETRACHORD, in Music, called by the moderns a fourth, is a concord or interval of 4 tones.—The tetrachord of the ancients, was a rank of 4 strings, accounting the tetrachord for one tone, as it is often taken in music.

TETRADIAPASON, or *Quadruple Diapason*, is a musical chord, otherwise called a quadruple eighth, or a nine-and-twentieth.

TETRAEDRON, or TETRAHEDRON, in Geometry, is one of the five Platonic or regular bodies or solids, comprehended under 4 equilateral and equal triangles. Or it is a triangular pyramid of 4 equal and equilateral faces. It is demonstrated in geometry, that the side of a tetraedron is to the diameter of its circumscribing sphere, as $\sqrt{2}$ to $\sqrt{3}$; consequently they are incommensurable.

If a denote the linear edge or side of a tetraedron, b its whole superficies, c its solidity, r the radius of its inscribed sphere, and R the radius of its circumscribing sphere; then the general relation among all these is expressed by the following equations, viz,

$$a = 2r\sqrt{6} = \tfrac{2}{3}R\sqrt{6} = \sqrt{\tfrac{1}{3}b\sqrt{3}} = \sqrt[3]{6c\sqrt{2}}.$$
$$b = 24r^2\sqrt{3} = \tfrac{8}{3}R^2\sqrt{3} = a^2\sqrt{3} = 6\sqrt[3]{c^2\sqrt{3}}.$$
$$c = 8r^3\sqrt{3} = \tfrac{8}{27}R^3\sqrt{3} = \tfrac{1}{12}a^3\sqrt{2} = \tfrac{1}{36}b\sqrt{2b\sqrt{3}}.$$
$$R = 3r = \tfrac{1}{4}a\sqrt{6} = \tfrac{1}{4}\sqrt{2b\sqrt{3}} = \tfrac{3}{2}\sqrt[3]{\tfrac{1}{3}c\sqrt{3}}.$$
$$r = \tfrac{1}{3}R = \tfrac{1}{12}a\sqrt{6} = \tfrac{1}{12}\sqrt{2b\sqrt{3}} = \tfrac{1}{2}\sqrt[3]{\tfrac{1}{3}c\sqrt{3}}.$$

See my Mensuration, pa. 186 &c, 4th edit. See also the articles REGULAR, and BODIES.

TETRAGON, in Geometry, a quadrangle, or a figure having 4 angles. Such as a square, a parallelogram, a rhombus, and a trapezium. It sometimes also means peculiarly a square.

TETRAGONIAS, a meteor, whose head is of a quadrangular figure, and its tail or train is long, thick, and uniform. It does not differ much from the meteor called *Trabs* or beam.

TETRAGONISM, a term which some authors use to express the quadrature of the circle, because the quadrature is the finding a square equal to it.

TETRASPASTON, in Mechanics, a machine in which are 4 pulleys.

TETRASTYLE, in the ancient Architecture, a building, and particularly a temple, with 4 columns in front.

THALES, a celebrated Greek philosopher, and the first of the seven wise men of Greece, was born at Miletum, about 640 years before Christ. After acquiring the usual learning of his own country, he travelled into Egypt and several parts of Asia, to learn astronomy, geometry, mystical divinity, natural knowledge or philosophy, &c. In Egypt he met for some time great favour from the king, Amasis; but he lost it again, by the freedom of his remarks on the conduct of kings, which it is said occasioned his return to his own country, where he communicated the knowledge he had acquired to many disciples, among the principal of whom were Anaximander, Anaximenes, and Pythagoras, and was the author of the Ionian sect of philosophers. He always however lived very retired, and refused the proffered favours of many great men. He was often visited by Solon; and it is said he took great pleasure in the conversation of Thrasybulus, whose excellent wit made him forget that he was tyrant of Miletum.

Laertius, and several other writers, agree that Thales was the father of the Greek philosophy; being the first that made any researches into natural knowledge and mathematics. His doctrine was, that water was the principle of which all the bodies in the universe are composed; that the world was the work of God; and that God sees the most secret thoughts in the heart of man. He observed that, in order to live well, we ought to abstain from what we find fault with in others: that bodily felicity consists in health, and that of the mind in knowledge: that the most ancient of beings is God, because he is uncreated: that nothing is more beautiful than the world, because it is the work of God; nothing more extensive than space, quicker than spirit, stronger than necessity, wiser than time. He used also to observe, that we ought never to say that to any one which may be turned to our prejudice; and that we should live with our friends as with persons that may become our enemies.

In geometry, it has been said, he was a considerable inventor, as well as an improver; particularly in that part concerning triangles. And all the writers agree, that he was the first, even in Egypt, who took the height of the pyramids by the shadow.

His knowledge and improvements in astronomy were very considerable. He divided the celestial sphere into five circles or zones, the arctic and antarctic circles, the two tropical circles, and the equator. He observed the apparent diameter of the sun, which he made equal to half a degree; and formed the constellation of the Little Bear. He also observed the nature and course of eclipses, and calculated them exactly; one in particular, memorably recorded by Herodotus, as it happened on a day of battle between the Medes and Lydians, which, Laertius says, he had foretold to the Ionians. And the same author informs us, that he divided the year into 365 days. Plutarch not only confirms his general knowledge of eclipses, but that his doctrine was, that an eclipse of the sun is occasioned by the intervention of the moon, and that an eclipse of the moon is caused by the intervention of the earth.

His morals were as just, as his mathematics well grounded, and his judgment in civil affairs equal to either. He was very averse to tyranny, and esteemed monarchy little better in any shape.—Diogenes Laertius relates, that, walking to contemplate the stars, he fell into a ditch; on which a good old woman, that attended him, exclaimed, "How canst thou know what is doing in the heavens, when thou seest not what is at thy feet?"—He went to visit Crœsus, who was marching a powerful army into Cappadocia, and enabled him to pass the river Halys without making a bridge. Thales died soon after, at above 90 years of age, it is said, at the Olympic games, where, oppressed with heat, thirst, and a load of years, he, in public view, sunk into the arms of his friends.

Concerning his writings, it remains doubtful whether he left any behind him; at least none have come down to us. Augustine mentions some books of Natural Philosophy; Simplicius, some written on Nautic Astrology; Laertius, two treatises on the Tropics and Equinoxes; and Suidas, a treatise on Meteors, written in verse.

THAMMUZ, in Chronology, the 10th month of the year of the Jews, containing 29 days, and answering to our June.

THEMIS, in Astronomy, a name given by some to the 3d satellite of Jupiter.

THEODOLITE, an instrument much used in surveying, for taking angles, distances, altitudes, &c. This instrument is variously made; different persons having their several ways of contriving it, each attempting to make it more simple and portable, more accurate and expeditious, than others. It usually consists of a brass circle, about a foot diameter, cut in form of fig. 5, pl. 36; having its limb divided into 360 degrees, and each degree subdivided either diagonally, or otherwise, into minutes. Underneath, at *cc*, are fixed two little pillars *bb* (fig. 6), which support an axis, bearing a telescope, for viewing remote objects.

On the centre of the circle moves the index c, which is a circular plate, having a compass in the middle, the meridian line of which answers to the fiducial line *aa*; at *bb* are fixed two pillars to support an axis, bearing a telescope like the former, whose line of collimation answers to the fiducial line *aa*. At each end of either telescope is, or may be, fixed a plain sight, for the viewing of nearer objects.

The ends of the index *aa* are cut circularly, to fit the divisions of the limb B; and when that limb is diagonally divided, the fiducial line at one end of the index shows the degrees and minutes on the limb. It is also furnished with cross spirit levels, for setting the plane of the circle truly horizontal; and a vertical arch, divided into degrees, for taking angles of elevation and depression. The whole instrument is mounted with a ball and socket, upon a three-legged staff.

Many theodolites however have no telescopes, but only four plain sights, two of them fastened on the limb, and two on the ends of the index. Two different ones, mounted on their stand, are represented in fig. 4 and 5, plate 21.

The use of the theodolite is abundantly shown in that of the semicircle, which is only half a theodolite. And the index and compass of the theodolite serve also for a circumferentor, and are used as such. The ingenious Mr. Ramsden made a most excellent theodolite, for the use of the military survey now carrying on in England.

THEODOSIUS, a celebrated mathematician, who flourished in the times of Cicero and Pompey; but the time and place of his death are unknown. This Theodosius, the Tripolite, as mentioned by Suidas, is probably the same with Theodosius the philosopher of Bithynia, who Strabo says excelled in the mathematical sciences, as also his sons; for the same person might have travelled from the one of those places to the other, and spent part of his life in each of them; like as Hipparchus was called by Strabo the Bithyman; but by Ptolemy and others the Rhodian.

Theodosius chiefly cultivated that part of geometry which relates to the doctrine of the sphere, concerning which he published three books. The first of these contains 22 propositions; the second 23; and the third 14; all demonstrated in the pure geometrical manner of the ancients. Ptolemy made great use of these propositions, as well as all succeeding writers. These books were translated by the Arabians, out of the original Greek, into their own language. From the Arabic, the work was again translated into Latin, and printed at Venice. But the Arabic version being very defective, a more complete edition was published in Greek and Latin, at Paris 1558, by John Pena, Regius Professor of Astronomy. And Vitello acquired reputation by translating Theodosius into Latin. This author's works were also commented on and illustrated by Clavius, Heleganius, and Gaurinus, and lastly by Dechales, in his Cursus Mathematicus. Theodosius's Spherics was also translated, and published, by our countryman the learned Dr. Barrow, in the year 1675, illustrated and demonstrated in a new and concise method. By this author's account, Theodosius appears not only to be a great master in this more difficult part of geometry, but the first considerable author of antiquity who has written on that subject. Another edition was published at Oxford 1707 in 8vo. by Jos. Hunt.

Theodosius wrote also concerning the Celestial Houses; also of Days and Nights; copies of which, in Greek, are in the king's library at Paris; of which there was a Latin edition, published by Peter Dasypody, in the year 1572.

THEON, of Alexandria, a celebrated Greek philosopher and mathematician, who flourished in the 4th century, about the year 380, in the time of Theodosius the Great; but the time and manner of his death are unknown. His genius and disposition for the study of philosophy were very early improved by a close application to study; so that he acquired such a proficiency in the sciences, as to render his name venerable in history; and to procure him the honour of being president of the famous Alexandrian school. One of his pupils was the admirable Hypatia, his daughter, who succeeded him in the presidency of the school; a trust, which, like himself, she discharged with the greatest honour and usefulness. [See her life in its place in the first volume of this Dictionary.]

The study of nature led Theon to many just conceptions concerning God, and to many useful reflections in the science of moral philosophy; hence, it is said, he wrote with great accuracy on divine providence. And he seems to have made it his standing rule, to judge the truth of certain principles, or sentiments, from their natural or necessary tendency. Thus, he says, that a full persuasion, that the Deity sees every thing we do, is the strongest incentive to virtue; for he insists, that the most profligate have power to refrain their hands, and hold their tongues, when they think they are observed, or overheard, by some person whom they fear or respect. With how much more reason then, says he, should the apprehension and belief, that God sees all things, restrain men from sin, and constantly excite them to their duty? He also represents this belief, concerning the Deity, as productive of the greatest pleasure imaginable, especially to the virtuous, who might depend with greater confidence on the favour and protection of Providence. For this reason, he recommends nothing so much as meditation on the presence of God: and he recommended it to the civil magistrate, as a restraint on such as were profane and wicked, to have the following inscription written, in large characters, at the corner of every street; GOD SEES THEE, O SINNER.

Theon wrote notes and commentaries on some of the ancient mathematicians. He composed also a book, entitled Progymnasmata, a rhetorical work, written with great judgment and elegance; in which he criticised on the writings of some illustrious orators and historians; pointing out, with great propriety and judgment, their beauties and imperfections; and laying down proper rules for propriety of style. He recommends conciseness of expression, and perspicuity, as the principal ornaments. This book was printed at Basle, in the year 1541; but the best edition is that of Leyden, in 1626, in 8vo.

THEOPHRASTUS, a celebrated Greek philosopher, was the son of Melanthus, and was born at Eretus in Bœotia. He was at first the disciple of Lucippus, then of Plato, and lastly of Aristotle; whom he succeeded in his school, about the 322d year before the Christian era, and taught philosophy at Athens with great applause. He said of an orator without judgment, "that he was a horse without a bridle." He used also to say, "There is nothing so valuable as time, and those who lavish it are the most inexcusable of all prodigals."—He died at about 100 years of age.

Theophrastus wrote many works, the principal of which are the following.—1. An excellent moral treatise entitled, Characters, which, he says in the preface, he composed at 99 years of age. Isaac Casaubon has written learned commentaries on this small treatise. It has been translated from the Greek into French, by Bruyere; and it has also been translated into English.—2. A curious treatise on Plants.—3. A treatise on fossils or stones; of which Dr. Hill has given a good edition, with an English translation, and learned notes, in 8vo.

THEOREM, a proposition which terminates in theory, and which considers the properties of things already made or done. Or, a theorem is a speculative proposition, deduced from several definitions compared together. Thus, if a triangle be compared with a parallelogram standing on the same base, and of the same altitude, and partly from their immediate definitions, and partly from other of their properties already determined, it is inferred that the parallelogram is double the triangle; that proposition is a theorem.

Theorem stands contradistinguished from problem, which denotes something to be done or constructed, as a theorem proposes something to be proved or demonstrated.

There are two things to be chiefly regarded in every theorem, viz, the proposition, and the demonstration. In the first is expressed what agrees to some certain thing, under certain conditions, and what does not. In the latter, the reasons are laid down by which the understanding comes to conceive that it does or does not agree to it. Theorems are of various kinds: as,

Universal THEOREM, is that which extends to any quantity without restriction, universally. As this, that the rectangle or product of the sum and difference of any two quantities, is equal to the difference of their squares.

Particular THEOREM, is that which extends only to a particular quantity. As this, in an equilateral rectilinear triangle, each angle is equal to 60 degrees.

Negative THEOREM, is that which expresses the impossibility of any assertion. As, that the sum of two biquadrate numbers cannot make a square number.

Local THEOREM, is that which relates to a surface. As, that triangles of the same base and altitude are equal.

Plane THEOREM, is that which relates to a surface that is either rectilinear or bounded by the circumference of a circle. As, that all angles in the same segment of a circle are equal.

Solid THEOREM, is that which considers a space terminated by a solid line; that is, by any of the three conic sections. As this, that if a right line cut two asymptotic parabolas, its two parts terminated by them shall be equal.

Reciprocal THEOREM, is one whose converse is true. As, that if a triangle have two sides equal, it has also two angles equal: the converse of which is likewise true, viz, that if the triangle have two angles equal, it has also two sides equal.

THEORY, a doctrine which terminates in the sole speculation or consideration of its object, without any view to the practice or application of it. To be learned in an art, &c, the theory is sufficient; to be a master of it, both the theory and practice are requisite.—Machines often promise very well in theory, but fail in the practice.—We say, theory of the moon, theory of the rainbow, of the microscope, of the camera obscura, &c.

THEORIES *of the Planets*, &c, are systems or hypotheses, according to which the astronomers explain the reasons of the phenomena or appearances of them.

THERMOMETER, an instrument for measuring the temperature of the air, &c, as to heat and cold.

The invention of the thermometer is attributed to several persons by different authors, viz, to Sanctorio, Galileo, father Paul, and to Drebbel. Thus, the invention is ascribed to Cornelius Drebbel of Alcmar, about the beginning of the 17th century, by his countrymen Boerhaave (Chem. 1, pa. 152, 156), and Musschenbroek (Introd. ad Phil. Nat. vol. 2, pa. 625).—Fulgenzio, in his Life of Father Paul, gives him the honour of the first discovery.—Vincenzio Viviani (Vit. de l'Galil. pa. 67; also Oper. di Galil. pref. pa. 47) speaks of Galileo as the inventor of thermometers.—But Sanctorino (Com. in Galen. Art. Med. pa. 736, 842, Com. in Avicen. Can. Fen. 1, pa. 22, 78, 219) expressly assumes to himself this invention: and Borelli (De Mot. Animal. 2, prop. 175) and Malpighi (Oper. Posth. pa. 30) ascribe it to him without reserve. Upon which Dr. Martine remarks, that these Florentine academicians are not to be suspected of partiality in favour of one of the Patavinian school.

But whoever was the first inventor of this instrument, it was at first very rude and imperfect; and as the various degrees of heat were indicated by the different contraction or expansion of air, it was afterwards found to be an uncertain and sometimes a deceiving measure of heat, because the bulk of the air was affected, not only by the difference of heat, but also by the variable weight of the atmosphere.—There are various kinds of thermometers, the construction, defects, theory, &c, of which, are as follow.

The Air THERMOMETER.—This instrument depends on the rarefaction of the air. It consists of a glass tube BE (fig. 1, pl. 39) connected at one end with a large glass ball A, and at the other end immersed in an open vessel, or terminating in a ball DE, with a narrow orifice at D; which vessel, or ball, contains any coloured liquor that will not easily freeze. Aquafortis tinged of a fine blue colour with solution of vitriol or copper, or spirit of wine tinged with cochineal, will answer this purpose. But the ball A must be first moderately warmed, so that a part of the air contained in it may be expelled through the orifice D; and then the liquor pressed by the weight of the atmosphere, will enter the ball DE, and rise, for example, to the middle of the tube at C, at a mean temperature of the weather; and in this state the liquor by its weight, and the air included in the ball and tube ABC, by its elasticity, will counterbalance the weight of the atmosphere. As the surrounding air becomes warmer, the air in the ball and the upper part of the tube, expanding by heat, will drive the liquor into the lower ball, and consequently its surface will descend; on the contrary, as the ambient air becomes colder, that in the ball is condensed, and the liquor, pressed by the weight of the atmosphere, will ascend: so that the liquor in the tube will ascend or descend more or less, according to the state of the air contiguous to instrument. To the tube is affixed a scale of the same length, divided upwards and downwards, from the middle C, into 100 equal parts, by means of which may be observed the ascent and descent of the liquor in the tube, and consequently the variations also in the temperature of the atmosphere.

A similar thermometer may be constructed by putting a small quantity of mercury, not exceeding the bulk of a pea, into the tube BC (fig. 4, pl. 39), bent into wreaths, that taking up the less height, it may be the more manageable, and less liable to harm; divide this tube into any number of equal parts to serve for a scale. Here the approaches of the mercury towards the ball A will show the increase of the degree of heat. The reason of which is the same as in the former.

The defect of both these instruments consists in this, that they are liable to be acted on by a double cause: for, not only a decrease of heat, but also an increase of weight of the atmosphere, will make the liquor rise in the one, and the mercury in the other; and, on the contrary, either an increase of heat, or decrease of the weight of the atmosphere, will cause them to descend.

For these, and other reasons, thermometers of this kind have long been disused. However, M. Amontons, in 1702, with a view of perfecting the aërial thermometer, contrived his Universal Thermometer. Finding that the changes produced by heat and cold in the bulk of the air were subject to invincible irregularities, he substituted for these the variations produced by heat in the elastic force of this fluid. This thermometer consisted of a long tube of glass (fig. 3, pl. 39) open at one end, and recurved at the other end, which terminated in a ball. A certain quantity of air was compressed into this ball by the weight of a column of mercury, and also by the weight of the atmosphere. The effect of heat on this included air was to make it sustain a greater or less weight; and this effect was measured by the variation of the column of mercury in the tube, corrected by that of the barometer, with respect to the changes of the weight of the external air. This instrument, though much more perfect than the former, is nevertheless subject to very considerable defects and inconveniences. Its length of 4 feet renders it unfit for a variety of experiments, and its construction is difficult and complex: it is extremely inconvenient for carriage, as a very small inclination of the tube would suffer the included air to escape: also the friction of the mercury in the tube, and the compressibility of the air, contribute to render the indications of this instrument extremely uncertain. Besides, the dilatation of the air is not so regularly proportional to its heat, nor is its dilatation by a given heat nearly so uniform as he supposed. This depends much on its moisture; for dry air does not expand near so much by a given heat, as air stored with watery particles. For these, and other reasons, enumerated by Deluc (Recherches sur les Mod. de l'Atmo. tom. 1, pa. 278 &c), this instrument was imitated by very few, and never came into general use.

Of the Florentine THERMOMETER.—The academists del Cimento, about the middle of the 17th century, considering the inconveniencies of the air thermometers above described, attempted another, that should measure heat and cold by the rarefaction and condensation of spirit of wine; though much less than those of air, and consequently the alterations in the degree of heat likely to be much less sensible.

The spirit of wine coloured, was included in a very fine and cylindrical glass tube (fig. 2, pl. 39), exhausted of its air, having a hollow ball at one end A, and hermetically sealed at the other end D. The ball and tube are filled with rectified spirit of wine to a convenient height, as to C, when the weather is of a mean temperature, which may be done by inverting the tube into a vessel of stagnant coloured spirit, under a receiver of the air-pump, or in any other way. When the thermometer is properly filled, the end D is heated red hot by a lamp, and then hermetically sealed, leaving the included air of about ⅓ of its natural density, to prevent the air which is in the spirit from dividing it in its expansion. To the tube is applied a scale, divided from the middle, into 100 equal parts, upwards and downwards.

Now spirit of wine rarefying and condensing very considerably; as the heat of the ambient atmosphere increases, the spirit will dilate, and so ascend in the tube; and as the heat decreases, the spirit will descend; and the degree or quantity of the motion will be shown by the attached scale.

These thermometers could not be subject to any inconvenience by an evaporation of the liquor, or a variable gravity of the incumbent atmosphere. Instruments of this kind were first introduced into England by Mr. Boyle, and they soon came into general use among philosophers in other countries. They are however subject to considerable inconveniences, from the weight of the liquor itself, and from the elasticity of the air above it in the tube, both which prevent the freedom of its ascent; besides, the rarefactions are not exactly proportional to the surrounding heat. Moreover spirit of wine is incapable of bearing very great heat or very great cold: it boils sooner than any other liquor; and therefore the degrees of heat of boiling fluids cannot be determined by this thermometer. And though it retains its fluidity in pretty severe cold, yet it seems not to condense very regularly in them: and at Torneao, near the polar circle, the winter cold was so severe, as Maupertuis informs us, that the spirits were frozen in all their thermometers. So that the degrees of heat and cold, which spirit of wine is capable of indicating, is much too limited to be of very great or general use.

Another great defect of these, and other thermometers, is, that their degrees cannot be compared with each other. It is true they mark the variations of heat and cold; but each marks for itself, and after its own manner; because they do not proceed from any point of temperature that is common to all of them.

From these and various other imperfections in these thermometers, it happens, that the comparisons of them become so precarious and defective: and yet the most curious and interesting use of them, is what ought to arise from such comparison. It is by this we should know the heat or cold of another season, of another year, another climate, &c; and what is the greatest degree of heat or cold that men and other animals can subsist in.

Reaumur contrived a new thermometer, (fig. 3, pl. 39) in which the inconveniences of the former are proposed to be remedied. He took a large ball and tube, the content or dimensions of which are known in every part; he graduated the tube, so that the space from one division to another might contain a 1000th part of the liquor, which liquor would contain 1000 parts when it stood at the freezing point: then putting the ball of his thermometer and part of the tube into boiling water, he observed whether it rose 80 divisions: if it exceeded these, he changed his liquor, and by adding water lowered it, till upon trial it should just rise 80 divisions; or if the liquor, being too low, fell short of 80 divisions, he raised it by adding rectified spirit to it. The liquor thus prepared suited his purpose, and served for making a thermometer of any size, whose scale would agree with his standard. Such liquor, or spirits, being about the strength of common brandy, may easily be had any where, or made of a proper degree of density by raising or lowering it.

The abbé Nollet made many excellent thermometers upon Reaumur's principle. Dr. Martine however expresses his apprehensions that thermometers of this kind cannot admit of such accuracy as might be wished. The balls or bulbs, being large, as 3 or 4 inches in diameter, are neither heated nor cooled soon enough to show the variations of heat. Small bulbs and small tubes, he says, are much more convenient, and may be constructed with sufficient accuracy. Though it must be allowed that Reaumur, by his excellent scale, and by depriving the spirit of its air, and expelling the air by means of heat from the ball and tube of his thermometer, has brought it to as much perfection as may be; yet it is liable to some of the inconveniences of spirit thermometers, and is much inferior to mercurial ones. These two kinds do not agree together in indicating the same degrees of intense cold; for when the mercury has stood at 22° below 0, the spirit indicated only 18°, and when the mercury stood at 28° or 37° below 0, the spirit rested at 25° or 29°. See the description of Reaumur's thermometer at large in Mem. de l'Acad. des Scienc. an. 1730, pa. 645, Hist. pa. 15. Ib. an. 1731, pa. 354, Hist. pa. 7.

Mercurial THERMOMETER.—It is a most important circumstance in the construction of thermometers, to procure a fluid that measures equal variations of heat by corresponding equal variations in its own bulk: and the fluid which possesses this essential requisite in the most perfect degree, is mercury: the variations in its bulk approaching nearer to a proportion with the corresponding variations of its heat, than any other fluid. Besides, it is the most easy to purge of its air; and is also the most proper for measuring very considerable variations of heat and cold, as it will bear more cold before freezing, and more heat before boiling, than any other fluid. Mercury is also more sensible than any other fluid, air excepted, or conforms more speedily to the several variations of heat. Moreover, as mercury is an homogeneous fluid, it will in every thermometer exhibit the same dilatation or condensation by the same variations of heat.

Dr. Halley, though apprised only of some of the remarkable properties of mercury above recited, seems to have been the first who suggested the application of this fluid to the construction of thermometers. Philos. Trans. vol. 3, pa. 505.

Boerhaave (Chem. 1, pa. 720) says, these mercurial thermometers were first contrived by Olaus Roemer; but the claims of Fahrenheit of Amsterdam, who gave an account of his invention to the Royal Society in 1724, (Philos. Trans. No. 381,) have been generally allowed. And though Prius and others, in England, Holland, France, and other countries, have made this instrument as well as Fahrenheit, yet most of the mercurial thermometers are graduated according to his scale, and are called Fahrenheit's thermometers.

The cone or cylinder, which these thermometers are often made with, instead of the ball, is made of glass of a moderate thickness, lest, when the exhausted tube is hermetically sealed, its internal capacity should be diminished by the weight of the ambient atmosphere. When the mercury is thoroughly purged of its air and moisture by boiling, the thermometer is filled with a sufficient quantity of it; and before the tube is hermetically sealed, the air is wholly expelled from it by heating the mercury, so that it may be rarefied and ascend to the top of the tube. To the side of the tube is annexed a scale (fig. 7, pl. 39), which Fahrenheit divided into 600 parts, beginning with that of the severe cold which he had observed in Iceland in 1709, or that produced by surrounding the bulb of the thermometer with a mixture of snow or beaten ice and sal ammoniac or sea salt. This he apprehended to be the greatest degree of cold, and accordingly he marked this, as the beginning of his scale, with 0; the point at which mercury begins to boil, he conceived to show the greatest degree of heat, and this he made the limit of his scale. The distance between these two points he divided into 600 equal parts or degrees; and by trials he found at the freezing point, when water just begins to freeze, or snow or ice just begins to thaw, that the mercury stood at 32 of these divisions, therefore called the degree of the freezing point; and when the tube was immersed in boiling water, the mercury rose to 212, which therefore is the boiling point, and is just 180 degrees above the former or freezing point. But the present method of making the scale of these thermometers, which is the kind in most common use, is first to immerge the bulb of the thermometer in ice or snow just beginning to thaw, and mark the place where the mercury stands with 32; then immerge it in boiling water, and again mark the place where the mercury stands in the tube, which mark with the No. 212, exceeding the former by 180; dividing therefore the intermediate space into 180 equal parts, will give the scale of the thermometer, and which may afterwards be continued upwards and downwards at pleasure.

Other thermometers of a similar construction have been accommodated to common use, having but a portion of the above scale. They have been made of a small size and portable form, and adapted with appendages to particular purposes; and the tube with its annexed scale has often been enclosed in another thicker glass tube, also hermetically sealed, to preserve the thermometer from injury. And all these are called Fahrenheit's thermometers.

In 1733, M. Delisle of Petersburg constructed a mercurial thermometer (see fig. 3, pl. 34), on the principles of Reaumur's spirit thermometer. In his thermometer, the whole bulk of quicksilver, when immerged in boiling water, is conceived to be divided into 100,000 parts; and from this one fixed point the various degrees of heat, either above or below it, are marked in these parts on the tube or scale, by the various expansion or contraction of the quicksilver in all imaginable varieties of heat.—Dr. Martine apprehends it would have been better if Delisle had made the integer 100,000 parts, or fixed point, at freezing water, and from thence computed the dilatations or condensations of the quicksilver in those parts; as all the common observations of the weather, &c, would have been expressed by numbers increasing as the heat increased, instead of decreasing, or counting the contrary way. However, in practice it will not be very easy to determine exactly all the divisions from the alteration of the bulk of the contained fluid. And besides, as glass itself is dilated by heat, though in a less proportion than quicksilver, it is only the excess of the dilatation of the contained fluid above that of the glass that is observed; and therefore if different kinds of glass be differently affected by a given degree of heat, this will make a seeming difference in the dilatations of the quicksilver in the thermometers constructed in the Newtonian method, either by Reaumur's rules or Delisle's. Accordingly it has been found, that the quicksilver in Delisle's thermometers has stood at different degrees of the scale when immerged in thawing snow: having stood in some at 154°, while in others it has been at 156 or even 158°.

Metallic THERMOMETER.—This is a name given to a machine composed of two metals, which, while it indicates the variations of heat, serves to correct the errors hence resulting in the going of pendulum clocks and watches. Instruments of this kind have been contrived by Graham, Le Roy, Ellicot, Harrison, and other eminent artificers. See the Philos. Trans. vol. 44, pa. 689, and vol. 45, pa. 129, and vol. 51, pa. 823, where the particular descriptions &c may be seen.

M. Deluc has likewise described two thermometers of metal, which he uses for correcting the effects of heat upon a barometer, and an hygrometer of his construction connected with them. See Philos. Trans. vol. 68, pa. 437.

Oil THERMOMETERS.—To this class belongs Newton's thermometer, constructed in 1701, with linseed oil, instead of spirit of wine. This fluid has the advantage of being sufficiently homogeneous, and capable of 15 times greater rarefaction than that of spirit of wine. It has not been observed to freeze even in very great colds; and it sustains a great heat, about 4 times that of water, before it boils. With these advantages it was made use of by Sir I. Newton, who discovered by it the comparative degree of heat for boiling water, melting wax, boiling spirit of wine, and melting tin; beyond which it does not appear that this thermometer was applied. The method he used for adjusting the scale of this oil thermometer, was as follows: supposing the bulb, when immerged in thawing snow, to contain 10,000 parts, he found the oil expanded by the heat of the human body so as to take up a 39th more space, or 10256 such parts; and by the heat of water boiling strongly 10725; and by the heat of melting tin 11516. So that, reckoning the freezing point as a common limit between heat and cold, he began his scale there, marking it 0, and the heat of the human body he made 12°; and consequently, the degrees of heat being proportional to the degrees of rarefaction, or 256 : 725 : : 12 : 34, this number 34 will express the heat of boiling water; and, by the same rule, 72 that of melting tin. Philos. Trans. No. 270.

There is an insuperable inconvenience attending all thermometers made with oil, or any other viscid fluid, viz, that such liquor adheres too much to the sides of the tube, and so inevitably disturbs the regularity and uniformity of the thermometer.

Of the fixed points of THERMOMETERS.—Various methods have been proposed by different authors, for finding a fixed point or degree of heat, from which to reckon the other degrees, and adjust the scale; so that different observations and instruments might be compared together. Mr. Boyle was very sensible of the inconveniencies arising from the want of a universal scale and mode of graduation; and he proposed either the freezing of the essential oil of aniseeds, or of distilled water, as a term to begin the numbers at, and from thence to graduate them according to the proportional dilatations or contractions of the included spirits.

Dr. Halley (Philos. Trans. vol. 3.) seems to have been fully apprised of the bad effects of the indefinite method of constructing thermometers, and wished to have them adjusted to some determined points. What he seems to prefer, for this purpose, is the degree of temperature found in subterranean places, where the heat in summer or cold in winter appears to have no influence. But this degree of temperature, Dr. Martine shows, is a term for the universal construction of thermometers, both inconvenient and precarious, as it cannot be easily ascertained, and as the difference of soils and depths may occasion a considerable variation. Another term of heat, which he thought might be of use in a general graduation of thermometers, is that of boiling spirit of wine that has been highly rectified.

The first trace that occurs of the method of actually applying fixed points or terms to the thermometer, and of graduating it, so that the unequal divisions of it might correspond to equal degrees of heat, is the project of Renaldini, professor at Padua, in 1694: it is thus described in the Acta Erud. Lips. "Take a slender tube, about 4 palms long, with a ball fastened to the same; pour into it spirit of wine, enough just to fill the ball, when surrounded with ice, and not a drop over: in this state seal the orifice of the tube hermetically, and provide 12 vessels, each capable of containing a pound of water, and somewhat more; and into the first pour 11 ounces of cold water, into the second 10 ounces, into the third 9, &c; this done, immerge the thermometer in the first vessel, and pour into it one ounce of hot water, observing how high the spirit rises in the tube, and noting the point with unity; then remove the thermometer into the second vessel, into which are to be poured 2 ounces of hot water, and note the place the spirit rises to with 2: by thus proceeding till the whole pound of water is spent, the instrument will be found divided into 12 parts, denoting so many terms or degrees of heat; so that at 2 the heat is double to that at 1, at 3 triple, &c."

But this method, though plausible, Wolfius shows, is deceitful, and built on false suppositions; for it takes for granted, that we have one degree of heat, by adding one ounce of hot water to 11 of cold; two degrees by adding 2 ounces to 10, &c: it supposes also, that a single degree of heat acts on the spirit of wine, in the ball, with a single force; a double with a double force, &c: lastly it supposes, that if the effect be produced in the thermometer by the heat of the ambient air, which is here produced by the hot water, the air has the same degree of heat with the water.

Soon after this project of Renaldini, viz, in 1701, Newton constructed his oil thermometer, and placed the base or lowest fixed point of his scale at the temperature of thawing snow, and 12 at that of the human body, &c, as above explained.—Deluc observes, that the 2d term of this scale should have been at a greater distance from the first, and that the heat of boiling water would have answered the purpose better than that of the human body.

In 1702, Amontons contrived his universal thermometer, the scale of which was graduated in the following manner. He chose for the first term, the weight that counterbalanced the air included in his thermometer, when it was heated by boiling water: and in this state he so adjusted the quantity of mercury contained in it, till the sum of its height in the tube, and of its height in the barometer at the moment of observation, was equal to 73 inches. Fixing this number at the point to which the mercury in the tube rose by plunging it in boiling water, it is evident that if the barometer at this time was at 28 inches, the height of the column of mercury in the thermometer, above the level of that in the ball, was 45 inches; but if the height of the barometer was less by a certain quantity, the column of the thermometer ought to be greater by the same quantity, and reciprocally. He formed his scale on the supposition, that the weight of the atmosphere was always equal to that of a column of mercury of 28 inches, and he divided it into inches from the point 73 downward, marking the divisions with 72, 71, 70, &c, and subdividing the inches into lines. But as the weight of the atmosphere is variable, the barometer must be observed at the same time with the thermometer, that the number indicated by this last instrument may be properly corrected, by adding or subtracting the quantity which the mercury is below or above 28 inches in the barometer. In this scale, then, the freezing point is at 51½ inches, corresponding to 32 degrees of Fahrenheit, and the heat of boiling water at 73 inches, answering to 212 of Fahrenheit's; and thus they may be easily compared together.

The fixed points of Fahrenheit's thermometer, as has been already observed, are the congelation produced by sal ammoniac and the heat of boiling water. The interval between these points is divided into 212 equal parts; the former of these points being marked 0, and the other 212.

Reaumur in his thermometer, the construction of which he published in 1730, begins his scale at an artificial congelation of water in warm weather, which, as he uses large bulbs for his glasses, gives the freezing point much higher than it should be, and at boiling water he marks 80 degrees, which point Dr. Martine thinks is more vague and uncertain than his freezing point. In order to determine the correspondence of his scale with that of Fahrenheit, it is to be considered that his boiling water heat, is really only the boiling heat of weakened spirit of wine, coinciding nearly, as Dr. Martine apprehends, with Fahrenheit's 180 degrees. And as his 10¼ degrees is the constant heat of the cave of the observatory at Paris, or Fahrenheit's 53°, he thence finds his freezing point, instead of answering just to 32°, to be somewhat above 34°.

In Celsius's thermometer (exhibited in plate 39, fig. 8), which is mercurial, the two fixed terms are the degree at which ice begins to thaw, and that which answers to the heat of boiling water. The interval between these two limits is divided into a hundred equal parts, and the zero of the scale, which is the inferior limit, corresponds to 32° of Fahrenheit; so that 9 degrees of Fahrenheit's scale are equivalent to 5 degrees of Celsius's. This thermometer is now generally called the Centigrade thermometer.

Delisle's thermometer, an account of which he presented to the Petersburg Academy in 1733, has only one fixed point, which is the heat of boiling water, and, contrary to the common order, the several degrees are marked from this point downward, according to the condensations of the contained quicksilver, and consequently by numbers increasing as the heat decreases. The freezing point of Delisle's scale, Dr. Martine makes near to his 150°, corresponding to Fahrenheit's 32°, by means of which they may be compared; but Ducrest says, that this point ought to be marked at least at 154°.

Ducrest, in his spirit thermometer, constructed in 1740, made use of two fixed points; the first, or 0, indicated the temperature of the earth, and was marked on his scale in the cave of the Paris Observatory; and the other was the heat of boiling water, which that spirit in his thermometer was made to endure, by leaving the upper part of the tube full of air. He divided the interval between these points into 100 equal parts; calling the divisions upward, degrees of heat, and those below 0, degrees of cold.—It is said that he has since regulated his thermometer by the degree of cold indicated by melting ice, which he found to be 10⅖.

The Florentine thermometers were of two kinds. In one sort the freezing point, determined by the degree at which the spirit stood in the ordinary cold of ice or snow (probably in a thawing state) and coinciding with 32° of Fahrenheit, fell at 20°; and in the other kind at 13½. And the natural heat of the viscera of cows and deer, &c, raised the spirit in the latter, or less sort, to about 40°, coinciding with their summer heat, and nearly with 102° in Fahrenheit's; and in their other or long thermometer, the spirit, when exposed to the great midsummer heat in their country, rose to the point at which they marked 80°.

In the thermometer of the Paris Observatory, made of spirit of wine by Lahire, the fluid always stands at 48° in the cave of the observatory, corresponding to 53 degrees in Fahrenheit's; and his 28° corresponded with 51 inches 6 lines in Amontons' thermometer, and consequently with the freezing point, or 32° of Fahrenheit's.

In Poleni's thermometer, made after the manner of Amontons', but with less mercury, 47 inches corresponded, according to Dr. Martine, with 51 in that of Amontons, and 53 with 59½.

In the standard thermometer of the Royal Society of London, according to which thermometers were for a long time constructed in England, Dr. Martine found that 34½ degrees answered to 64° in Fahrenheit, and 0 to 89.

In the thermometers graduated for adjusting the degrees of heat proper for exotic plants, &c, in stoves and greenhouses, the middle temperature of the air is marked at 0, and the degrees of heat and cold are numbered both above and below. Many of these are made on no regular and fixed principles. But in that formerly much used, called Fowler's regulator, the spirit fell, in melting snow, to about 34° below 0; and Dr. Martine found that his 16° above 0, nearly coincided with 64°, of Fahrenheit.

Dr. Hales (Statical Essays, vol. 1, pa. 58), in his thermometer, made with spirit of wine, and used in experiments on vegetation, began his scale with the lowest degree of freezing, or 32° of Fahrenheit, and carried it up to 100°, which he marked where the spirit stood when the ball was heated in hot water, upon which some wax floating first began to coagulate, and this point Dr. Martine found to correspond with 142° of Fahrenheit. But by experience it is found that Hales's 100 falls considerably above 142.

In the Edinburgh thermometer, made with spirit of wine, and used in the meteorological observations published in the Medical Essays, the scale is divided into inches and tenths. In melting snow the spirit stood at $8\frac{2}{10}$, and the heat of the human skin raised it to $22\frac{2}{10}$. Dr. Martine found that the heat of the person who graduated it, was 97 of Fahrenheit.

The new French thermometer, called the Centigrade Thermometer, contains 100 degrees between the freezing and boiling points of water; and those degrees further divided decimally by a vernier, &c.

From the abstract of the history of the construction of thermometers, it appears that freezing and boiling water have furnished the distinguishing points that have been marked upon almost all thermometers. The inferior fixed point is that of freezing, which some have determined by the freezing of water, and others by the melting of ice, plunging the ball of the thermometer into the water and ice, while melting, which is the best way. The superior fixed point of almost all thermometers, is the heat of boiling water. But this point cannot be considered as fixed and certain, unless the heat be produced by the same degree of boiling, and under the same weight of the atmosphere; for it is found that the higher the barometer, or the heavier the atmosphere, the greater is the heat when the water boils. It is now agreed therefore that the operation of plunging the ball of the thermometer in the boiling water, or suspending it in the steam of the same in an enclosed vessel, should be performed when the water boils violently, and when the barometer stands at 30 English inches, in a temperature of 55° of the atmosphere, marking the height of the thermometer then for the degree of 212 of Fahrenheit; the point of melting ice being 32 of the same; thus having 180 degrees between those two fixed points, so determined. This was Mr. Bird's method, who it is apprehended first attended to the state of the barometer, in the making of thermometers. But these instruments may be made equally true under any pressure of the atmosphere, by making a proper allowance for the difference in the height of the barometer from 30 inches. M. Deluc, in his Recherches sur les Mod. de l'Atmosphere, from a series of experiments, has given an equation for the allowance on account of this difference, in Paris measure, which has been verified by sir George Shuckburgh, Philos. Trans. 1775 and 1778; also Dr. Horsley, Dr. Maskelyne, and sir George Shuckburgh have adapted the equation and rules, to English measures, and have reduced the allowances into tables for the use of the artist. Dr. Horsley's rule, deduced from Deluc's, is this: $\frac{99000}{899}$ log. z − 92·804 = h, where h denotes the height of a thermometer plunged in boiling water, above the point of melting ice, in degrees of Bird's Fahrenheit, and z the height of the barometer in 10ths of an inch. From this rule he has computed the following table, for finding the heights, to which a good Bird's Fahrenheit will rise, when immersed in boiling water, in all states of the barometer, from 27 to 31 English inches; which will serve, among other uses, to direct instrument-makers in making a true allowance for the effect of the variation of the barometer, if they should be obliged to finish a thermometer at a time when the barometer is above or below 30 inches; though it is best to fix the boiling point when the barometer is at that height.

Equation of the Boiling Point.

Barometer.	Equation.	Difference.
31·0	+ 1·57	0·78
30·5	+ 0·79	0·79
30·0	0·00	0·80
29·5	− 0·80	0·82
29·0	− 1·62	0·83
28·5	− 2·45	0·85
28·0	− 3·31	0·86
27·5	− 4·16	0·88
27·0	− 5·04	

The numbers in the first column of this table express heights of the quicksilver in the barometer in English inches and decimal parts: the 2d column shows the equation to be applied, according to the sign prefixed, to 212° of Bird's Fahrenheit, to find the true boiling point for every such state of the barometer. The boiling point for all intermediate states of the barometer may be had with sufficient accuracy by taking proportional parts, by means of the 3d column of differences of the equations. See Philos. Trans. vol. 64, art. 30; also Dr. Maskelyne's paper, vol. 64, art. 20.

Sir Geo. Shuckburgh (Philos. Trans. vol. 69, pa. 362) has also given several tables and rules relating to the boiling point, both from his own observations and Deluc's, from which is extracted the following table, for the use of artists in constructing the thermometer.

Height of the Barom.	Corr. of the Boiling Point.	Differences.	Correct. accord. to Deluc.	Differences.
26·0	− 7·09	0·91	− 6·83	0·90
26·5	− 6·18	0·91	− 5·93	0·89
27·0	− 5·27	0·90	− 5·04	0·88
27·5	− 4·37	0·89	− 4·16	0·87
28·0	− 3·48	0·89	− 3·31	0·86
28·5	− 2·59	0·87	− 2·45	0·83
29·0	− 1·72	0·87	− 1·62	0·82
29·5	− 0·85	0·85	− 0·80	0·80
30·0	0·00	0·85	0·00	0·79
30·5	+ 0·85	0·84	+ 0·79	0·78
31·0	+ 1·60		+ 1·57	

The Royal Society too, fully sensible of the importance of adjusting the fixed points of thermometers, appointed a committee of seven gentlemen to consider of the best method for this purpose; and their report may be seen in the Philos. Trans. vol. 67, art. 37.

They observe, that though the boiling point be placed so much higher on some of the thermometers now made, than on others, yet this does not produce any considerable error in the observations of the weather, at least in this climate; for an error of 1½ degree in the position of the boiling point, will make an error only of half a degree in the position of 92°, and of not more than a quarter of a degree in the point of 62°. It is only in nice experiments, or in trying the heat of hot liquors, that this error in the boiling point can be of much signification.

In adjusting the freezing, as well as the boiling point, the quicksilver in the tube ought to be kept of the same heat as that in the ball. When the freezing point is placed at a considerale distance from the ball, the pounded ice should be piled up very near to it; if it be not so piled, then the observed point, to be very accurate, should be corrected, according to the annexed table.

Heat of the Air.	Correction.
42°	·00087
52	·00174
62	·00261
72	·00348
82	·00435

The correction in this table is expressed in 1000th parts of the distance between the freezing point and the surface of the ice: ex. gr. if the freezing point stand 6 inches above the surface of the ice, and the heat of the room be 62, then the point of 32 should be placed 6 × ·00261, or ·01566 of an inch below the observed point.

The committee further observe, that in examining the heat of liquors, care should be taken that the quicksilver in the tube of the thermometer be heated to the same degree as that in the ball; or if this cannot be done conveniently, the observed heat should be corrected on that account; for the manner of doing which, and a table calculated for that purpose, see Philos. Trans. vol. 67, art. 37.

It was for some time thought, especially from the experiments at Petersburg, that quicksilver suffered a cold of several hundred degrees below 0 before it congealed and became fixed and malleable; but later experiments have shown that this persuasion was merely owing to a deception in the experiments, and later ones have made it appear that its point of congelation is no lower than − 40°, or rather − 39°, of Fahrenheit's scale. But that it will bear however to be cooled a few degrees below that point, to which it leaps up again on beginning to congeal; and that its rapid descent in a thermometer, through many hundred degrees, when it has once passed the above-mentioned limit, proceeds merely from its great contraction in the act of freezing. See Philos. Trans. vol. 73, art. *20, 20, 21.

Miscellaneous Observations.

It is absolutely necessary that those who would derive any advantage from these instruments, should agree in using the same liquor, and in determining, according to the same method, the two fundamental points. If they agree in these fixed points, it is of no great importance whether they divide the interval between them into a greater or a less number of equal parts. The scale of Fahrenheit, in which the fundamental interval between 212°, the point of boiling water, and 32° that of melting ice, is divided into 180 parts, should be retained in the northern countries, where Fahrenheit's thermometer is used: and the scale in which the fundamental interval is divided into 80 parts, will serve for those countries where Reaumur's thermometer is adopted. But no inconvenience is to be apprehended from varying the scale for particular uses, provided care be taken to signify into what number of parts the fundamental interval is divided, and the point where 0 is placed.

With regard to the choice of tubes, it is best to have them exactly cylindrical through their whole length. The capillary tubes are preferable to others, because they require smaller bulbs, and they are also more sensible, and less brittle. The most convenient size for common experiments has the internal diameter about the 40th or 50th of an inch, about 9 inches long, and made of thin glass, that the rise and fall of the mercury may be better seen.

For the whole process of filling, marking, and graduating, see Deluc's Recherches &c, tom. 1, pa. 393, &c.

To change the Degrees of one Thermometer to another.

The most usual thermometers employed in Europe, are, Fahrenheit's, Reaumur's, and the new French or Centigrade. Now the range or space on the tube, between the points of freezing and boiling water, in the first is divided into 180 degrees, in the second 80, and in the last 100, which three numbers are in the proportion of the three 9, 4, 5; by means of which small proportional numbers, therefore, any number of degrees of one of these scales, is easily changed into the corresponding number of either of the others; viz, by saying, as the proportional number of the latter, is to that of the former, so is the proposed degrees of the former, to those on the latter: observing, however, that when Fahrenheit's is one of the thermometers compared, which begins with the freezing point at 32, where the other two begin with 0, then the degrees of Fahrenheit must be diminished or increased by 32, as the case may require.

Also the same may be done by the following simple theorems; in which R denotes the degrees in Reaumur's scale, F those of Fahrenheit's, and C those of the Centigrade thermometer.

1 . . . . . $F = \frac{9}{4} R + 32 = \frac{9}{5} C + 32.$
2 . . . . . $R = \frac{4}{9} (F - 32) = \frac{4}{5} C.$
3 . . . . . $C = \frac{5}{9} (F - 32) = \frac{5}{4} R.$

Experiments with THERMOMETERS.

The following is a table of some observations made with Fahrenheit's thermometer, the barometer standing at 29 inches, or little higher.

At 600° Mercury boils.
546 Oil of vitriol boils.
242 Spirit of nitre boils.
240 Lixivium of tartar boils.
213 Cow's milk boils.
212 Water boils.
206 Human urine boils.
190 Brandy boils.
175 Alcohol boils.
156 Serum of blood and white of eggs harden.
146 Kills animals in a few minutes.
108 to 99, Hens hatch eggs.
107 / 103 { Heat of skin in ducks, geese, hens, pigeons, partridges, and swallows.
106 Heat of skin in a common ague and fever.
103 / 100 { Heat of skin in dogs, cats, sheep, oxen, swine, and most other quadrupeds.
99 to 92, Heat of the human skin in health.
97 Heat of a swarm of bees.
96 A perch died in 3 minutes in water so warm.
80 Heat of air in the shade, in very hot weather.
74 Butter begins to melt.
64 Heat of air in the shade, in warm weather.
55 Mean temperature of air in England.
43 Oil of olives begins to stiffen and grow opake.
32 { Water just freezing, or snow and ice just melting.
30 Milk freezes.
28 Urine and common vinegar freeze.
25 Blood out of the body freezes.
20 Burgundy, Claret, and Madeira freeze.
5 { Greatest cold in Pennsylvania in 1731-2, lat. 40°.
4 Greatest cold at Utrecht in 1728-9.
0 { A mixture of snow and salt, which can freeze oil of tartar per deliquium, but not brandy.
−39 Mercury freezes.

Martine's Essays, pa. 284, &c.

Deluc's Recherches sur les Modif. &c, tom. 1, part. 2, ch. 2. Nollet's Leçons de Physique, tom. 4, pa. 375.

THERMOMETERS *for particular uses.*—In 1757, lord Cavendish presented to the Royal Society an account of a curious construction of thermometers, of two different forms; one contrived to show the greatest degree of heat, and the other the greatest cold, that may happen at any time in a person's absence. Philos. Trans. vol. 50, pa. 300.

Since the publication of Mr. Canton's discovery of the compressibility of spirits of wine and other fluids, there are two corrections necessary to be made in the result given by lord Cavendish's thermometer. For in estimating, for instance, the temperature of the sea at any depth, the thermometer will appear to have been colder than it really was: and besides, the expansion of spirits of wine by any given number of degrees of Fahrenheit's thermometer, is greater in the higher degrees than in the lower. For the method of making these two corrections by Mr. Cavendish, see Phipps's Voyage to the North Pole, pa. 145.

Instruments of this kind, for determining the degree of heat or cold in the absence of the observer, have been invented and described by others. Van Swinden (Diss. sur la Comparaison du Therm. pa. 253 &c) describes one, which he says was the first of the kind, made on a plan communicated by Bernoulli to Leibnitz. Mr. Kraft, he also informs us, made one nearly like it. Mr. Six has, in 1782, proposed another construction of a thermometer of the same kind, described in the Philos. Trans. vol. 72, pa. 72 &c.

M. Deluc has described the best method of constructing a thermometer, fit for determining the temperature of the air, in the measuring of heights by the barometer. He has also shown how to divide the scale of a thermometer, so as to adapt it for astronomical purposes in the observation of refractions. See Recherches &c, tom. 2, pa. 35 and 265.

Mr. Cavallo, in 1781, proposed the construction of a

Thermometrical Barometer, which, by means of boiling water, might indicate the various gravity of the atmosphere, or the height of the barometer. This thermometer, he observes, with its apparatus, might be packed up into a small portable box, and serve for determining the heights of mountains &c, with greater facility, than with the common portable barometer. The instrument, in its present state, consists of a cylindrical tin vessel, about 2 inches in diameter, and 5 inches high, in which vessel the water is contained, which may be made to boil by the flame of a large wax-candle. The thermometer is fastened to the tin vessel in such a manner, as that its bulb may be about an inch above the bottom. The scale of this thermometer, which is of brass, exhibits on one side of the glass tube a few degrees of Fahrenheit's scale, viz, from 200° to 216°. On the other side of the tube are marked the various barometrical heights, at which the boiling water shows those particular degrees of heat which are set down in sir Geo. Shuckburgh's table. With this instrument the barometrical height is shown within one-10th of an inch. The degrees of this thermometer are rather longer than one 9th of an inch, and therefore may be divided into many parts, especially by a Nonius. But a considerable imperfection arises from the smallness of the tin vessel, which does not admit a sufficient quantity of water; but when the quantity of water shall be sufficiently large, as for instance 10 or 12 ounces, and is kept boiling in a proper vessel, its degree of heat under the same pressure of the atmosphere is very settled; whereas when a thermometer is kept in a small quantity of boiling water, the mercury in its stem does not stand very steady, sometimes rising or falling so much as half a degree. Mr. Cavallo proposes a further improvement of this instrument, in the Philos. Trans. vol. 71, pa. 524.

The ingenious Mr. Wedgwood, so well known for his various improvements in the different sorts of pottery ware, has contrived to make a thermometer for measuring the higher degrees of heat, by means of a distinguishing property of argillaceous bodies, viz, the diminution of their bulk by fire. This diminution commences in a low red heat, and proceeds regularly, as the heat increases, till the clay becomes vitrified. The total contraction of some good clays which he has examined in the strongest of his own fires, is considerably more than one-fourth part in every dimension. By measuring the contraction of such substances then, Mr. Wedgwood contrived to measure the most intense heats of ovens, furnaces, &c. For the curious particulars of which, see Philos. Trans. vol. 72, pa. 305 &c.

In 1790 a paper was presented to the Royal Society of Edinburgh, describing two thermometers, newly invented, by Dr. John Rutherford, of Middle Balilish; the one for registering the highest, and the other for registering the lowest degree of heat, to which the thermometer has risen or fallen during the absence of the observer. An account of them may be found in the third volume of the Transactions of the Society.

A new self-registering thermometer has more lately been invented by Mr. Keith of Ravelstone, which we consider as the most ingenious, simple, and perfect, of any that has hitherto appeared. Its simplicity is so great that it requires only a very short description to make it intelligible.

AB (fig. 5, pl. 39) is a thin glass tube about 14 inches long and $\frac{3}{4}$ths of an inch caliber, close or hermetically sealed at the top. To the lower end, which is open, there is joined the crooked glass-tube BE, 7 inches long, and $\frac{1}{10}$ths of an inch caliber, and open at top. The tube AB is filled with the strongest spirit of wine, and the tube BE with mercury. This is properly a spirit of wine thermometer, and the mercury is used merely to support a piece of ivory or glass, to which is affixed a wire for raising one index and depressing another, according as the mercury rises or falls. F is a small conical piece of ivory or glass, of such a weight as to float on the surface of the mercury. To the float is joined a wire called the float-wire, which reaches upwards to H, where it terminates in a knee bent at right angles. The float-wire, by means of an eye at a, moves easily along the small harpsichord wire GK. L, L are two indexes made of thin black oiled silk, which slide upwards or downwards with a force not more than two grains. The one placed above the knee, points out the greatest rise, and the one placed below it points out the greatest fall of the thermometer.

When the instrument is to be prepared for an observation, both indexes are to be brought close to the knee H. It is evident that when the mercury rises, the float and float-wire, which can be moved with the smallest force, will be pushed upwards till the mercury becomes stationary. As the knee of the float-wire moves upwards, it will carry along with it the upper index L. When the mercury again subsides, it leaves the index at the highest point to which it was raised, for it will not descend by its own weight. As the mercury falls, the float-wire does the same; it therefore brings along with it the lower index L, and continues to depress it till it again become stationary, or ascend in the tube; in which case it leaves the lower index behind it as it had formerly left the upper. The scale to which the indexes point is placed parallel to the slender harpsichord wire. It may be seen more distinctly in fig. 6. That the scale and indexes may not be injured by the wind and rain, a cylindrical glass cover, close at top, and made so as exactly to fit the part FG, is placed over it.

Mr. Leslie, the author of the very ingenious Treatise on Heat, has invented a differential thermometer for the measurement of minute variations of temperature. It consists of two tubes, each terminating in a small bulb of the same dimensions, joined by the blow-pipe, and bent in the form of a U, a small portion of dark coloured liquor having previously been introuduced into one of the bulbs. After many trials, the fluid best adapted to the purpose was found to be a solution of carmine in concentrated sulphuric acid. By managing the included air with the heat of the hand, this red liquor is made to stand at the required point of the opposite tube. This is the zero of a scale fastened to that tube, and divided into equal parts above and below that point. The instrument is then fixed on a stand. It is manifest, that when the liquor is at rest, or points at zero, the column is pressed in opposite directions by two portions of air equal in elasticity, and containing equal quantities of caloric. Whatever heat then may be applied to the whole instrument, provided both bulbs receive it in the same degree, the liquor must remain at rest. But if the one ball receive the slightest excess of temperature, the air which it contains will be proportionally expanded, and will push the liquor against the air in the other full with a force varying as the difference between the temperatures of these two portions of air: thus the equilibrium will be destroyed, and the fluid will rise in the opposite tube. The degrees of the scale through which it passes will mark the successive augmentations in the temperature of the ball which is exposed to the greatest heat. So that this instrument is a balance of extreme delicacy for comparing the temperatures of its two scales.

When thermometers are contrived to measure very great degrees of heat by the expansions they produce in substances, or, on the contrary, the expansions corresponding to different temperatures, they are denominated *Pyrometers*. See the descriptions of the principal of these under their proper article.—On the subject of thermometers, see also my Philosophical Recreations, &c. vol. 4, pa. 43, &c.

THERMOSCOPE, the same as Thermometer.

THIR, in Chronology, the name of the 5th month of the Ethiopians, which corresponds, according to Ludolf, to the month of January.

THIRD, in Music, a concord resulting from a mixture of two sounds containing an interval of 2 degrees: being called a third, because containing 3 terms, or sounds, between the extremes.

There is a greater and a less third. The former takes its form from the sesquiquarta ratio, 4 to 5. The logarithm or measure of the octave $\frac{2}{1}$ being 1·00000, the measure of the greater third $\frac{5}{4}$ will be 0·32193—The greater third is by practitioners often taken for the third part of an octave; which is an error, since three greater thirds fall short of the octave by a diesis; for $\frac{5}{4} \times \frac{5}{4} \times \frac{5}{4} \times \frac{128}{125} = \frac{2}{1}$.

The lesser third takes its form from the sesquiquinta ratio 5 to 6; the measure or logarithm of this lesser third $\frac{6}{5}$, being 0·26303, that of the octave $\frac{2}{1}$ being 1·00000.—Both these thirds are of great use in melody; making as it were the foundation and life of harmony.

THIRD-*Point*, or *Tierce-point*, in Architecture, the point of section in the vertex of an equilateral triangle.—Arches or vaults of the third point, are those consisting of two arches of a circle, meeting in an angle at top.

THREE-*legged-Staff*, an instrument consisting of three wooden legs, made with joints, so as to shut up together, and to take off in the middle for the better carriage. It has usually a ball and socket on the top; and its use is to support and adjust instruments for astronomy, surveying, &c.

THUNDER, a noise in the lower region of the air, excited by a sudden explosion of electrical clouds; which are therefore called thunder-clouds.—The phenomenon of thunder is variously accounted for. Seneca, Rohault, and some other authors, both ancient and modern, account for thunder, by supposing two clouds impending over each other, the upper and rarer of which, becoming condensed by a fresh accession of air raised by warmth from the lower parts of the atmosphere, or driven upon it by the wind, immediately falls forcibly down upon the lower and denser cloud; by which fall, the air interposed between the two being compressed, that next the extremities of the two clouds is forced out, and leaves room for the extremity of the upper cloud to close tight upon the under; thus a great quantity of the air is enclosed, which at length escaping through some winding irregular vent or passage, occasions the noise called thunder.

But this lame device could only reach at most to the case of thunder heard without lightning; and therefore recourse has been had to other modes of solution. Thus, it has been said that thunder is not occasioned by the falling of clouds, but by the kindling of sulphurous exhalations, in the same manner as the noise of the aurum fulminans. "There are sulphurous exhalations," says Newton, "always ascending in to the air when the earth is dry; there they ferment with the nitrous acids, and, sometimes taking fire, generate thunder, lightning, &c."

The effects of thunder are so like those of fired gunpowder, that Dr. Wallis thinks we need not scruple to ascribe them to the same cause; and the principal ingredients in gunpowder, we know, are nitre and sulphur; charcoal only serving to keep the parts separate, for their better kindling. Hence, if we conceive in the air a convenient mixture of nitrous and sulphurous particles; and those, by any cause, to be set on fire, such explosion may well follow, and with such noise and light as attend the firing of gunpowder; and being once kindled, it will run from place to place, different ways, as the exhalations happen to lead it; much as is found in a train of gunpowder.

But a third, and most probable opinion is, that thunder is the report or noise produced by an electrical explosion in the clouds. Ever since the year 1752, in which the identity of the matter of lightning and of the electrical fluid has been ascertained, philosophers have generally agreed in considering thunder as a concussion produced in the air by an explosion of electricity. For the illustration and proof of this theory, see ELECTRICITY, and LIGHTNING.

It may here be observed, that Mr. Henry Eeles, in a letter written in 1751, and read before the Royal Society in 1752, considers the electrical fire as the cause of thunder, and accounts for it on this hypothesis; and he tells us, that he did not know of any other person's having made the same conjecture. Philos. Trans. vol. 47, p. 524 &c.—That rattling in the noise of thunder, which makes it seem as if it passed through arches, or were variously broken, is probably owing to the sound being excited among clouds hanging over one another, and the agitated air passing irregularly between them.—The explosion, if high in the air, and remote from us, will do no mischief; but when near, it may destroy trees, animals, &c.

This proximity, or small distance, may be estimated nearly by the interval of time between seeing the flash of lightning and hearing the report of the thunder, estimating the distance after the rate of 1142 feet per second of time, or $3\frac{5}{7}$ seconds to the mile. Dr. Wallis observes, that commonly the difference between the two is about 7 seconds, which, at the rate above mentioned, gives the distance almost 2 miles. But sometimes it comes in a second or two, which argues the explosion very near us, and even among us. And in such cases, the doctor assures us, he has sometimes foretold the mischiefs that followed.

The noise of thunder, and the flame of lightning, are easily made by art. If a mixture of oil or spirit of vitriol be made with water, and some filings of steel added to it, there will immediately arise a thick smoke, or vapour, out of the mouth of the vessel; and if a lighted candle be applied to this, it will take fire, and the flame will immediately descend into the vessel, which will be burst to pieces with a noise like that of a cannon. This is so far analogous to thunder and lightning, that a great explosion and fire are occasioned by it; but in this they differ, that this matter when once fired is destroyed, and can give no more explosions; whereas, in the heavens, one clap of thunder usually follows another, and there is a continued succession of them for a long time. Mr. Homberg explained this by the lightness of the air above us, in comparison of that near, which therefore would not suffer all the matter so kindled to be dissipated at once, but keeps it for several returns.

THUNDERBOLT. When lightning acts with extraordinary violence, and breaks or shatters any thing, it is called a thunderbolt, which the vulgar, to fit it for such effects, suppose to be a hard body, and even a stone.—But that we need not have recourse to a hard solid body to account for the effects commonly attributed to the thunderbolt, will be evident to any one, who considers those of the pulvis fulminans, and of gunpowder; but more especially the astonishing powers of electricity, when only collected and employed by human art, and much more when directed and exercised in the course of nature.—When we consider the known effects of electrical explosions, and those produced by lightning, we shall be at no loss to account for the extraordinary operations vulgarly ascribed to thunderbolts. As stones and bricks struck by lightning are often found in a vitrified state, we may reasonably suppose, with Beccaria, that some stones in the earth, having been struck in this manner, gave occasion to the vulgar opinion of the thunderbolt.

THUNDER-*Clouds*, in Physiology, are those clouds which are in a state fit for producing lightning and thunder.—From Beccaria's exact and circumstantial account of the external appearances of thunder-clouds, the following particulars are extracted. The first appearance of a thunder storm, which usually happens when there is little or no wind, is one dense cloud, or more, increasing very fast in size, and rising into the higher regions of the air. The lower surface is black and nearly level; but the upper finely arched, and well defined. Many of these clouds often seem piled upon one another, all arched in the same manner; but they are continually uniting, swelling, and extending their arches.

At the time of the rising of this cloud, the atmosphere is commonly full of a great many separate clouds, that are motionless, and of whimsical shapes. All these, on the appearance of the thunder-cloud, draw towards it, and become more uniform in their shapes as they approach; till, coming very near the thunder-cloud, their limbs mutually stretch towards each other, and they immediately coalesce into one uniform mass. These he calls adscititious clouds, from their coming in, to enlarge the size of the thunder-cloud. But sometimes the thunder-cloud will swell, and increase very fast, without the conjunction of any adscititious clouds; the vapours in the atmosphere forming themselves into clouds wherever it passes. Some of the adscititious clouds appear like white fringes, at the skirts of the thunder-cloud, or under the body of it, but they keep continually getting darker and darker, as they approach to unite with it.

When the thunder-cloud is grown to a great size, its lower surface is often ragged, particular parts being detached towards the earth, but still connected with the rest. Sometimes the lower surface swells into various large protuberances bending uniformly downward; and sometimes one whole side of the cloud will have an inclination to the earth, and the extremity of it nearly touch the ground. When the eye is under the thunder-cloud, after it is grown larger and well formed, it is seen to sink lower, and to darken prodigiously; at the same time that a number of small adscititious clouds (the origin of which can never be perceived) are seen in a rapid motion, driving about in very uncertain directions under it. While these clouds are agitated with the most rapid motions, the rain commonly falls in the greatest plenty, and if the agitation be exceedingly great, it commonly hails.

While the thunder-cloud is swelling, and extending its branches over a large tract of country, the lightning is seen to dart from one part of it to another, and often to illuminate its whole mass. When the cloud has acquired a sufficient extent, the lightning strikes between the cloud and the earth, in two opposite places, the path of the lightning lying through the whole body of the cloud and its branches. The longer this lightning continues, the less dense does the cloud become, and the less dark its appearances; till at length it breaks in different places, and shows a clear sky.

These thunder-clouds were sometimes in a positive as well as a negative state of electricity. The electricity continued longer of the same kind, in proportion as the thunder-cloud was simple, and uniform in its direction; but when the lightning changed its place, there commonly happened a change in the electricity of the apparatus over which the clouds passed. It would change suddenly after a very violent flash of lightning, but the change would be gradual when the lightning was moderate, and the progress of the thunder-cloud slow. Beccar. Lettere dell' Elettricismo pa. 107; or Priestley's Hist. Elec. vol. 1, pa. 397. See also LIGHTNING.

THUNDER-*House*, in Electricity, is an instrument invented by Dr. James Lind, for illustrating the manner in which buildings receive damage from lightning, and to evince the utility of metallic conductors in preserving them from it.

A (fig. 1, pl. 40), is a board about ¾ of an inch thick, and shaped like the gable end of a house. This board is fixed perpendicularly on the bottom board B, upon which the perpendicular glass pillar CD is also fixed in a hole about 8 inches distant from the basis of the board A. A square hole ILMK, about a quarter of an inch deep, and nearly one inch wide, is made in the board A, and is filled with a square piece of wood, nearly of the same dimensions. It is nearly of the same dimensions, because it must go so easily into the hole, that it may drop off, by the least shaking of the instrument. A wire LK is fastened diagonally to this square piece of wood. Another wire IH of the same thickness, having a brass ball H, screwed on its pointed extremity, is fastened upon the board A: so also is the wire MN, which is shaped in a ring at O. From the upper extremity of the glass pillar CD, a crooked wire proceeds, having a spring socket F, through which a double knobbed wire slips perpendicularly, the lower knob G of which falls just above the knob H. The glass pillar DC must not be made very fast into the bottom board; but it must be fixed so that it may be pretty easily moved round its own axis, by which means the brass ball G may be brought nearer to or farther from the ball H, without touching the part EFG. Now when the square piece of wood LMIK (which may represent the shutter of a window or the like) is fixed into the hole so that the wire LK stands in the dotted representation IM, then the metallic communication from H to O is complete, and the instrument represents a house furnished with a proper metallic conductor; but if the square piece of wood LMIK be fixed so that the wire LK stands in the direction LK, as represented in the figure, then the metallic conductor HO, from the top of the house to its bottom, is interrupted at IM, in which case the house is not properly secured.

Fix the piece of wood LMIK, so that its wire may be as represented in the figure, in which case the metallic conductor HO is discontinued. Let the ball H be fixed at about half an inch perpendicular distance from the ball H; then, by turning the glass pillar DC, remove the former ball from the latter; by a wire or chain connect the wire EF with the wire Q of the jar P; and let another wire or chain, fastened to the hook O, touch the outside coating of the jar. Connect the wire Q with the prime conductor, and charge the jar; then, by turning the glass pillar DC, let the ball G come gradually near the ball H, and when they are arrived sufficiently near together, you will observe, that the jar explodes, and the piece of wood LMIK is pushed out of the hole to a considerable distance from the thunder-house.

Now the ball G, in this experiment, represents an electrified cloud, which, when it is arrived sufficiently near the top of the house A, the electricity strikes it; and as this house is not secured with a proper conductor, the explosion breaks part of it, i. e. knocks off the piece of wood IM.

Repeat the experiment with only this variation, viz, that this piece of wood IM be situated so that the wire LK may stand in the situation IM; in which case the conductor HO is not discontinued; and you will observe that the explosion will have no effect on the piece of wood LM; this remaining in the hole unmoved; which shows the usefulness of the metallic conductor.

Farther, unscrew the brass ball H from the wire HI, so that this may remain pointed, and with this difference only in the apparatus repeat both the above experiments, and you will find that the piece of wood IM is in neither case moved from its place, nor will any explosion be heard; which not only demonstrates the preference of conductors with pointed terminations to those with blunted ones, but also shows that a house, furnished with sharp terminations, though not furnished with a regular conductor, is almost sufficiently guarded against the effects of lightning.

Mr. Henley, having connected a jar containing 509 square inches of coated surface with his prime conductor, observed that if it was so charged as to raise the index of his electrometer to 60°, by bringing the ball on the wire of the thunder-house, to the distance of half an inch from that connected with the prime conductor, the jar would be discharged, and the piece in the thunder-house thrown out to a considerable distance. Using a pointed wire for a conductor to the thunder-house, instead of the knob, the charge being the same as before, the jar was discharged silently, though suddenly; and the piece was not thrown out of the thunder-house. In another experiment, having made a double circuit to the thunder-house, the first by the knob, the second by a sharp-pointed wire, at an inch and a quarter distance from each other, but of exactly the same height (as in fig. 2) the charge being the same; though the knob was brought first under that connected with the prime conductor, which was raised half an inch above it, and followed by the point, yet no explosion could fall upon the knob; the point drew off the whole charge silently, and the piece in the thunder-house remained unmoved.—Philos. Trans. vol. 64, pa. 136. See POINTS in Electricity.

THURSDAY, the 5th day of the Christians' week, but the 6th of the Jews.' The name is from Thor, one of the Saxon gods.

THUS, in Sea-Language, a word used by the pilot in directing the helmsman or steersman to keep the ship in her present situation when sailing with a scant wind, so that she may not approach too near the direction of the wind, which would shiver her sails, nor fall to leeward, and run farther out of her course.

TIDES, two periodical motions of the waters of the sea; called also the flux and reflux, or the flow and ebb.

The tides are found to follow periodically the course of the sun and moon, both as to time and quantity. And hence it has been suspected, in all ages, that the tides were somehow produced by the influence of these luminaries. Thus, several of the ancients, and among others, Pliny, Ptolemy, and Macrobius, were acquainted with the influence of the sun and moon on the tides; and Pliny says expressly, that the cause of the ebb and flow is in the sun, which attracts the waters of the ocean; and adds, that the waters rise in proportion to the proximity of the moon to the earth. It is indeed now well known, from the discoveries of Newton, that the tides are caused by the gravitation of the earth towards the sun and moon. Indeed the sagacious Kepler, long ago, conjectured this to be the cause of the tides: "If," says he, "the earth ceased to attract its waters towards itself, all the water in the ocean would rise and flow into the moon; the sphere of the moon's attraction extends to our earth, and draws up the water." Thus thought Kepler, in his Introd. ad Theor. Mart. This surmise, for it was then no more, is now abundantly verified in the theory laid down by Newton, and by Halley, as well as other eminent mathematicians, from his principles.

As to the Phenomena of the TIDES: 1. The sea is observed to flow, for about 6 hours, from south towards north; the sea gradually swelling; so that, entering the mouths of rivers, it drives back the river-waters towards their heads, or springs. After a continual flux of 6 hours, the sea appears to rest for about a quarter of an hour; after which it begins to ebb, or retire back again, from north to south, for 6 hours more; in which time, the waters sinking, the rivers resume their natural course. Then, after another seeming pause of a quarter of an hour, the sea again begins to flow, as before; and so on alternately.

2. Hence, the sea ebbs and flows twice a day, but falling every day gradually later and later, by about 48 minutes, the period of a flux and reflux being on an average about 12 hours 24 minutes, and the double of each 24 hours and 48 minutes; which is the period of a lunar day, or the time between the moon's passing a meridian and coming to it again. So that the sea flows as often as the moon passes the meridian, both the arch above the horizon, and that below it; and ebbs as often as she passes the horizon, both on the eastern and western side.

Other phenomena of the tides are as below; and the reasons of them will be noticed in the theory of the tides that follows.

3. The elevation towards the moon a little exceeds the opposite one. And the quantity of the ascent of the water is diminished from the equator towards the poles.

4. From the sun, every natural day, the sea is twice elevated, and twice depressed, the same as for the moon. But the solar times are much less than the lunar ones, on account of the immense distance of the sun; yet they are both subject to the same laws.

5. The tides which depend on the actions of the sun and moon, are not distinguished, but compounded, and so

forming as to sense one united tide, increasing and decreasing, and thus making neap and spring tides: for, by the action of the sun, the lunar tide is only changed; which change varies every day, by reason of the inequality between the natural and lunar day.

6. In the syzygies the elevations from the action of both luminaries concur, and the sea is more elevated. But the sea ascends less in the quadratures; for where the water is elevated by the action of the moon, it is depressed by the action of the sun; and vice versa. Therefore, while the moon passes from the syzygy to the quadrature, the daily elevations are continually diminished: on the contrary, they are increased while the moon moves from the quadrature to the syzygy. At a new moon also, *cæteris paribus*, the elevations are greater; and those that follow one another the same day, are more different than at full moon.

7. The greatest elevations and depressions are not observed till the 2d or 3d day after the new or full moon. And if we consider the luminaries receding from the plane of the equator, we shall perceive that the agitation is diminished, and becomes less, according as the declination of the luminaries becomes greater.

8. In the syzygies, and near the equinoxes, the tides are observed to be the greatest, both luminaries being in or near the equator.

9. The actions of the sun and moon are greater, the nearer those bodies are to the earth; and the less, as they are farther off. Also the greatest tides happen near the equinoxes, or rather when the sun is a little to the south of the equator, that is, a little before the vernal, and after the autumnal equinox. But yet this does not happen regularly every year, because some variation may arise from the situation of the moon's orbit, and the distance of the syzygy from the equinox.

10. All these phenomena obtain, as described, in the open sea, where the ocean is extended enough to be subject to these motions. But the particular situations of places, as to shores, capes, straits, &c, disturb these general rules. Yet it is plain, from the most common and universal observations, that the tides follow the laws above laid down.

11. The mean force of the moon to move the sea, is to that of the sun, nearly as 4½ to 1. And therefore, if the action of the sun alone produce a tide of 2 feet, which it has been stated to do, that of the moon will be 9 feet; from which it follows, that the spring tides will be 11 feet, and the neap tides 7 feet high. But as to such elevations as far exceed these, they happen from the motion of the waters against some obstacles, and from the sea violently entering into straits or gulphs where the force is not broken till the water rises higher.

Theory of the Tides.

1. If the earth were entirely fluid, and quiescent, it is evident that its particles, by their mutual gravity towards each other, would form the whole mass into the figure of an exact sphere. Then suppose some power to act on all the particles of this sphere with an equal force, and in parallel directions; by such a power the whole mass will be moved together, but its figure will suffer no alteration by it, being still the same perfect sphere, whose centre will have the same motion as each particle.

On this supposition, if the motion of the earth, round the common centre of gravity of the earth and moon, were destroyed, and the earth left to the influence of its gravitation towards the moon, as the acting power above mentioned; then the earth would fall or move straight towards the moon, but still retaining its true spherical figure.

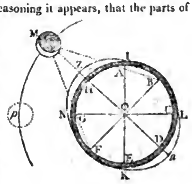
But the fact is, that the effects of the moon's action, as well as the action itself, on different parts of the earth, are not equal: those parts, by the general law of gravity, being most attracted that are nearest the moon, and those being least attracted that are farthest from her, while the parts that are at a middle distance are attracted by a mean degree of force: besides, all the parts are not acted on in parallel lines, but in lines directed towards the centre of the moon: on both which accounts the spherical figure of the fluid earth must suffer some change from the action of the moon. So that, in falling, as above, the nearer parts, being most attracted, would fall quickest; the farther parts, being least attracted, would fall slowest; and the fluid mass would be lengthened out, and take a kind of spheroidical form.

Hence it appears, and what must be carefully observed, that it is not the action of the moon itself, but the inequalities in that action, that cause any variation from the spherical figure; and that, if this action were the same in all the particles as in the central parts, and operating in the same direction, no such change would ensue.

Let us now admit the parts of the earth to gravitate towards its centre: then, as this gravitation far exceeds the action of the moon, and much more exceeds the differences of her actions on different parts of the earth, the effect that results from the inequalities of these actions of the moon, will be only a small diminution of the gravity of those parts of the earth which it endeavoured in the former supposition to separate from its centre; that is, those parts of the earth which are nearest to the moon, and those that are farthest from her, will have their gravity toward the earth somewhat abated, to say nothing of the lateral parts. So that supposing the earth fluid, the columns from the centre to the nearest, and to the farthest parts, must rise, till by their greater height they be able to balance the other columns, whose gravity is less altered by the inequalities of the moon's action. And thus the figure of the earth must still be an oblong spheroid.

Considering now the earth, instead of falling toward the moon by its gravity, as projected in any direction, so as to move round the centre of gravity of the earth and moon: it is evident that in this case, the several parts of the fluid earth will still preserve their relative positions; and the figure of the earth will remain the same as if it fell freely toward the moon; that is, the earth will still assume a spheroidal form, having its longest diameter directed toward the moon.

From the above reasoning it appears, that the parts of the earth directly under the moon, as at H, and also the opposite parts at D, will have the flood or high water at the same time; while the parts, at B and F, at 90° distance, or where the moon appears in the horizon, will have the ebbs or lowest wa-



ters at that time. Hence, as the earth turns round its axis from the moon to the same body again in 24 hours 48 minutes, this oval of water must shift with it; and thus there will be two tides of flood and two of ebb in that time.

But it is farther evident that, by the motion of the earth about her axis, the most elevated part of the water is carried beyond the moon in the direction of the rotation. So that the water continues to rise after it has passed directly under the moon, though the immediate action of the moon there begins to decrease, and comes not to its greatest elevation till it has got about half a quadrant farther. It continues also to descend after it has passed at 90° distance from the point below the moon, to a like distance of about half a quadrant. The greatest elevation therefore is not in the line drawn through the centres of the earth and moon, nor the lowest points where the moon appears in the horizon, but all these about half a quadrant removed eastward from these points, in the direction of the motion of rotation. Thus in open seas, where the water flows freely, the moon M is generally past the north and south meridian, as at *p*, when the high water is at *z* and at *n*: the reason of which is plain, because the moon acts with the same force after she has passed the meridian, and thus adds to the libratory or waving motion, which the water acquired when she was in the meridian; and therefore the time of high water is not precisely at the time of her coming to the meridian, but some time after, &c.

Besides, the tides answer not always to the same distance of the moon, from the meridian, at the same places; but are variously affected by the action of the sun, which brings them on sooner when the moon is in her first and third quarters, and keeps them back later when she is in her 2d and 4th; because, in the former case the tide raised by the sun alone would be earlier than the tide raised by the moon, and in the latter case later.

2. We have hitherto adverted only to the action of the moon in producing tides; but it is manifest that, for the same reasons, the inequality of the sun's action on different parts of the earth, would produce a like effect, and a like variation from the exact spherical figure of a fluid earth. So that in reality there are two tides every natural day from the action of the sun, as there are in the lunar day from that of the moon, subject to the same laws; and the lunar tide, as we have observed, is somewhat changed by the action of the sun, and the change varies every day on account of the inequality between the natural and the lunar day. Indeed the effect of the sun in producing tides, because of his immense distance, must be considerably less than that of the moon, though the gravity toward the sun be much greater: for it is not the action of the sun or moon itself, but the inequalities in that action, that have any effect: the sun's distance is so great, that the diameter of the earth is but as a point in comparison with it, and therefore the difference between the sun's actions on the nearest and farthest parts, becomes vastly less than it would be if the sun were as near as the moon. However the immense bulk of the sun makes the effect still sensible, even at so great a distance; and therefore, though the action of the moon has the greatest share in producing the tides, the action of the sun adds sensibly to it when they conspire together, as in the full and change of the moon, when they are nearly in the same line with the centre of the earth, and therefore unite their forces; consequently, in the syzygies, or at new and full moon, the tides are the greatest, being what are called the Spring-Tides. But the action of the sun diminishes the effect of the moon's action in the quarters, because the one raises the water in that case where the other depresses it; therefore the tides are the least in the quadratures, and are called Neap-Tides.

Newton has calculated the effects of the sun and moon respectively on the tides, from their attractive powers. The former he finds to be to the force of gravity, as 1 to 12868200, and to the centrifugal force at the equator as 1 to 44527. The elevation of the waters by this force is considered by Newton as an effect similar to the elevation of the equatorial parts above the polar parts of the earth, arising from the centrifugal force at the equator; and as it is 44527 times less, he finds it to be 24½ inches, or 2 feet and ½ an inch.

To find the force of the moon on the water, Newton compares the spring-tides at the mouth of the river Avon, below Bristol, with the neap-tides there, and finds the proportion as 9 to 5; whence, after several necessary corrections, he concludes that the force of the moon to that of the sun, in raising the waters of the ocean, is as 4·4815 to 1; so that the force of the moon is able of itself to produce an elevation of 9 feet 1½ inch, and the sun and moon together may produce an elevation of about 11 feet 2 inches, when at their mean distances from the earth, or an elevation of about 12½ feet, when the moon is nearest the earth. The height to which the water is found to rise, on coasts of the open and deep ocean, is agreeable enough to this computation.

Dr. Horsley estimates the force of the moon to that of the sun, as 5·0469 to 1, in his edit. of Newton's Princip. See the Princip. lib. 3, sect. 3, pr. 36 and 37; also Maclaurin's Dissert. de Causa Physica Fluxus et Refluxus Maris apud Phil. Nat. Princ. Math. Comment. le Seur & Jacquier, tom. 3, pa. 272. And other calculators make the proportion still more different.

3. It must be observed, that the spring-tides do not happen precisely at new and full moon, nor the neap-tides at the quarters, but a day or two after; because, as in other cases, so in this, the effect is not greatest or least when the immediate influence of the cause is greatest or least. As, for example, the greatest heat is not on the day of the solstice, when the immediate action of the sun is greatest, but some time after; so likewise, if the actions of the sun and moon should suddenly cease, yet the tides would continue to have their course for some time; and like also as the waves of the sea continue after a storm.

4. The different distances of the moon from the earth produce a sensible variation in the tides. When the moon approaches toward the earth, her action on every part increases, and the differences of that action, on which the tides depend, also increase; and as the moon approaches, her action on the nearest parts increases more quickly than that on the remote parts, so that the tides increase in a higher proportion as the moon's distances decrease. In fact, it is shown by Newton, that the tides increase in proportion as the cubes of the distances decrease; so that the moon at half her distance would produce a tide 8 times greater.

The moon describes an oval about the earth, and at her nearest distance produces a tide sensibly greater than at her greatest distance from the earth: and hence it is that two great spring-tides never succeed each other immediately; for if the moon be at her least distance from the earth at the change, she must be at her greatest distance at the full, having made half a revolution in the intervening time, and therefore the spring-tide then will be much less than that at the last change was; and for the same reason, if a great spring-tide happen at the time of full moon, the tide at the ensuing change will be less.

5. The spring-tides are highest, and the neap-tides lowest, about the time of the equinoxes, or the latter end of March and September; and, on the contrary, the spring-tides are the lowest, and the neap-tides the highest, at the solstices, or about the latter end of June and December: so that the difference between the spring and neap tides, is much more considerable about the equinoctial than the solstitial seasons of the year. To illustrate and evince the truth of this observation, let us consider the effect of the luminaries on the tides, when in and out of the plane of the equator. Now it is manifest, that if either the sun or moon were in the pole, they could not have any effect on the tides; for their action would raise all the water at the equator, or at any parallel, quite around, to a uniform height; and therefore any place of the earth, in describing its parallel to the equator, would not meet, in its course, with any part of the water more elevated than another; so that there could be no tide in any place, that is, no alteration in the height of the waters.

On the other hand, the effect of the sun or moon is greatest when in the equinoctial; for then the axis of the spheroidal figure, arising from their action, moves in the greatest circle, and the water is put into the greatest agitation; and hence it is that the spring-tides produced when the sun and moon are both in the equinoctial, are the greatest of any, and the neap-tides the least of any about that time. And when the luminary is any where between the equinoctial and the pole, the tides are the smaller.

6. The highest spring-tides are after the autumnal and before the vernal equinox: the reason of which is, because the sun is nearer the earth in winter than in summer.

7. Since the greatest of the two tides happening in every diurnal revolution of the moon, is that in which the moon is nearest the zenith or nadir; for this reason, while the sun is in the northern signs, the greater of the two diurnal tides in our climates, is that arising from the moon above the horizon; when the sun is in the southern signs, the greatest is that arising from the moon below the horizon. Thus it is found by observation that the evening tides in the summer exceed the morning tides, and in winter the morning tides exceed the evening tides. The difference is found at Bristol to amount to 15 inches, and at Plymouth to 12. It would be still greater, but that the fluid always retains an impressed motion for some time; so that the preceding tides affect always those that follow them. Upon the whole, while the moon has a north declination, the greatest tides in the northern hemisphere are when she is above the horizon, and the reverse while her declination is south.

8. Such would the tides regularly be, if the earth were all over covered with the sea very deep, so that the water might freely follow the influence of the sun and moon; but, by reason of the shoalness of some places, and the narrowness of the straits in others, through which the tides are propagated, there arises a great diversity in the effect according to the various circumstances of the places. Thus, a very slow and imperceptible motion of the whole body of water, where it is very deep, as 2 miles for instance, will suffice to raise its surface 10 or 12 feet during the period of a tide: whereas, if the same quantity of water were to be conveyed through a channel of 40 fathoms deep, it would require a very rapid stream to effect it in so large inlets as are the English channel, and the German ocean; whence the tide is found to set strongest in those places where the sea grows narrowest, the same quantity of water being in that case to pass through a smaller passage. This is particularly observable in the straits between Portland and Cape la Hogue in Normandy, where the tide runs like a sluice: and would be yet more so between Dover and Calais, if the tide coming round the island did not check it.

This force, when once impressed, continues to carry the water above the ordinary height in the ocean, especially where the water meets a direct obstacle, as it does in St. Maloes; and where it enters into a long channel which, running far into the land, becomes very strait at its extremity, as it does into the Severn sea at Chepstow and Bristol.

This shoalness of the sea, and the intercurrent continents, are the reasons that in the open ocean the tides rise but to very small heights in proportion to what they do in wide-mouthed rivers, opening in the direction of the stream of the tide; and that high water is not soon after the moon's appulse to the meridian, but some hours after it, as it is observed on all the western coast of Europe and Africa, from Ireland to the Cape of Good Hope; in all which a south-west moon makes high water; and the same it is said is the case on the western side of America. So that tides happen to different places at all distances of the moon from the meridian, and consequently at all hours of the day.

To allow the tides their full motion, the ocean in which they are produced, ought to be extended from east to west 90 degrees at least; because that is the distance between the places where the water is most raised and depressed by the moon. Hence it appears that it is only in the great oceans that such tides can be produced, and why in the larger Pacific ocean they exceed those in the Atlantic ocean. Hence also it is obvious, why the tides are not so great in the torrid zone, between Africa and America, where the ocean is narrower, as in the temperate zones on either side; and hence we may also understand why the tides are so small in islands that are very far distant from the shores. It is farther manifest that, in the Atlantic ocean, the water cannot rise on one shore but by descending on the other; so that at the intermediate islands it must continue at a mean height between its elevations on those two shores. But when tides pass over shoals, and through straits into bays of the sea, their motion becomes more various, and their height depends on many circumstances.

To be more particular. The tide that is produced on the western coasts of Europe, in the Atlantic, corresponds to the situation of the moon already described. Thus it is high water on the western coasts of Ireland, Portugal and Spain, about the 3d hour after the moon has passed the meridian: from thence it flows into the adjacent channels, as it finds the easiest passage. One current from it, for instance, runs up by the south of England, and another comes in by the north of Scotland; they take a considerable time to move through this extent, making always high water sooner in the places to which they first come; and it begins to fall at these places while the currents are still going on to others that are farther distant in their course. As they return, they are not able to raise the tide, because the water runs faster off than it returns, till, by a new tide propagated from the open ocean, the return of the current is stopped, and the water begins to rise again. The tide propagated by the moon in the German ocean, when she is 3 hours past the meridian, takes 12 hours to come from thence to London bridge: so that when it is high water there, a new tide is already come to its height in the ocean; and in some intermediate place it must be low water at the same time. Consequently when the moon has north declination, and we should expect the tide at London to be the greatest when the moon is above the horizon, we find it is least; and the contrary when she has south declination.

At several places it is high water 3 hours before the moon comes to the meridian; but that tide, which the moon drives as it were before her, is only the tide opposite to that which was raised by her when she was 9 hours past the opposite meridian.

It would be endless to recount all the particular solutions, which are easy consequences from this doctrine: as, why the lakes and seas, such as the Caspian sea and the Mediterranean sea, the Black sea and the Baltic, have little or no sensible tides: for lakes are usually so small, that when the moon is vertical she attracts every part of them alike, so that no part of the water can be raised higher than another: and having no communication with the ocean, it can neither increase nor diminish their water, to make it rise and fall; and seas that communicate by such narrow inlets, and are of so immense an extent, cannot speedily receive and empty water enough to raise or sink their surface in any sensible degree.

In general; when the time of high water at any place is mentioned, it is to be understood on the days of new and full moons.—Among pilots, it is customary to reckon the time of flood, or high water, by the point of the compass the moon bears on, at that time, allowing ¾ of an hour for each point. Thus, on the full and change days, in places where it is flood at noon, the tide is said to flow north and south, or at 12 o'clock: in other places, on the same days, where the moon bears 1, 2, 3, 4, or more points to the east or west of the meridian when it is high water, the tide is said to flow on such point; thus, if the moon bears SE, at flood, it is said to flow SE and NW, or 3 hours before the meridian, that is, at 9 o'clock; if it bears SW, it flows SW and NE, or at 3 hours after the meridian; and in like manner for the other points of the moon's bearing.

The times of high water in any place fall about the same hours after a period of about 15 days, or between one spring tide and another; but during that period, the times of high water fall each day later by about 48 minutes.

On the subject of this article, see Newton Princ. Math. lib. 3, prop. 24, and De System. Mundi sect. 38, &c. Apud Opera edit. Horsley, tom. 3, pa. 52 &c, pa. 203 &c. Maclaurin's Account of Newton's Discoveries, book 4, ch. 7. Ferguson's Astron. ch. 17. Robertson's Navig. book 6, sect. 7, 8, 9. Lalande's Astron. vol. 4. See also the article Physical Astronomy in this dictionary.

TIDE *Dial*, an instrument contrived by Mr. Ferguson, for exhibiting and determining the state of the tides: for the construction and use of which, see his Astron. pa. 297.

TIDE *Tables*, are tables commonly exhibiting the times of high water at sundry places, as they fall on the days of the full and change of the moon, and sometimes the height of them also. These are common in most books on navigation, particularly Robertson's, and the tables requisite to be used with the Nautical Almanac. See one at HIGH-*water*.

TIERCE, or TEIRCE, a liquid measure, as of wine, oil, &c, containing 42 gallons, or the 3d part of a pipe; whence its name.

TIME, a succession of phenomena in the universe; or a mode of duration, marked by certain periods and measures; chiefly indeed by the motion and revolution of the luminaries, and particularly of the sun.

The idea of time in general, Locke observes, we acquire by considering any part of infinite duration, as set out by periodical measures: the idea of any particular time, or length of duration, as a day, an hour, &c, we acquire first by observing certain appearances at regular and seemingly equidistant periods. Now, by being able to repeat these lengths or measures of time as often as we will, we can imagine duration, where nothing really endures or exists; and thus we imagine to-morrow, or next year, &c.

Some of the later school-philosophers define time to be the duration of a thing whose existence is neither without beginning nor end: by this, time is distinguished from eternity.

Aristotle and the Peripatetics define it, numerus motus secundum prius et posterius, or a multitude of transient parts of motion, succeeding each other, in a continual flux, in the relation of priority and posteriority. Hence it should follow that time is motion itself, or at least the duration of motion, considered as having several parts, some of which are continually succeeding to others. But on this principle, time or temporal duration would not agree to bodies at rest, which yet nobody will deny to exist in time, or to endure for a time.

To avoid this inconvenience, the Epicureans and Corpuscularians made time to be a kind of flux different from motion, consisting of infinite parts, continually and immediately succeeding each other, and this from eternity to eternity. But others directly explode this notion, as establishing an eternal being, independent of God. For how should there be a flux before any thing existed to flow? and what should that flux be, a substance, or an accident? According to the philosophic poet,

"Time of itself is nothing, but from thought
Receives its rise; by labouring fancy wrought
From things consider'd, while we think on some
As present, some as past, or yet to come.
No thought can think on time, that's still confest,
But thinks on things in motion or at rest."

And so on. Vide Lucretius, book i.

Time may be distinguished, like place, into absolute and relative.

Absolute TIME, is time considered in itself, and without any relation to bodies, or their motions.

Relative or *Apparent* TIME, is the sensible measure of any duration by means of motion.

Some authors divide time into astronomical and civil.

Astronomical TIME, is that which is taken purely from the motion of the heavenly bodies, without any other regard.

Civil TIME, is the former time accommodated to civil uses, and formed or distinguished into years, months, days, &c.

Apparent TIME, is that deduced from the motion of the heavenly bodies, as of the sun: which is unequal. And

Equal, Mean, or *True* TIME, is that which is shown by a good clock, which it is supposed never varies in its rate of going.

Equation of TIME, is the difference between true and apparent time.

TIME, in Music, is an affection of sound, by which it is said to be long or short, with regard to its continuance in the same tone or degree of tune.

Musical time is distinguished into common or duple time, and triple time.

Double, Duple, or *Common Time,* is when the notes are in a duple duration of each other, viz, a semibreve equal to 2 minims, a minim to 2 crotchets, a crotchet to 2 quavers, &c.

Common or double time is of two kinds. The first when every bar or measure is equal to a semibreve, or its value in any combination of notes of a less quantity. The second is where every bar is equal to a minim, or its value in less notes. The movements of this kind of measure are various, but there are three common distinctions; the first slow, denoted at the beginning of the line by the mark c; the 2d brisk, marked

thus ; and the 3d very brisk, thus marked .

Triple Time is when the durations of the notes are triple of each other, that is, when the semibreve is equal to 3 minims, the minim to 3 crotchets, &c; and it is marked T.

TIME-*keepers*, in a general sense, denote instruments adapted for measuring time. See CHRONOMETER. In a more peculiar and definite sense, time-keeper is a term first applied by Mr. John Harrison to his watches, constructed and used for determining the longitude at sea, and for which he received, at different times, the parliamentary reward of 20 thousand pounds. And several other artists have since received also considerable sums for their improvements of time-keepers; as Arnold, Mudge, &c. See LONGITUDE. This appellation is now become common among artists, to distinguish such watches as are made with extraordinary care and accuracy for nautical or astronomical observations.

The principles of Mr. Harrison's time-keeper, as they were communicated by himself, to the commissioners appointed to receive and publish the same in the year 1765, are as below: "In this time-keeper there is the greatest care taken to avoid friction, as much as can be, by the wheel moving on small pivots, and in ruby-holes, and high numbers in the wheels and pinions.

"The part which measures time goes but the 8th part of a minute without winding up; so that part is very simple, as this winding-up is performed at the wheel next to the balance-wheel; by which means there is always an equal force acting at that wheel, and all the rest of the work has no more to do in the measuring of time than the person that winds up once a day.

"There is a spring in the inside of the fusee, which I will call a secondary main spring. This spring is always kept stretched to a certain tension by the main spring; and during the time of winding-up the time keeper, at which time the main-spring is not suffered to act, this secondary spring supplies its place.

"In common watches in general, the wheels have about one-third the dominion over the balance, that the balance-spring has; that is, if the power which the balance-spring has over the balance be called three, that from the wheel is one: but in this my time-keeper, the wheels have only about one 18th part of the power over the balance that the balance spring has; and it must be allowed, the less the wheels are connected with the balance, the better. The wheels in a common watch having this great dominion over the balance, they can, when the watch is wound up, and the balance at rest, set the watch a-going; but when my time-keeper's balance is at rest, and the spring is wound up, the force of the wheels can no more put it in motion, than the wheels of a common regulator can, when the weight is wound-up, set the pendulum a vibrating; nor will the force from the wheels move the balance when at rest, to a greater angle in proportion to the vibration that it is to fetch, than the force of the wheels of a common regulator can move the pendulum from the perpendicular when it is at rest.

"My time-keeper's balance is more than three times the weight of a large sized common watch balance, and three times its diameter; and a common watch balance goes through about 6 inches of space in a second, but mine goes through about 24 inches in that time: so that had my instrument only these advantages over a common watch, a good performance might be expected from it. But my time-keeper is not affected by the different degrees of heat and cold, nor agitation of the ship; and the force from the wheels is applied to the balance in such a manner, together with the shape of the balance-spring, and (if I may be allowed the term) an artificial cycloid, which acts at this spring; so that from these contrivances, let the balance vibrate more or less, all its vibrations are performed in the same time; and therefore if it go at all, it must go true. So that it is plain from this, that such a time-keeper goes entirely from principle, and not from chance."—Those who may desire to see a minute account of the construction of Mr. Harrison's time-keeper, may consult the publication by order of the commissioners of longitude.

We shall here subjoin a short view of the improvements in Mr. Harrison's watch, from the account presented to the board of longitude by Mr. Ludlam, one of the gentlemen to whom, by order of the commissioners, Mr. Harrison discovered and explained the principle on which his time-keeper is constructed. The defects in common watches which Mr. Harrison proposes to remedy, are chiefly these: 1. That the main spring acts not constantly with the same force on the wheels, and through them on the balance: 2. That the balance, either urged with an unequal force, or meeting with a different resistance from the air, or the oil, or the friction, vibrates through a greater or less arch: 3. That these unequal vibrations are not performed in equal times: and, 4. That the force of the balance-spring is altered by a change of heat.

To remedy the first defect, Mr. Harrison has contrived that his watch shall be moved by a very tender spring, which never unrolls itself more than one-eighth part of a turn, and acts upon the balance through one wheel only. But such a spring cannot keep the watch in motion a long time. He has therefore, joined another, whose office is to wind up the first spring 8 times in every minute; and which is itself wound up but once a day. To remedy the second defect, he uses a much stronger balance spring than in a common watch. For if the force of this spring upon the balance remains the same, while the force of the other varies, the errors arising from that variation will be the less, as the fixed force is the greater. But a stronger spring will require either a heavier or a larger balance. A heavier balance would have a greater friction. Mr. Harrison therefore increases the diameter of it. In a common watch it is under an inch, but in Mr. Harrison's 2 inches 2 tenths. However, the methods already described only lessening the errors, and not removing them, Mr. Harrison uses two ways to make the times of the vibrations equal, though the arches may be unequal: one is, to place a pin, so that the balance-spring pressing against it, has its force increased, but increased less when the variations are larger: the other, to give the pallets such a shape, that the wheels press them with less advantage, when the vibrations are larger. To remedy the last defect, Mr. Harrison uses a bar compounded of two thin plates of brass and steel, about 2 inches in length, riveted in several places together, fastened at one end and having two pins at the other, between which the balance spring passes. If this bar be straight in temperate weather (brass changing its length by heat more than steel) the brass side becomes convex when it is heated, and the steel side when it is cold: and thus the pins lay hold of a different part of the spring in different degrees of heat, and lengthen or shorten it as the regulator does in a common watch.

The principles on which Mr. Arnold's time-keeper is constructed are these: The balance is unconnected with the wheel work, except at the time it receives the impulse to make it continue its motion, which is only while it vibrates 10° out of 380° which is the whole vibration; and during this small interval it has little or no friction, but what is on the pivots, which work in ruby holes on diamonds. It has but one pallet, which is a plane surface formed out of a ruby, and has no oil on it. Watches of this construction, says Mr. Lyons, go while they are wound up; they keep the same rate of going in every position, and are not affected by the different forces of the spring; and the compensation for heat and cold is absolutely adjustable. Phipps's Voyage to the North Pole, pa. 230. See LONGITUDE.

TISRI, or TIZRI, in Chronology, the first Hebrew month of the civil year, and the 7th of the ecclesiastical or sacred year. It answered to part of our September and October.

TOD *of wool*, is mentioned in the statute 12 Carol. II. c. 32, as a weight containing 2 stone, or 28 pounds.

TOISE, a French measure, containing 6 of their feet, similar to our fathom.—The length of the French toise, is to the English fathom, as 1065 to 1000, or as 213 to 200.

TON, is 20 hundred weight, or 2240 lbs.

TONDIN, or TANDINO, in Architecture. See TORE.

TONE, or TUNE, in Music, a property of sound, by which it comes under the relation of grave and acute; or the degree of elevation any sound has, from the degree of swiftness of the vibrations of the parts of the sonorous body.—For the cause, measure, degree, difference, &c, of tones, see TUNE.

The word Tone is taken in four different senses among the ancients. 1, For any sound. 2, For a certain interval; as when it is said the difference between the diapente and diatessaron is a tone. 3, For a certain locus or compass of the voice; in which sense they used the Dorian, Phrygian, Lydian tones. 4. For tension; as when they speak of an acute, a grave, or a middle tone. Wallis's Append. Ptolem. Harm. pa. 172.

TONE is more particularly used, in music, for a certain degree or interval of tune, by which a sound may be either raised or lowered from one extreme of a concord to the other, so as still to produce true melody. In tempered scales of music, the tones are made equal, but in a true and accurate practice of singing they are not so. Pepusch, in Philos. Trans. No. 481. Besides the concords, or harmonical intervals, musicians admit three less kinds of intervals, which are the measures and component parts of the greater, and are called degrees. Of these degrees, two are called tones, and the third a semitone. Their ratios in number are 8 to 9, called a greater tone; 9 to 10 called a lesser tone; and 15 to 16, a semitone.

The tones arise out of the simple concords, and are equal to their differences. Thus the greater tone, 8 : 9, is the difference of a 5th and a 4th; the less tone 9 : 10, the difference of a less 3d and a 4th, or of a 5th and a greater 6th; and the semitone 15 : 16, the difference of a greater 3d and a 4th.

Of these tones and semitones every concord is compounded, and consequently every one is resolvable into a certain number of them. Thus, the less 3d consists of one greater tone and one semitone: the greater 3d, of one greater tone and one less tone: the 4th, of one greater tone, one less tone, and one semitone: and the 5th, of two greater tones, one less tone, and one semitone.

TONNAGE, of a ship, is the weight or loading it is supposed to bear. The rule commonly used for computing it, is to multiply the length of the keel by the breadth of the beam, and that again by half the same breadth of the beam; the last product divided by 94, gives the number of tons burthen. Thus, if the length of keel be 100 feet, and the breadth of beam 30; then $\frac{100 \times 30 \times 15}{94} = 478$, is the tonnage.

TONSTALL (CUTHBERT), a learned English divine and mathematician, was born in the year 1476. He entered a student at the university of Oxford about the year 1491; but afterwards, being driven from thence by the plague, he went to Cambridge, and shortly after to the university of Padua in Italy, which was then in a flourishing state of literature, where his genius and learning acquired him great respect from every one, particularly for his knowledge in mathematics, philosophy, and jurisprudence.

On his return home, he met with great favours from the government, obtaining several church preferments, and the office of secretary to the cabinet of the king, Henry the 8th. This prince, having also employed him on several foreign embassies, was so well satisfied with his conduct, that he first gave him the bishopric of London in 1522, and afterwards that of Durham in 1530.

Tonstall approved at first of the dissolution of the marriage of his benefactor with Catharine of Spain, and even wrote a book in favour of that dissolution; but he afterwards condemned that work, and experienced a great reverse of fortune. He was ejected from the see of Durham for his religion in the time of Edward the 6th, to which however he was restored again by queen Mary in the beginning of her reign, but was again expelled in 1559 when queen Elizabeth was settled in her throne; and he died in a prison a few months after, in the 84th year of his age.

Tonstall was doubtless one of the most learned men of his time. "He was," says Wood, "a very good Grecian and Ebritian, an eloquent rhetorician, a skilful mathematician, a noted civilian and canonist, and a profound divine. But that which maketh for his greatest commendation, is, that Erasmus was his friend, and he a fast friend to Erasmus, in an epistle to whom from Sir Thomas More, I find this character of Tonstall, that, "As there was no man more adorned with knowledge and good literature, no man more severe and of greater integrity for his life and manners; so there was no man a more sweet and pleasant companion, with whom a man would rather choose to converse."

His writings that were published, were chiefly, 1. In Laudem Matrimonii, Lond. 1518, 4to.—But that for which he is chiefly entitled to a place in this work, was his book on arithmetic, viz,—2. De Arte Supputandi, Lond. 1522, 4to, dedicated to Sir Thomas More. This was afterwards several times printed abroad.—3. A Sermon on Palm Sunday before king Henry the 8th, &c. Lond. 1539 and 1633, 4to.—4. De Veritate Corporis & Sanguinis Domini in Eucharistia. Lutet. 1554, 4to.—5. Compendium in decem Libros Ethicorum Aristotelis. Par. 1554, in 8vo.—6. Contra impios Blasphematores Dei prædestinationis opera. Antw. 1555, 4to.—7. Godly and devout Prayers in English and Latin. 1558, in 8vo.

TOPOGRAPHY, is a description or draught of some particular place, or small tract of land; as that of a city, or town, manor or tenement, field, garden, house, castle, or the like; such as surveyors set out in their plots, or make draughts of, for the information and satisfaction of the proprietors. Topography differs from chorography, as a particular from a more general.

TORELLI (Joseph), a respectable Italian mathematician, was born at Verona in November 1721, and died in Sept. 1781. His father was a merchant, in good circumstances, who died soon after his son's birth; so that the care of Torelli's education devolved on his mother; by whom his infant mind was most attentively cultivated, and to whose care might be ascribed many of those amiable qualities, which distinguished his more advanced age. Having laid a good foundation by private instruction at Verona, he prosecuted his studies at the university of Padua, with great assiduity, in the various branches of literature and science.

Having spent four years at Padua, where he conciliated the general esteem of the learned, and where he obtained a doctor's degree, he returned to his own country. Being in easy circumstances, he declined engaging in any profession, but devoted his whole time and attention to general study, both of languages and mathematics. He became accordingly an excellent proficient in several of the ancient and modern tongues. The Greek and Hebrew he well understood; he wrote Latin with ease and correctness; and his acquaintance with the French, Spanish, and English, enabled him to peruse the best writers with pleasure and improvement. To his knowledge of the languages he added a very extensive acquaintance with the arts and sciences; so that he was no less distinguished as a mathematician and philosopher, than as a critical scholar.

Torelli was author of a great number and variety of compositions, which sufficiently evince his distinguished abilities and application. But that from which he has obtained his chief celebrity, is an edition of the collected works of Archimedes, printed at Oxford, 1792, folio, in Greek and Latin. The preparing of this work had been indeed the labour of most part of his life. Having been completely prepared for publication, and even the diagrams cut which were to accompany the demonstrations, the manuscript was disposed of after his death to the curators of the Clarendon press, by whose order it was printed under the immediate care of Dr. Robertson.

It appears that there have been few persons, in any country, or in any period of time, who were better qualified for preparing a correct edition of Archimedes. As a Greek scholar, he was capable of correcting the mistakes, supplying the defects, and illustrating the obscure passages, that occurred in treatises originally written in the Greek tongue; his knowledge of Latin, and a facility, acquired by habit, of writing in this language, rendered him a fit person to translate the Greek into pure and correct Latin; and his comprehensive acquaintance with mathematics and philosophy qualified him for conducting the whole work with judgment and accuracy.

TORNADO, a violent gust of wind arising suddenly from the shore, and afterwards veering round all points of the compass like a hurricane. It is very frequent on the coast of Guinea.

TORRENT, in Hydrography, a temporary stream of water, falling suddenly from mountains, &c, where there have been great rains, or an extraordinary thaw of snow; sometimes making great ravages in the plains.

TORRICELLI (Evangeliste), an illustrious mathematician and philosopher of Italy, was born at Faenza in 1608, and trained up in Greek and Latin literature by an uncle, who was a monk. Natural inclination led him to cultivate mathematical knowledge, which he pursued some time without a master; but at about 20 years of age, he went to Rome, where he continued the pursuit of it under father Benedict Castelli. Castelli had been a scholar of the great Galileo, and had been appointed by the pope professor of mathematics at Rome. Torricelli made such progress under this master, that having read Galileo's Dialogues, he composed a Treatise concerning motion on his principles. Castelli, surprised at the performance, carried it and read it to Galileo, who heard it with great pleasure, and conceived a high esteem and friendship for the author. On this, Castelli proposed to Galileo, that Torricelli should come and live with him; recommending him as the most proper person he could have, since he was the most capable of comprehending those sublime speculations, which his own great age, infirmities, and want of sight, prevented him from giving to the world. Galileo accepted the proposal, and Torricelli the employment, as things of all others the most advantageous to both. Galileo was at Florence, at which place Torricelli arrived in 1641, and began to take down what Galileo dictated, to regulate his papers, and to act in every respect according to his directions. But he did not long enjoy the advantages of this situation, as Galileo died at the end of only three months.

Torricelli was then about returning to Rome; but the Grand Duke engaged him to continue at Florence, making him his own mathematician for the present, and promising him the professor's chair as soon as it should be vacant. Here he applied himself intensely to the study of mathematics, physics, and astronomy, making many improvements and some discoveries. Among others, he greatly improved the art of making microscopes and telescopes; and it is generally acknowledged that he first found out the method of ascertaining the weight of the atmosphere by a proportionate column of quicksilver, the barometer being called from him the Torricellian tube, and Torricellian experiment. In short, great things were expected from him, and great things would probably have been further performed by him, if he had lived: but he died, after a few days illness, in 1647, when he had just completed the 39th year of his age.

Torricelli published at Florence in 1644, a volume of ingenious pieces, entitled, Opera Geometrica, in 4to. There was also published at the same place, in 1715, Lezzioni Accademiche, consisting of 96 pages in 4to. These are discourses that had been pronounced by him on different occasions. The first of them was to the academy of La Crusca, by way of thanks for admitting him into their body. The rest are upon subjects of mathematics and physics. Prefixed to the whole is a long life of Torricelli by Thomas Buonaventuri, a Florentine gentleman.

TORRICELLIAN, a term very frequent among physical writers, used in the phrases, Torricellian tube, or Torricellian experiment, on account of the inventor Torricelli, a disciple of the great Galileo.

Torricellian *Tube*, is the barometer tube, being a glass tube, open at one end, and hermetically sealed at the other, about 3 feet long, and $\frac{1}{4}$ of an inch in diameter.

Torricellian *Experiment*, or the filling the barometer tube, is performed by filling the Torricellian tube with mercury, then stopping the open orifice with the finger, inverting the tube, and plunging that orifice into a vessel of stagnant mercury. This done, the finger is removed, and the tube sustained perpendicular to the surface of the mercury in the vessel.

The consequence is, that part of the mercury falls out of the tube into the vessel, and there remains only enough in the tube to fill about 30 inches of its capacity, above the surface of the stagnant mercury in the vessel; these being sustained in the tube by the pressure of the atmosphere on the surface of the stagnant mercury; and according as the atmosphere is more or less heavy, or as the winds, blowing upward or downward, heave up or depress the air, and so increase or diminish its weight and spring, more or less mercury is sustained, from 28 to 31 inches.—The Torricellian experiment constitutes what is now called the barometer.

Torricellian *Vacuum*, is the vacuum produced by filling a tube with mercury, and when inverted allowing it to descend to such a height as is counterbalanced by the pressure of the atmosphere, as in the Torricellian experiment and barometer, the vacuum being that part of the tube above the surface of the mercury.

TORRID *Zone*, is that round the middle of the earth, extending to 23½ degrees on both sides of the equator.

TORUS, or Tore, in Architecture, is a large round moulding in the bases of the columns.

TOUCAN, or *American Goose*, is one of the modern constellations of the southern hemisphere, consisting of 9 small stars.

TRACTION, or *Drawing*, is the act of a moving power, by which the moveable is brought nearer to the mover, called also attraction.

Traction, *Angle of*, in Mechanics, is the angle which the direction of the power makes with any given plane.

TRACTRIX, or Tractix, in Geometry, a curve line called also Catenaria; which see.

TRAJECTORY, a term often employed to denote the path of any body moving either in a void, or in a medium that resists its motion; or even for any curve passing through a given number of points. Thus Newton, Princip. lib. 1, prob. 22, proposes to describe a trajectory that shall pass through five given points.

Trajectory *of a Comet*, is its path or orbit, or the line it describes in its motion. This path, Hevelius, in his Cometographia, will have to be very nearly a right line; but Dr. Halley concludes it to be, as it really is, a very excentric ellipsis; though its place may often be well computed on the supposition of its being a parabola. —Newton, in prop. 41 of his 3d book, shows how to determine the trajectory of a comet from three observations; and in his last prop. how to correct a trajectory graphically described.

TRAMMELS, in Mechanics, an instrument used by artificers for drawing ovals upon boards, &c. One part of it consists of a cross with two grooves at right angles; the other is a beam carrying two pins which slide in those grooves, and also the describing pencil. All the engines for turning ovals are constructed on the same principles with the trammels: the only difference is, that in the trammels the board is at rest, and the pencil moves upon it: in the turning engine, the tool, which supplies the place of the pencil, is at rest, and the board moves against it. See a demonstration of the chief properties of these instruments by Mr. Ludlam, in the Philos. Trans. vol. 70, pa. 378 &c.

TRANSACTIONS, *Philosophical*, are a collection of the principal papers and matters read before certain philosophical societies, as the Royal Society of London, and the Royal Society of Edinburgh. These transactions contain the several discoveries and histories of nature and art, either made by the members of those societies, or communicated by them from their correspondents, with the various experiments, observations, &c, made by them, or transmitted to them, &c.

The Philos. Trans. of the Royal Society of London were begun in 1665, by Mr. Oldenburg, the then secretary of that Society, and were continued by him till the year 1677. They were then discontinued on his death, till January 1678, when Dr. Grew resumed the publication of them, and continued it for the months of December 1678, and January and February 1679, after which they were intermitted till January 1683. During this last interval their want was in some measure supplied by Dr. Hooke's Philosophical Collections. They were also interrupted for 3 years, from December 1687 to January 1691, besides other smaller interruptions, amounting to near a year and a half more, before October 1695, since which time the transactions have been carried on regularly to the present day, with various degrees of credit and merit.

Till the year 1752 these transactions were published in numbers quarterly, and the printing of them was always the single act of the respective secretaries till that time; but then the Society thought fit that a committee should be appointed to consider the papers read before them, and to select out of them such as they should judge most proper for publication in the future transactions. For this purpose, the members of the council, for the time being, constitute a standing committee: they meet on the first Thursday of every month, and no less than

7 of the members of the committee (of which number the president, or in his absence a vice-president, is always to be one) are allowed to be a quorum, capable of acting in relation to such papers; and the question with regard to the publication of any paper, is always decided by the majority of votes taken by ballot.

They are published annually in two parts, at the expence of the Society; and each fellow, or member, is entitled to receive one copy gratis of every part published after his admission into the Society. For many years past, the collection, in two parts, has made one volume in each year; and in the year 1793 the number of the volumes was 83, being 10 less than the number of the year in the century. They were formerly much respected for the great number of excellent papers and discoveries contained in them; but of late years there has been a great falling off, and the volumes have been sometimes considered as of very inferior merit, as well as quantity.

There was also an useful abridgment of those volumes of the transactions that were published before the year 1752, when the Society began to publish the transactions on their own account. Those to the end of the year 1700 were abridged, in 3 volumes, by Mr. John Lowthorp: those from the year 1700 to 1720 were abridged, in 2 volumes, by Mr. Henry Jones: and those from 1719 to 1733 were abridged, in 2 volumes, by Mr. John Eames and Mr. John Martyn; Mr. Martyn also continued the abridgment of those from 1732 to 1744 in 2 volumes, and of those from 1744 to 1750 in 2 volumes; making in all 11 volumes. But lately a complete Abridgment, in 18 large 4to volumes, of the whole, from the beginning, to the end of the year 1800, has been published by Dr. Charles Hutton, Dr. George Shaw, and Dr. Richard Pearson. In this abridgment all the papers are given in their original order, and a copious index is added, by which is shown the place of any article, either in the original or in the abridgment.

The Royal Society of Edinburgh instituted in 1783, have also published several volumes of their Philosophical Transactions; which are deservedly held in the highest respect for the importance of their contents.

The Society of Arts, &c, have also published a number of volumes of transactions, abounding with mechanical inventions and discoveries. There are also transactions of the American Society, of the Manchester Philosophical Society, of the Connecticut Society, &c. The Irish Academy, and most of the foreign philosophical societies, give to their transactions the title of Memoirs.

TRANSCENDENTAL *Quantities*, among Geometricians, are indeterminate ones; or such as cannot be expressed or fixed to any constant equation: such is a transcendental curve, or the like. M. Leibnitz has a dissertation in the Acta Erud. Lips. in which he endeavours to show the origin of such quantities; viz, why some problems are neither plain, solid, nor sursolid, nor of any certain degree, but transcend all algebraic equations. He also shows how it may be demonstrated without calculus, that an algebraic quadratrix for the circle or hyperbola is impossible: for if such a quadratrix could be found, it would follow, that by means of it any angle, ratio, or logarithm, might be divided in a given proportion of one right line to another, and this by one universal construction: and consequently the problem of the section of an angle, or the invention of any number of mean proportionals, would be of a certain finite degree. Whereas the different degrees of algebraic equations, and therefore the problem understood in general of any number of parts of an angle, or mean proportionals, is of an indefinite degree, and transcends all algebraical equations.

Others define transcendental equations, to be such fluxional equations as do not admit of fluents in common finite algebraical equations, but as expressed by means of some curve, or by logarithms, or by infinite series; thus the expression $\dot{y} = \frac{\dot{x}}{\sqrt{(aa-xx)}}$ is a transcendental equation, because the fluents cannot both be expressed in finite terms. And the equation which expresses the relation between an arc of a circle and its sine, is a transcendental equation; for Newton has demonstrated that this relation cannot be expressed by any finite algebraic equation, and therefore it can only be by an infinite or a transcendental equation.

It is also usual to rank exponential equations among transcendental ones; because such equations, though expressed in finite terms, have variable exponents, which cannot be expunged but by putting the equation into fluxions, or logarithms, &c. Thus, the exponential equation

$y = a^x$, gives $x \times \log. a = \log. y$, or $\dot{x} \times \log. a = \frac{\dot{y}}{y}$.

TRANSCENDENTAL *Curve*, in the Higher Geometry, is such a one as cannot be defined by an algebraic equation; or of which, when it is expressed by an equation, one of the terms is a variable quantity, or a curve line. And when such curve line is a geometrical one, or one of the first degree or kind, then the transcendental curve is said to be of the second degree or kind, &c.

These curves are the same with what Descartes, and others after him, call mechanical curves, and which they would have excluded out of geometry; contrary however to the opinion of Newton and Leibnitz; for as much as, in the construction of geometrical problems, one curve is not to be preferred to another as it is defined by a more simple equation, but as it is more easily described than that other: besides, some of these transcendental, or mechanical curves, are found of greater use than almost all the algebraical ones.

M. Leibnitz, in the Acta Erudit. Lips. has given a kind of transcendental equations, by which these transcendental curves are actually defined, and which are of an indefinite degree, or are not always the same in every point of the curve. Now whereas algebraists use to assume some general letters or numbers for the quantities sought, in these transcendental problems Leibnitz assumes general or indefinite equations for the lines sought; thus, for example, putting x and y for the abscis and ordinate, the equation he uses for a line required, is $a + bx + cy + exy + fxx + gyy$ &c $= 0$: by the help of which indefinite equation, he seeks for the tangent; and comparing that which results with the given property of tangents, he finds the value of the assumed letters a, b, c, &c, and thus defines the equation of the line sought.

If the comparison abovementioned do not succeed, he pronounces the line sought not to be an algebraical, but a transcendental one. This supposed, he proceeds to find the species of transcendency: for some transcendentals depend on the general division or section of a ratio, or upon logarithms, others on circular arcs, &c. Here then, besides the symbols x and y, he assumes a third, as v, to denote the transcendental quantity; and of these three he forms a general equation of the line sought, from which he finds the tangent according to the differential method, which succeeds even in transcendental quantities. This found, he compares it with the given properties of the tangents, and so discovers not only the values of a, b, c, &c, but also the particular nature of the transcendental quantity.

Transcendental problems are very well managed by the method of fluxions. Thus, for the relation of a circular arc and right line, let a denote the arc, and x the versed sine, to the radius 1, then is $a =$ fluent of $\frac{\dot{x}}{\sqrt{(2x-xx)}}$; and if the ordinate of a cycloid be y, then is $y = \sqrt{(2x-xx)} +$ fluent of $\frac{\dot{x}}{\sqrt{(2x-xx)}}$.

Thus is the analytical calculus extended to those lines which have hitherto been excluded, for no other cause but that they were thought incapable of it.

TRANSFORMATION, in Geometry, is the changing or reducing of a figure, or of a body, into another of the same area, or the same solidity, but of a different form. As, to transform or reduce a triangle to a square, or a pyramid to a parallelopipedon.

TRANSFORMATION *of Equations*, in Algebra, is the changing equations into others of a different form, but of equal value. This operation is often necessary, to prepare equations for a more easy solution, some of the principal cases of which are as follow.—1. The signs of the roots of an equation are changed, viz, the positive roots into negative, and the negative roots into positive ones, by only changing the signs of the 2d, 4th, and all the other even terms of the equation. Thus, the roots of the equation $x^4-x^3-19x^2+49x-30 = 0$, are $+1, +2, +3, -5$; whereas the roots of the same equation having only the signs of the 2d and 4th terms changed, viz, of $x^4+x^3-19x^2-49x-30 = 0$, are $-1, -2, -3, +5$.

2. To transform an equation into another that shall have its roots greater or less than the roots of the proposed equation by some given difference, proceed as follows: Let the proposed equation be the cubic $x^3-ax^2+bx-c = 0$; and let it be required to transform it into another, whose roots shall be less than the roots of this equation by some given difference d; if the root y of the new equation must be the less, take it $y = x - d$, and hence $x = y + d$; then instead of x and its powers substitute $y + d$ and its powers, and there will arise this new equation

$$(\text{A})\quad \left.\begin{matrix} y^3 & + & 3dy^2 & + & 3d^2y & + & d^3 \\ & - & ay^2 & - & 2ady & - & ad^2 \\ & & & + & by & + & bd \\ & & & & & - & c \end{matrix}\right\} = 0,$$

whose roots are less than the roots of the former equation by the difference d. If the roots of the new equation had been required to be greater than those of the original one, we must then have substituted $y = x + d$, or $x = y - d$, &c.

3. To take away the 2d or any other particular term out of an equation; or to transform an equation, so as the new equation may want its 2d, or 3d, or 4th, &c term of the given equation $x^3 - ax^2 + bx - c = 0$, which is transformed into the equation (A) in the last article. Now to make any term of this equation (A) vanish, is only to make the coefficient of that term $= 0$, which will form an equation that will give the value of the assumed quantity d, so as to produce the desired effect, viz, to make that term vanish. So, to take away the 2d term, make $3d - a = 0$, which makes the assumed quantity $d = \frac{1}{3}a$. To take away the 3d term, we must put the sum of the coefficients of that term $= 0$, that is $3d^2 - 2ad + b = 0$, or $3d^2 - 2ad = -b$; then by resolving this quadratic equation, there is found the assumed quantity $d = \frac{1}{3}a \pm \frac{1}{3}\sqrt{(a^2 - 3b)}$, by the substitution of which for d, the 3d term will be taken away out of the equation.

In like manner, to take away the 4th term, we must make the sum of its coefficients $d^3 - ad^2 + bd - c = 0$; and so on for any other term whatever. And in the same manner we must also proceed when the proposed equation is not a cubic, but of any height whatever, as

$$x^n - ax^{n-1} + bx^{n-2} - cx^{n-3} \;\&c = 0;$$

this is first, by substituting $y + d$ for x, to be transformed to this new equation

$$\left.\begin{matrix} y^n + ndy^{n-1} + \frac{1}{2}n(n-1)d^2y^{n-2} \;\&c \\ -\; ay^{n-1} - a(n-1)dy^{n-2} \;\&c \\ +\; by^{n-2} \;\&c \end{matrix}\right\} = 0;$$

then, to take away the 2d term, we must make $nd - a = 0$, or $d = \frac{a}{n}$; to take away the 3d term, we must make $\frac{1}{2}n(n-1)d^2 - a(n-1)d + b = 0$, or $d^2 - \frac{2a}{n}d = -\frac{2b}{n(n-1)}$; and so on.

Whence it appears that, to take away the 2d term of an equation, we must resolve a simple equation; for the 3d term, a quadratic equation; for the 4th term, a cubic equation, and so on.

4. To multiply or divide the roots of an equation by any quantity; or to transform a given equation to another, that shall have its roots equal to any multiple or submultiple of those of the proposed equation. This is done by substituting, for x and its powers, $\frac{y}{m}$ or py, and their powers, viz, $\frac{y}{m}$ for x, to multiply the roots by m; and py for x, to divide the roots by p. Thus, to multiply the roots by m, substituting $\frac{y}{m}$ for x in the proposed equation

$x^n - ax^{n-1} + bx^{n-2}$ &c $= 0$, and it becomes

$$\frac{y^n}{m^n} - \frac{ay^{n-1}}{m^{n-1}} + \frac{by^{n-2}}{m^{n-2}} \;\&c = 0;$$

or multiply all by m^n, then is

$$y^n - amy^{n-1} + bm^2y^{n-2} - cm^3y^{n-3} \;\&c = 0,$$

an equation that has its roots equal to m times the roots of the proposed equation.

In like manner, substituting py for x, in the proposed equation, &c, it becomes

$$y^n - \frac{ay^{n-1}}{p} + \frac{by^{n-2}}{p^2} - \frac{cy^{n-3}}{p^3} \;\&c = 0,$$

an equation that has its roots equal to those of the proposed equation divided by p.

Whence it appears, that to multiply the roots of an equation by any quantity m, we must multiply its terms, beginning at the 2d term, respectively by the terms of the geometrical series, m, m^2, m^3, m^4, &c. And to divide the roots of an equation by any quantity p, that we must divide its terms, beginning at the 2d, by the corresponding terms of this series p, p^2, p^3, p^4, &c.

5. And sometimes, by these transformations, equations are cleared of fractions, or even of surds. Thus the equation

$x^3 - ax^2\sqrt{p} + bx - c\sqrt{p} = 0$, by putting $y = x\sqrt{p}$, or multiplying the terms, from the 2d, by the geometricals $\sqrt{p}$, p, $p\sqrt{p}$, is transformed to

$$y^3 - apy^2 + bpy - cp^2 = 0.$$

6. An equation, as $x^3 - ax^2 + bx - c = 0$, may be

transformed into another, whose roots shall be the reciprocals of the roots of the given equation, by substituting $\frac{1}{y}$ for x; by which it becomes

$\frac{1}{y^3} - \frac{a}{y^2} + \frac{b}{y} - c = 0$, or, multiplying all by y^3, the same becomes $cy^3 - by^2 + ay - 1 = 0$.

On this subject, see Newton's Alg. on the Transmutation of Equations; Maclaurin's Algeb. pt. 2, chap. 3 and 4. Saunderson's Algebra, vol. 2, pa 687, &c.

TRANSIT, in Astronomy, denotes the passage of any planet, just before or over another planet or star; or the passing of a star or planet over the meridian, or before an astronomical instrument. Venus and Mercury, in their transits over the sun, appear like dark specks.

The transits of Venus and Mercury over the sun's disc are very interesting phenomena, not merely on account of their rare and singular appearance, but also because of their use in determining the sun's parallax, and thence the real dimensions of the earth's orbit. Hence the times when these transits are to be seen have been very carefully computed. Dr. Halley computed the times of a number of these visible transits, for the 17th and 18th centuries, which were published in the Philos. Trans. No. 193, or my Abridg. vol. 3, pa. 448; and several others have been since computed. The following are the times when there were or will be transits of Mercury, from the year 1753 to 1894 inclusive.

1753 - - -	May 5	1832 - - -	May 5
1756 - - -	Nov. 6	1835 - - -	Nov. 7
1769 - - -	Nov. 9	1845 - - -	May 8
1776 - - -	Nov. 2	1848 - - -	Nov. 9
1782 - - -	Nov. 12	1861 - - -	Nov. 11
1786 - - -	May 5	1868 - - -	Nov. 4
1789 - - -	Nov. 5	1878 - - -	May 5
1799 - - -	May 7	1881 - - -	Nov. 7
1802 - - -	Nov. 8	1891 - - -	May 9
1815 - - -	Nov. 11	1894 - - -	Nov. 10
1822 - - -	Nov. 4		

It appears from this table, that the transits of Mercury always occur either in May or in November; but most frequently in the latter month; depending on the position of the elliptic projection of Mercury's orbit on the plane of the ecliptic. This ellipse is now so placed, that it presents to us its perihelion, during the winter, and its aphelion during the summer; and as it is very excentric, Mercury is much nearer the sun in the month of November than in May. Now if it be considered that the luminous cone formed by the visual rays, drawn from the earth to the sun, is contracted in the vicinity of the earth, while it is enlarged near the sun, the disc of which serves for its base; Mercury ought therefore to cut it more readily when it is near the sun, than when it is remote from it; and consequently the transits of Mercury ought to occur most frequently in the winter part of the year.

From the observations of the transit of Nov. 8, 1802, it was inferred that the node of the planet's orbit was in 1ˢ 15° 52′ 56″.

The transits of Venus across the sun's disc happen much less frequently than those of Mercury, because Venus is more distant from the sun. The following are all that occur between 1631 and 2110.

1631 - - -	Dec. 6	1874 - - -	Dec. 8
1639 - - -	Dec. 4	1882 - - -	Dec. 6
1761 - - -	June 5	2004 - - -	June 7
1769 - - -	June 3	2109 - - -	Dec. 10

Now the chief use of these conjunctions is, accurately to determine the sun's distance from the earth, or his parallax, which astronomers have in vain attempted to find by various other methods; for the minuteness of the requisite angles easily eludes the nicest instruments. But in observing the ingress of Venus into the sun, and her egress from the same, the interval between the moments of the internal contacts, observed to a second of time, that is, to $\frac{1}{15}$ of a second, or 4‴ of an arch, may be obtained by the assistance of a moderate telescope, and a pendulum clock that goes uniformly for 6 or 8 hours. Now from two such observations, rightly made in proper places, the distance of the sun, within a 500th part, may be certainly concluded, &c.—The only observations that have been made, were those of 1639, 1761, and 1769; whence the sun's parallax has been inferred to be 8″.6. See PARALLAX and VENUS.

TRANSIT *Instrument*, in Astronomy, is a telescope fixed at right angles to a horizontal axis; this axis being so supported that the line of collimation may move in the plane of the meridian.

The axis, to the middle of which the telescope is fixed, should gradually taper towards its ends, and terminate in cylinders well turned and smoothed; and a proper weight or balance is put on the tube, so that it may stand at any elevation when the axis rests on the supporters. Two upright posts of wood or stone, firmly fixed at a proper distance, are to sustain the supporters to this instrument; these supporters are two thick brass plates, having well smoothed angular notches in their upper ends to receive the cylindrical arms of the axis; each of the notched plates is contrived to be moveable by a screw, which slides them upon the surfaces of two other plates immoveably fixed to the two upright posts; one plate moving in a vertical direction, and the other horizontally, they adjust the telescope to the planes of the horizon and meridian; to the plane of the horizon, by a spirit level hung in a position parallel to the axis, and to the plane of the meridian in the following manner. Observe the times by the clock when a circumpolar star, seen through this instrument, transits both above and below the pole; then if the times of describing the eastern and western parts of its circuit be equal, the telescope is then in the plane of the meridian; otherwise the notched plates must be gently moved till the time of the star's revolution is bisected by both the upper and lower transits, taking care at the same time that the axis keeps its horizontal position.

When the telescope is thus adjusted, a mark must be set up, or made, at a considerable distance (the greater the better) in the horizontal direction of the intersection of the cross wires, and in a place where it can be illuminated in the night-time by a lanthorn near it, which mark, being on a fixed object, will serve at all times afterwards to examine the position of the telescope, by first adjusting the transverse axis by the level.

To adjust a clock by the sun's transit over the meridian, note the times by the clock, when the preceding and following edges of the sun's limb touch the cross wires: the difference between the middle time and 12 hours, shows how much the mean, or clock time, is faster and slower than the apparent or solar time, for that day; to which the equation of time being applied, it will show the time of mean noon for that day, by which the clock may be adjusted.

TRANSMISSION, in Optics, &c, denotes the property of a transparent or translucent body, by which it admits the rays of light to pass through its substance; in which sense, the word stands opposed to reflection.—For the cause of transmission, or the reason why some bodies transmit the rays, and others reflect them, see TRANSPARENCY and OPACITY.—The rays of light, Newton observes, are subject to fits of easy transmission and reflection. See LIGHT, and REFLECTION.

TRANSMUTATION, or TRANSFORMATION, in Geometry, denotes the reduction or change of one figure or body into another of the same area or solidity; as a triangle into a square, a pyramid into a cube, &c.

TRANSMUTATION, in the Higher Geometry, has been used for the converting of a figure into another of the same kind and order, whose respective parts rise to the same dimensions in an equation, and admit the same tangents, &c.—If a rectilineal figure be to be transmuted into another, it is sufficient that the intersections of the lines which compose it be transferred, and lines drawn through the same in the new figure. But if the figure to be transmuted be curvilinear the points, tangents, and other right lines, by means of which the curve line is to be defined, must be transferred.

TRANSOM, among Builders, the piece that is framed across a double light window.

TRANSOM, among Mathematicians, denotes the vane of a cross-staff; being a wooden member fixed across it, with a square upon which it slides, &c.

TRANSPARENCY, or TRANSLUCENCY, in Physics, a quality in certain bodies, by which they give passage to the rays of light. The transparency of natural bodies, as glass, water, air, &c, is ascribed by some, to the great number and size of the pores or interstices between the particles of those bodies. But this account is very defective; for the most solid and opaque body in nature, that we know of, contains a great deal more of pores than it does matter; surely a great deal more than is necessary for the passage of so very fine and subtle a body as light.

Aristotle, Descartes, &c, make transparency to consist in straightness or rectilineal direction of the pores; by means of which, say they, the rays can pass freely through, without striking against the solid parts, and so being reflected back again. But this account, Newton shows, is imperfect; the quantity of pores in all bodies being sufficient to transmit all the rays that fall upon them, however those pores be situated with respect to each other.

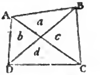
The reason then why all bodies are not transparent, is not to be ascribed to their want of rectilineal pores; but either to the unequal density of the parts, or to the pores being filled with some foreign matters, or to their being quite empty, by means of which the rays, in passing through, undergoing a great variety of reflections and refractions, are perpetually diverted different ways, till at length falling on some of the solid parts of the body, they are extinguished and absorbed.

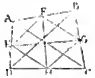
Thus cork, paper, wood, &c, are opake; while glass, diamonds, &c, are transparent; and the reason is, that in the neighbourhood of parts equal in density with respect to each other, as these latter bodies, the attraction being equal on every side, no reflection or refraction ensues: but the rays which entered the first surface of the body proceed quite through it without interruption, those few only excepted that chance to meet with the solid parts: but in the neighbourhood of parts that differ much in density, such as the parts of wood and paper are, both in respect of themselves and of the air, or the empty space in their pores; as the attraction is very unequal, the reflections and refractions must be very great; and therefore the rays will not be able to make their way through such bodies, but will be variously deflected, and at length quite stopped. See OPACITY.

TRANSPOSITION, in Algebra, is the bringing any term of an equation over to the other side of it. Thus if $a + x = c$, and we make $x = c - a$, then a is said to be transposed. This operation is to be performed in order to bring all the known terms to one side of the equation, and all those that are unknown to the other side of it; and every term thus transposed must always have its sign changed, from + to −, or from − to +; which in fact is no more than subtracting or adding such term on both sides of the equation. See REDUCTION of Equations.

TRANSVERSE-*Axis*, or *Diameter*, in the Conic Sections, is the first or principal diameter, or axis. See AXIS, DIAMETER, and LATUS TRANSVERSUM. In an ellipse, the transverse is the longest of all the diameters; but the shortest of all in the hyperbola; and in the parabola the diameters are all equal, or at least in a ratio of equality.

TRAPEZIUM, in Geometry, a plane figure of four straight sides, of which the opposites are not parallel.—When this figure has two of its sides parallel to each other, it is sometimes called a trapezoid.—The chief properties of the trapezium are as follow: 1. Any three sides of a trapezium taken together, are greater than the 4th side.—2. The two diagonals of any trapezium divide it into four proportional triangles, a, b, c, d; that is, the triangle $a : b :: c : d$.—3. The sum of all the four inward angles, A, B, C, D, taken together, is equal to 4 right angles, or 360°.





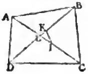
4. In a trapezium ABCD, if all the sides be bisected, in the points E, F, G, H, the figure EFGH formed by joining the points of bisection will be a parallelogram, having its opposite sides parallel to the corresponding diagonals of the trapezium, and the area of the said inscribed parallelogram is just equal to half the area of the trapezium.—5. The sum of the squares of the diagonals of the trapezium, is equal to double the sum of the squares of the diagonals of the parallelogram, or of the two lines drawn to bisect the opposite sides of the trapezium. That is,

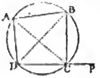
$$AC^2 + BD^2 = 2EG^2 + 2FH^2.$$

6. In any trapezium, the sum of the squares of all the four sides, is equal to the sum of the squares of the two diagonals together with 4 times the square of the line KI joining their middle points. That is,

$$AB^2 + BC^2 + CD^2 + DA^2 = AC^2 + BD^2 + 4IK^2.$$

7. In any trapezium, the sum of the two diagonals, is less than the sum of any four lines that can be drawn, to the four angles, from any point within the figure, besides the intersection of the diagonals.—8. The area of any trapezium, is equal to half the rectangle or product under





either diagonal and the sum of the two perpendiculars drawn upon it from the two opposite angles.—9. The area of any trapezium may also be found thus: Multiply the two diagonals together, then that product, multiplied by the sine of their angle of intersection, to the radius 1, will be the area. That is, $AC \times BD \times \sin. \angle L = \text{area}$. —10. The same area will be otherwise found thus: Square each side of a trapezium, add the squares of each pair of opposite sides together, subtract the less sum from the greater, multiply the remainder by the tangent of the angle of intersection of the diagonals (to radius 1), and ¼ of the product will be the area: that is,

$$[(AB^2 + DC^2) - (AD^2 + BC^2)] \times \tfrac{1}{4} \text{ tang. } \angle L = \text{area}.$$

11. The area of a trapezoid, or one that has two sides parallel, is equal to the rectangle or product under the sum of the two parallel sides and the perpendicular distance between them.—12. If a trapezium be inscribed in a circle; the sum of any two opposite angles is equal to two right angles; and if the sum of two opposite angles be equal to two right angles, the sum of the other two will also be equal to two right angles, and a circle may be described about it; and farther, if one side, as DC, be produced, the external angle will be equal to the interior opposite angle. That is, (last fig. above)

$$\angle A + \angle C = \angle B + \angle D = 2 \text{ right angles},$$

and $\angle A = \angle BCP$.

13. If a trapezium be inscribed in a circle; the rectangle of the two diagonals, is equal to the sum of the two rectangles contained under the opposite sides. That is, $AC \times BD = AB \times DC + AD \times BC$.

14. If a trapezium be inscribed in a circle; its area may be found thus: Multiply any two adjacent sides together, and the other two sides together; then add these two products together, and multiply the sum by the sine of the angle included by either of the pairs of sides that are multiplied together, and half this last product will be the area. That is, the area is equal either

to $(AB \times AD + CB \times CD) \times \tfrac{1}{2} \sin. \angle A$ or $\angle C$,
or $(AB \times BC + AD \times DC) \times \tfrac{1}{2} \sin. \angle B$ or $\angle D$.

15. Or, when the trapezium can be inscribed in a circle, the area may be otherwise found thus: Add all the four sides together, and take half the sum; then from this half sum subtract each side severally; multiply the four remainders continually together, and the square root of the last product will be the area.

16. Lastly, the area of the trapezium inscribed in a circle may be otherwise found thus:

$$\text{Put } m = AB \times BC + AD \times DC,$$
$$n = BA \times AD + BC \times CD,$$
$$p = AB \times DC + AD \times BC,$$
$$r = \text{radius of the circumscribing circle},$$

then $\sqrt{mnp} \div 4r =$ the area of the trapezium.

TRAPEZOID, sometimes denotes a trapezium that has two of its sides parallel to each other; and sometimes an irregular solid figure, having four sides not parallel to each other. See Trapezium.

TRAVERSE, in Gunnery, is the turning a piece of ordnance about, as upon a centre, to make it point in any particular direction.

Traverse, in Fortification, is a trench with a little parapet, sometimes two, one on each side, to serve as a cover from the enemy that might come in flank.

Traverse, in a wet foss, is a kind of gallery, made by throwing saucissons, joists, fascines, stones, earth, &c, into the foss, opposite the place where the miner is to be put, in order to fill up the ditch, and make a passage over it.

Traverse also denotes a wall of earth, or stone, raised across a work, to stop the shot from rolling along it.

Traverse is also used for any retrenchment, or line fortified with fascines, barrels or bags of earth, or gabions.

Traverse, in Navigation, is the variation of a ship's course, occasioned by the shifting of the winds, or currents, &c; or a traverse is a compound course, consisting of several different courses and distances.

Traverse *Sailing*, is the method of working, or calculating traverses, or compound courses, so as to bring them into one, &c. Traverse sailing is used when a ship, having sailed from one port towards another, whose course and distance from the former is known, is by reason of contrary winds, or other accidents, forced to shift and sail upon several courses, which are to be reduced into one course, in order to determine, after so many turnings and windings, the true course and distance made good, or the true point the ship is arrived at; and so to know what is the true distance, and the new course to be steered, to arrive at the intended port.

To Construct a Traverse. Assume a convenient point or centre, to begin at, to represent the place sailed from. From that point as a centre, with the chord of 60°, describe a circle, which quarter with two perpendicular lines intersecting in the centre, one to represent the meridian, or north-and-south line, and the other the east-and-west line. From the intersections of these lines with the circle, set off upon the circumference, the arcs or degrees, taken from the chords, for the several courses that have been sailed upon, marking the points they reach to, in the circumference, with the figures for the order or number of the courses, 1, 2, 3, 4, &c; and from the centre draw lines to these several points in the circumference, or conceive them to be drawn. On the first of these lines lay off the first distance sailed; from the extremity of this distance draw a line parallel to the second radius, or line drawn in the circle, upon which lay off the 2d distance; through the end of this 2d distance draw a line parallel to the 3d radius, for the direction of the 3d course, and on it lay off the 3d distance; and so on, through all the courses and distances. This done, draw a line from the centre to the end of the last distance, which will be the whole distance made good, and it will cut the circle in a point showing the course made good. Lastly, draw a line from the end of the last distance to the point representing the port bound to, and it will show the distance and course yet to be sailed, to gain that port.

To work a Traverse, or to compute it by the Traverse Table, of Difference of Latitude and Departure.

Make a little tablet with 6 columns; the 1st for the courses, the 2d for the distances, the 3d for the northing, the 4th for the southing, the 5th for the easting, and the 6th for the westing; first entering the several courses and distances, in so many lines, in the 1st and 2d columns. Then, from the traverse table, take out the quantity of the northings or southings, and eastings or westings, answering to the several given courses and distances, entering them on their corresponding lines, and in the proper columns of easting, westing, northing and southing. This done, add up into one sum the numbers in each of these last four columns, which will give four sums showing the whole quantity of easting, westing, northing, and southing made good; then take the difference between the whole easting and westing, and also between the northing and southing, so shall these show the spaces made good in these two directions, viz, east or west, and north or south; which being compared with the given difference of latitude and departure, will show those yet to be obtained in sailing to the desired port, and thence the course and distance to it.

Example. A ship from the latitude 28° 32′ north, bound to a port distant 100 miles, and bearing NE by N, has run the following courses and distances, viz, 1st, NW by N dist. 20 miles; 2d, SW 40 miles; 3d, NE by E 60 miles; 4th, SE 55 miles; 5th, W by S 41 miles; 6th, ENE 66 miles. Required her present latitude, with the direct course and distance made good, and those for the port bound to.

The numbers being taken out of the traverse table, and entered opposite the several courses and distances, the tablet will be as here follows:

Courses.	Dist.	N.	S.	E.	W.
NW by N	20	16·6	.	.	11·1
SW	40	.	28·3	.	28·3
NE b E	60	33·3	.	49·9	.
SE	55	.	38·9	38·9	.
W b S	41	.	8·0	.	40·2
ENE	66	25·3	.	61·0	.
		75·2	75·2	149·8	79·6
		75·2		79·6	
		0		70·2	Dep.

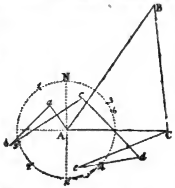
where the sums of the northings and southings, being both alike, 75·2, shows that the ship is come to the same parallel of latitude she set out from. And the difference between the sums of the eastings and westings, shows that the ship is 70·2 miles more to the eastward, that being the greater. Consequently the course made good is due east, and the distance is 70·2 miles.

But, by the traverse table, the northing and easting to the proposed course NE by N, and distance 100, are thus,

viz, northing 83·1 and easting 55·6
diff. from made good 0 and easting 70·2
give - - northing 83·1 and westing 14·6

yet to be made good to arrive at the intended port; and therefore, by finding these in the traverse table, answering to them are the intended course and distance, viz, distance 85, and course N 10° W.

The geometrical construction, according to the method before described, gives the figure annexed: where A is the port sailed from, B is the port bound to, C is the place come to, by sailing the several courses and distances A*a*, *ab*, *bc*, *cd*, *de*, and *e*C; then CB is the distance to be sailed to arrive at the port B, and its course, or direction with the meridian, is nearly 10°, or the angle ACB, made with the east-and-west line, nearly 80°.—*Note*, the radii from the centre to the several points in the circumference, are omitted, to prevent a confusion in the figure.



TRAVERSE-*Board*, in a ship, a small round board, hanging up in the steerage, and pierced full of holes in lines showing the points of the compass: upon which, by moving a small peg from hole to hole, the steersman keeps an account how many glasses, that is half hours, the ship steers upon any point.

TRAVERSE-*Table*, in Navigation, is the same with a table of difference of latitude and departure; being the difference of latitude and departure ready calculated to every point, half point, quarter point, degree, &c, of the quadrant; and for every distance, up to 50 or 100 or 120, &c. Though it may serve for any greater distance whatever, by adding two or more together; or by taking their halves, thirds, fourths, &c, and then doubling, tripling, quadrupling, &c, the difference of latitude and departure found to those parts of the distance.

This table is one of the most necessary and useful things a navigator has occasion for; for by it he can readily reduce all his courses and distances, run in the space of 24 hours, into one course and distance; whence he finds the latitude he is in, and the departure from the meridian.

One of the best tables of this kind is in Robertson's Navigation, at the end of book 7, vol. 1. The distances are there carried to 120, for the sake of more easy subdivisions; and it is divided into two parts; the first containing the courses for every quarter point of the compass, and the 2d adapted to every 15′, or quarter of a degree, in the quadrant. See TRAVERSE *Sailing*.

A specimen of such a traverse table is the following, otherwise called a table of difference of latitude and departure. The distances are placed at top and bottom of the columns, from 1 to 10; but may be extended to any quantity by multiplying the parts, and taking out at several times. The courses, or angles of a right-angled triangle, are in a column, on both sides, each in two parts, the one containing the even points and quarter points, and the other whole degrees, as far as to 45°, or half the quadrant, on the left-hand side, and the other half quadrant, from 45° to 90°, returned upwards from bottom to top on the right-hand side. The corresponding difference of latitude and departure are in two columns below or above the distances, viz, below them when the course or angle is within 45°, or found on the left-hand side; but above them when between 45 and 90°, or found on the right-hand side.

The same table serves also to work all cases of right-angled triangles, for any other purposes. For example, Suppose a given course be 15°, and distance 35 miles, to find the corresponding difference of latitude and the departure: Or, in a right-angled triangle, given the hypothenuse 35, and one angle 15°, to find the two legs.—Here, the distance 3 in the table must be accounted 30, moving the decimal point proportionally or one place in the other numbers; and those numbers taken out at twice, viz, once from the columns under 3 for the 30, and the other from the columns under the distance 5. Thus, on the line of 15°, and under the

	Dist.		*Lat.*		*Dep.*
	30	are	28·978	and	7·765
	5	are	4·830	and	1·294
therefore for	35	are	33·808	and	9·059

So that the other two legs of the triangle are 33·808 and 9·059. If the course had been 75°, or the complement of the former, which is only the other angle of the same triangle, and which is found on the same line of the table, but on the right-hand side of it; then the numbers in the columns will be the same as before, and will give the same sums for the two legs of the triangle, only with the contrary names, as to latitude and departure, which change places.

A Table of the Difference of Latitude and Departure, for Degrees and Quarter Points.

TREBLE, in Music, the highest or acutest of the four parts in symphony, or that which is heard the clearest and shrillest in a concert. In the like sense we say, a treble violin, treble hautboy, &c. In vocal music, the treble is usually committed to boys and girls; their proper part being the treble. The treble is divided into first or highest treble, and second or bass treble. The half treble is the same with the counter-tenor.

TRENCHES, in Fortification, are ditches which the besiegers cut to approach more securely to the place attacked; whence they are called lines of approach. Their breadth is 8 or 10 feet, and depth 6 or 7.—They say, mount the trenches, that is, go upon duty in them. To relieve the trenches, is to relieve such as have been upon duty there. The enemy is said to have cleared the trenches, when he has driven away or killed the soldiers who guarded them.

Tail of the TRENCH, is the place where it was begun. And the *Head* is the place where it ends.

Opening of the TRENCHES, is when the besiegers first begin to work upon them, or to make them; which is usually done in the night.

TREPIDATION, in the ancient astronomy, denotes what was called a libration of the 8th sphere; or a motion which the Ptolemaic system attributed to the firmament, to account for certain almost insensible changes and motions observed in the axis of the world; by means of which the latitudes of the fixed stars come to be gradually changed, and the ecliptic appears to approach reciprocally, first towards one pole and then towards the other.—This motion is also called the motion of the first libration.

TRET, in Commerce, is an allowance made for the waste, or the dust, that may be mixed with any commodity; which is always 4 pounds on every 104 pounds weight. See TARE.

TRIANGLE, in Geometry, a figure bounded or contained by three lines or sides, and which consequently has three angles, whence the figure takes its name.

Triangles are either plane or spherical or curvilinear. Plane when the three sides of the triangle are right lines; but spherical when some or all of them are arcs of great circles on the sphere.

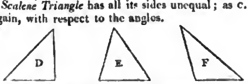
Plane triangles take several denominations, both from the relation of their angles, and of their sides, as below. And 1st with regard to the sides.

An *Equilateral Triangle*, is that which has all its three sides equal to one another; as A.

An *Isosceles* or *Equicrural Triangle*, is that which has two sides equal; as B.

A *Scalene Triangle* has all its sides unequal; as C.

Again, with respect to the angles.



A *Rectangular* or *Right-angled Triangle*, is that which has one right angle; as D.

An *Oblique Triangle* is that which has no right angle, but all oblique ones; as E or F.

An *Acutangular* or *Oxygone Triangle*, is that which has three acute angles; as E.

An *Obtusangular* or *Amblygone Triangle*, is that which has an obtuse angle; as F.

A *Curvilinear* or *Curvilineal Triangle*, is one that has all its three sides curve lines.

A *Mixtilinear Triangle*, is one that has its sides some of them curves, and some right lines.

A *Spherical Triangle* is one that has its sides, or at least some of them, arcs of great circles of the sphere.

Similar Triangles are such as have the angles in the one equal to the angles in the other, each to each.

The *Base* of a triangle, is any side on which a perpendicular is drawn from the opposite angle, called the vertex: and the two sides about the perpendicular, or the vertex, are called the legs.

The chief properties of plane triangles, are as follow, viz, In any plane triangle,

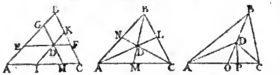
1. The greatest side is opposite to the greatest angle, and the least side to the least angle, &c. Also, if two sides be equal, their opposite angles are equal; and if the triangle be equilateral, or have all its sides equal, it will also be equiangular, or have all its angles equal to one another.—2. Any side of a triangle is less than the sum, but greater than the difference, of the other two sides.—3. The sum of all the three angles, taken together, is equal to two right angles.—4. If one side of a triangle be produced, the external angle, made by it and the adjacent side, is equal to the sum of the two opposite internal angles.—5. A line drawn parallel to one side of a triangle, cuts the other two sides proportionally, the corresponding segments being proportional, each to each, and to the whole sides; and the triangle cut off is similar to the whole triangle.

If a perpendicular be let fall from any angle of a triangle, as a vertical angle, upon the opposite side as a base; then, 6. The rectangle of the sum and difference of the sides, is equal to twice the rectangle of the base and the distance of the perpendicular from the middle of the base.—Or, which is the same thing in other words, 7. The difference of the squares of the sides, is equal to the difference of the squares of the segments of the base. Or, as the base is to the sum of the sides, so is the difference of the sides, to the difference of the segments of the base.—8. The rectangle of the legs or sides, is equal to the rectangle of the perpendicular and the diameter of the circumscribing circle.

If a line be drawn bisecting any angle, to the base or opposite side; then, 9. The segments of the base, made by the line bisecting the opposite angle, are proportional to the sides adjacent to them.—10. The square of the line bisecting the angle, is equal to the difference between the rectangle of the sides and the rectangle of the segments of the base.

If a line be drawn from any angle to the middle of the opposite side, or bisecting the base; then, 11. The sum of the squares of the sides, is equal to twice the sum of the squares of half the base and the line bisecting the base.—12. The angle made by the perpendicular from any angle and the line drawn from the same angle to the middle of the base, is equal to half the difference of the angles at the base.—13. If through any point D, within a triangle ABC, three lines EF, GH, IK, be drawn parallel to the three sides of the triangle; the continual products or solids made by the alternate segments of these lines will be equal; viz,

DE × DK × DH = DG × DF × DI.



14. If three lines AL, BM, CN, be drawn from the three angles through any point D within a triangle, to the opposite sides; the solid products of the alternate segments of the sides are equal; viz,

AN × BL × CM = AM × CL × BN.

15. Three lines drawn from the three angles of a triangle to bisect the opposite sides, or to the middle of the opposite sides, do all intersect one another in the same point D, and that point is the centre of gravity of the triangle, and the distance AD of that point from any angle as D, is equal to double the distance DL from the opposite side; or one segment of any of these lines is double the other segment: moreover the sum of the squares of the three bisecting lines, is $\frac{3}{4}$ of the sum of the squares of the three sides of the triangle.—16. Three perpendiculars bisecting the three sides of a triangle, all intersect in one point, and that point is the centre of the circumscribing circle.—17. Three lines bisecting the three angles of a triangle, all intersect in one point, and that point is the centre of the inscribed circle.—18. Three perpendiculars drawn from the three angles of a triangle, upon the opposite sides, all intersect in one point.—19. If the three angles of a triangle be bisected by the lines AD, BD, CD (3d fig above), and any one as BD be continued to the opposite side at O, and DP be drawn perp. to that side; then is ∠ADO = ∠CDP, or ∠ADP = ∠CDO.

20. Any triangle may have a circle circumscribed about it, or touching all its angles, and a circle inscribed within it, or touching all its sides.—21. The square of the side of an equilateral triangle, is equal to 3 times the square of the radius of its circumscribing circle.—22. If the three angles of one triangle be equal to the three angles of another triangle, each to each; then those two triangles are similar, and their like sides are proportional to one another, and the areas of the two triangles are to each other as the squares of their like sides.—23. If two triangles have any three parts of the one (except the three angles), equal to three corresponding parts of the other, each to each; those two triangles are not only similar, but also identical, or having all their six corresponding parts equal, and their areas also equal.—24. Triangles standing on the same base, and between the same parallels, are equal; and triangles on equal bases, and having equal altitudes, are equal.—25. Triangles on equal bases, are to one another as their altitudes: and triangles of equal altitudes, are to one another as their bases; also equal triangles have their bases and altitudes reciprocally proportional.—26. Any triangle is equal to half its circumscribing parallelogram, or half the parallelogram on the same or an equal base, and of the same or equal altitude.—27. Therefore the area of any triangle is found, by multiplying the base by the altitude, and taking half the product.—28. The area is also found thus: Multiply any two sides together, and multiply the product by the sine of their included angle, to radius 1, and divide by 2.—29. The area is also otherwise found thus, when the three sides are given: Add the three sides together, and take half their sum; then from this half sum subtract each side severally, and multiply the three remainders and the half sum continually together; then the square root of the last product will be the area of the triangle.—30. In a right-angled triangle, if a perpendicular be let fall from the right angle upon the hypothenuse, it will divide it into two other triangles similar to each other, and to the whole triangle.—31. In a right-angled triangle, the square of the hypothenuse is equal to the sum of the squares of the two sides; and, in general, any figure described on the hypothenuse, is equal to the sum of two similar figures described on the two sides.—32. In an isosceles triangle, if a line be drawn from the vertex to any point in the base; the square of that line together with the rectangle of the segments of the base, is equal to the square of one of the equal sides.—33. If one angle of a triangle be equal to 120°; the square of the base will be equal to the squares of both the sides, together with the rectangle of those sides; and if those sides be equal to each other, then the square of the base will be equal to three times the square of one side, or equal to 12 times the square of the perpendicular from the angle upon the base.—34. In the same triangle, viz, having one angle equal to 120°; the difference of the cubes of the sides, about that angle, is equal to a solid contained by the difference of the sides and the square of the base; and the sum of the cubes of the sides, is equal to a solid contained by the sum of the sides and the difference between the square of the base and twice the rectangle of the sides.

There are many other properties of triangles to be found in the geometrical writings; indeed Gregory St. Vincent has written a folio volume upon triangles; there are also several in his quadrature of the circle. See also other properties under the article TRIGONOMETRY, and under RIGHT-*Angled Triangle*.

Solution of TRIANGLES. See TRIGONOMETRY.

TRIANGLE, in Astronomy, one of the 48 ancient constellations, situated in the northern hemisphere. There is also the southern triangle in the southern hemisphere, which is a modern constellation. The stars in the northern triangle are, in Ptolemy's catalogue 4. in Tycho's 4. in Hevelius's 12, and in the British catalogue 16. The stars in the southern triangle are, in Sharp's catalogue, 5.

Arithmetical TRIANGLE, a kind of numeral triangle, or triangle of numbers, being a table of certain numbers disposed in form of a triangle. It was so called by Pascal; but he was not the inventor of this table, as some writers have imagined, its properties having been treated of by other authors, some centuries before him, as is shown in my Mathematical Tracts, vol. 1, tract 12.

The form of the triangle is as follows:

1	1				
1	2	1			
1	3	3	1		
1	4	6	4	1	
1	5	10	10	5	1
1	6	15	20	&c	
1	7	21	&c		
1	8	&c			
1	9				
1					

And it is constructed by adding always the last two numbers of the next two preceding columns together, to give the next succeeding column of numbers.

The first vertical column consists of units; the 2d a series of the natural numbers 1, 2, 3, 4, 5, &c; the 3d a series of triangular numbers 1, 3, 6, 10, &c; the 4th a series of pyramidal numbers, &c. The oblique diagonal rows, descending from left to right, are also the same as the vertical columns. And the numbers taken on the horizontal lines are the co-efficients of the different powers of a binomial. Many other properties and uses of these numbers have been delivered by various authors, as may be seen in the Introduction to my Mathematical Tables, pa. 7, 8, 75, 76, 77, 89, 2d edition.

After these, Pascal wrote a treatise on the Arithmetical Triangle, which is contained in the 5th volume of his works, published at Paris and the Hague in 1779, in 5 volumes, 8vo. In this publication is also a description, taken from the 1st volume of the French Encyclopedie, art. Arithmetique Machine, of that admirable machine invented by Pascal at the age of 19, furnishing an easy and expeditious method of making all kinds of arithmetical calculations without any other assistance than the eye and the hand.

TRIANGULAR, relating to a triangle; as

TRIANGULAR *Canon*, tables relating to trigonometry; as of sines, tangents, secants, &c.

TRIANGULAR *Compasses*, are such as have three legs or feet, by which any triangle, or three points, may be taken off at once. These are very useful in the construction of maps, globes, &c.

TRIANGULAR *Numbers*, are a kind of polygonal numbers; being the sums of arithmetical progressions, which have 1 for the common difference of their terms.

Thus, from these arithmeticals -	1	2	3	4	5	6,
are formed the triang. numb. -	1	3	6	10	15	21,

or the 3d column of the arithmetical triangle above mentioned.

Because the sum of n terms of such arithmetical progression is expressed by $\frac{n^2+n}{2}$; we shall evidently have the same formula to express generally the triangular numbers; or the triangle, which answers to any side represented by n.

Thus, if $n = 6$, the sixth triangular number taken in order will be $\frac{36+6}{2} = 21$. And if $n = 15$, the triangle is $\frac{225+15}{2} = 120$.

The sum of any number n of the terms of the triangular numbers, 1, 3, 6, 10, &c, is =

$$\frac{n^3}{6} + \frac{n^2}{2} + \frac{n}{3}, \text{ or } \frac{n}{1} \times \frac{n+1}{2} \times \frac{n+2}{3},$$

which is also equal to the number of shot in a triangular pile of balls, the number of rows, or the number in each side of the base, being n.

The sum of the reciprocals of the triangular series, infinitely continued, is equal to 2; viz,

$$1 + \tfrac{1}{3} + \tfrac{1}{6} + \tfrac{1}{10} + \tfrac{1}{15} \,\&c = 2.$$

For the rationale and management of these numbers, see Malcolm's Arith. book 5, ch. 2; and Simpson's Algeb. sec. 15.

TRIANGULAR *Quadrant*, is a sector furnished with a loose piece, by which it forms an equilateral triangle. Upon it is graduated and marked the calendar, with the sun's place, and other useful lines; and by the help of a string and a plummet, with the divisions graduated on the loose piece, it may be made to serve for a quadrant.

TRIBOMETER, in Mechanics, a term applied by Musschenbroek to an instrument invented by him for measuring the friction of metals. It consists of an axis formed of hard steel, passing through a cylindrical piece of wood: the ends of the axis, which are highly polished, are made to rest on the polished semicircular cheeks of various metals, and the degree of friction is estimated by means of a weight suspended by a fine silken string or ribband over the wooden cylinder. For a farther description and the figure of this instrument, with the results of various experiments performed with it, see Musschenb. Introd. ad Phil. Nat. vol. 1, p. 151.

TRIDENT, is a particular kind of parabola, used by Descartes in constructing equations of 6 dimensions. See the article *Cartesian* PARABOLA.

TRIGLYPH, in Architecture, is a member of the Doric frize, placed directly over each column, and at equal distances in the intercolumnation, having two entire glyphs or channels engraven in it, meeting in an angle, and separated by three legs from the two demi-channels of the sides.

TRIGON, a figure of three angles, or a triangle.

TRIGON, in Astronomy, denotes an aspect of two planets when they are 120 degrees distant from each other; called also a trine, being the 3d part of 360 degrees.

TRIGON, in Dialling, an instrument of a triangular form.

TRIGON, in Music, denoted a musical instrument, used among the ancients. It was a kind of triangular lyre, or harp, invented by Ibycus; and was used at feasts, being played on by women, who struck it either with a quill, or beat it with small rods of different lengths and weights, to occasion a diversity in the sounds.

TRIGONAL *Numbers*. See TRIANGULAR *Numbers*.

TRIGONOMETER, *Armillary*. See ARMILLARY *Trigonometer*.

TRIGONOMETRY, the art of measuring the sides and angles of triangles, either plane or spherical; whence it is accordingly called either plane trigonometry, or spherical trigonometry.

Every triangle has 6 parts, viz, 3 sides, and 3 angles; and it is necessary that three of these parts be given, to find the other three. In spherical trigonometry, the three parts that are given, may be of any kind, either all sides, or all angles, or part the one and part the other. But in plane trigonometry, it is necessary that one of the three parts at least be a side, since from three angles can only be found the proportions of the sides, but not the real quantities of them.

Trigonometry is an art of the greatest use in the mathematical sciences, especially in astronomy, navigation, surveying, dialling, geography, &c, &c. By the aid of it, we can determine the magnitude of the earth, the planets and stars, their distances, motions, eclipses, and almost all other useful arts and sciences. Accordingly we find this art has been cultivated from the earliest ages of mathematical knowledge.

Trigonometry, or the resolution of triangles, is founded on the mutual proportions which subsist between the sides and angles of triangles; which proportions are known by finding the relations between the radius of a circle and certain other lines drawn in and about the same, called chords, sines, tangents, and secants. The ancients Menelaus, Hipparchus, Ptolemy, &c, performed their trigonometry, by means of the chords. As to the sines, and the common theorems relating to them, they were introduced into trigonometry by the Moors or Arabians, from whom this art passed into Europe, with several other branches of science. The Europeans have introduced, since the 15th century, the tangents and secants, with the theorems relating to them. See the history and improvements at large, in the Introduction to my Mathematical Tables.

The proportion of the sines, tangents, &c, to their radius, is sometimes expressed in common or natural numbers, which constitute what are called the tables of natural sines, tangents, and secants. Sometimes it is expressed in logarithms, being the logarithms of the said natural sines, tangents, &c; and these constitute the table of artificial sines, &c. Lastly, sometimes the proportion is not expressed in numbers; but the several sines, tangents, &c, are actually laid down upon lines of scales; whence the line of sines, of tangents, &c. See SCALE.

In trigonometry, as angles are measured by arcs of a circle described about the angular point, so the whole circumference of the circle is divided into a great number of parts, as 360 degrees, and each degree into 60 minutes, and each minute into 60 seconds, &c; then any angle is said to consist of so many degrees, minutes, and seconds, as are contained in the arc that measures the angle, or that is intercepted between the legs or sides of the angle.

Now the sine, tangent, and secant, &c, of every degree and minute, &c, of a quadrant, are calculated to the radius 1, and ranged in tables for use; as also the logarithms of the same; forming the triangular canon. And these numbers, so arranged in tables, form every species of right-angled triangles, so that no such triangle can be proposed, but one similar to it may be there found, by comparison with which, the proposed one may be computed by analogy or proportion.

As to the scales of chords, sines, tangents, &c, usually placed on instruments, the method of constructing them is exhibited in the scheme annexed to the article SCALE; which, having the names added to each, needs no farther explanation.

There are usually three methods of resolving triangles, or the cases of trigonometry; viz, geometrical construction, arithmetical computation, and instrumental operation. In the 1st method, the triangle is constructed by drawing and laying down the several parts of their magnitudes given, viz, the sides from a scale of equal parts, and the angles from a scale of chords, or other instrument; then the unknown parts are measured by the same scales, and so they become known.

In the 2d method, having stated the terms of the proportion according to rule, which terms consist partly of the numbers of the given sides, and partly of the sines, &c, of angles taken from the tables, the proportion is then resolved like all other proportions, in which a 4th term is to be found from three given terms, by multiplying the 2d and 3d together, and dividing the product by the first. Or, in working with the logarithms, adding the log. of the 2d and 3d terms together, and from the sum subtracting the log. of the 1st term, then the number answering to the remainder is the 4th term sought.

To work a case instrumentally, as suppose by the log. lines on one side of the two-foot scales: Extend the compasses from the 1st term to the 2d, or 3d, which happens to be of the same kind with it; then that extent will reach from the other term to the 4th. In this operation, for the sides of triangles, is used the line of numbers (marked Num.); and for the angles, the line of sines or tangents (marked sin. and tan.) according as the proportion respects sines or tangents.

In every case of triangles, as has been hinted before, there must be given three parts, one at least of which must be a side. And then the different circumstances, as to the three parts that may be given, admit of three cases or varieties only; viz,

1st. When two of the three parts given, are a side and its opposite angle.—2d, When there are given two sides and their contained angle.—3d, And thirdly, when the three sides are given.

To each of these cases there is a particular rule, or proportion, adapted, for resolving it by.

1st. *The Rule for the 1st Case*, or that in which, of the three parts that are given, an angle and its opposite side are two of them, is this, viz, That the sides are proportional to the sines of their opposite angles,

That is,

As one side given :
To the sine of its opposite angle : :
So is another side given :
To the sine of its opposite angle.

Or, As the sine of an angle given :
To its opposite side : :
So is the sine of another angle given :
To its opposite side.

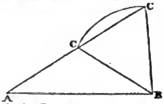
So that, to find an angle, we must begin the proportion with a given side that is opposite to a given angle; and to find a side, we must begin with an angle opposite to a given side.

Note. An angle found by this rule is ambiguous, or uncertain whether it be acute or obtuse, unless it be a right angle, or unless its magnitude be such as to prevent the ambiguity; because the sine answers to two angles, which are supplements to each other; and accordingly the geometrical construction forms two triangles with the same parts that are given, as in the example below; and when there is no restriction or limitation included in the question, either of them may be taken. The degrees in the table, answering to the sine is the acute angle; but if an angle be obtuse, subtract those degrees from 180°, and the remainder will be the obtuse angle. When a given angle is obtuse or a right one, there can be no ambiguity; for then neither of the other angles can be obtuse, and the geometrical construction will form but one triangle.

Ex. Suppose in the plane triangle ABC, there be given

AB = 345 yards
BC = 232 yards
∠A = 37° 20′

to find the other side and the angles.



1. *Geometrically, by Construction.*

Draw an indefinite line, upon which set off AB = 345, from some convenient scale of equal parts.—Make the angle A = 37° 20′.—With a radius of 232, taken from the same scale of equal parts, and centre B, cross AC in the two points C, C. Lastly, join BC, BC, and the figure is constructed, which gives two triangles, and showing that the case is ambiguous.

Then the sides AC measured by the scale of equal parts, and the angles B and C measured by the line of chords, or other instrument, will be found to be nearly as follow; viz,

AC 174	∠B 27°	∠C $115\frac{2}{3}$°
or $374\frac{1}{2}$	or $78\frac{1}{4}$°	or $64\frac{1}{3}$.

2. *Arithmetically, by Tables of Logs.*

First, to find the angles at C.

As side BC 232	- -	log. 2·3654880
To sin. op. ∠A 37° 20′	- -	9·7827958
So side AB 345	- -	2·5378191
To sin. op. ∠C 115° 36′ or 64° 24′	-	9·9551269
add ∠A 37 20 37 20		
the sum 152 56 101 44		
taken from 180 00 180 00		
leaves ∠B 27 04 or 78 16.		

Then, to find the side AC.

As sin ∠A 37° 20′	-	log. 9·7827958
To op. side BC 232	- -	2·3654880
So sin ∠B { 27 04	-	9·6580371
{ 78 16	-	9·9908291
To op. side AC 174·07	- -	2·2407293
or, 374·56	- -	2·5735215.

3. *Instrumentally, by Gunter's Lines.*

In the first proportion.—Extend the compasses from 232 to 345 upon the line of numbers; then that extent will reach, in the sines, from $37\frac{1}{3}$° to $64\frac{1}{3}$°, the angle C.

In the second proportion.—Extend the compasses from $37\frac{1}{3}$° to 27° or $78\frac{1}{4}$°, on the sines; then that extent will reach, on the line of numbers, from 232 to 174 or $374\frac{1}{2}$; the two values of the side AC.

2d Case, when there are given two sides and their contained angle, to find the rest, the rule is this:

As the sum of the two given sides :
Is to the difference of those sides : :
So is the tang. of half the sum of the two opposite angles, or cotangent of half the given angle :
To tang. of half the diff. of those angles.

Then the half diff. added to the half sum, gives the greater of the two unknown angles; and subtracted, leaves the less of the same two angles.

Hence, the angles being now all known, the remaining 3d side will be found by the former case.

Note. When the triangle is isosceles, the angles at the base are each equal to half the supplement of the given angle, or that at the vertex; whence the third side may be found directly by the former case.

Ex. Suppose, in the triangle ABC, there be given
AC = 154·33
BC = 309·86
∠C = 98° 3′
to find the other side and the angles.

1. *Geometrically.*—Draw two indefinite lines making the angle C = 98° 3′: upon these lines set off CA = $154\frac{1}{3}$, and CB = 310: Join the points A and B, and the figure is constructed. Then, by measurement, as before, we find the ∠A = $57\frac{1}{5}$; ∠B $24\frac{3}{4}$; and side AB = 365.

2. *By Logarithms.*

As CB + CA	= 464·19	-	log. 2·6666958
To CB − CA	= 155·53	-	2·1918142
So tan. $\frac{1}{2}$A + $\frac{1}{2}$B	= 40° $58\frac{1}{2}$′	- -	9·9387803
To tan $\frac{1}{2}$A − $\frac{1}{2}$B	= 16 $13\frac{1}{2}$	- -	9·4638987
sum gives ∠A	57 12		
diff. gives ∠B	24 45		
Then, As sin. ∠B	= 24° 45′	-	log. 9·6218612
To side AC	= 154·33	- -	2·1884504
So sin ∠C	= 98° 3′, or 81° 57′	-	9·9956993
To side AB	= 365	- - -	2·5622885

3. *Instrumentally.*—Extend the compasses from 464 to $155\frac{1}{2}$ upon the line of numbers; then that extent will reach, upon the line of tangents, from 41° to $16\frac{1}{4}$°. Then, in the 2d proportion, extend the compasses from $24\frac{3}{4}$° to 82° on the sines; and that extent will reach, upon the numbers, from $154\frac{1}{3}$ to 365, which is the third side.

3d *Case,* is when the three sides are given, to find the three angles; and the method of resolving this case is, to let a perpendicular fall from the greatest angle, upon the opposite side or base, dividing it into two segments, and the whole triangle into two right-angled triangles: then it will be,

As the base, or sum of the two segments :
Is to the sum of the other two sides : :
So is the difference of those sides :
To the difference of the segments of the base.

Then half this difference of the two segments added to the half sum, or half the base, gives the greater segment, and subtracted, gives the less. Hence, in each of the two right-angled triangles, there are given the hypothenuse, and the base, besides the right angle, to find the other angles by the 1st case.

Ex. In the triangle ABC, suppose there are given the three sides, to find the three angles, viz,
AB = 365
AC = 154·33
BC = 309·86
to find the angles.

1. *Geometrically.*—Draw the base AB = 365: with the radius $154\frac{1}{3}$ and centre A describe an arc; and with the radius 310 and centre B describe another arc, cutting the former in C; then join AC, and BC, and the triangle is constructed. And by measuring the angles, they are found, viz,

∠A = $57\frac{1}{4}$°; ∠B = $24\frac{3}{4}$°; ∠C = 98° nearly.

2. *Arithmetically.*—Having let fall the perpendicular CP, dividing the base into the two segments AP, PB, and the given triangle ABC into the two right-angled triangles ACP, BCP. Then

As AB	= 365	-	log. 2·5622929
To CB + CA	= 464·19	-	2·6666958
So CB − CA	= 155·53	-	2·1918142
To BP − PA	= 197·80		2·2962171
its half	= 98·90		
$\frac{1}{2}$AB	= 182·50		
sum BP	= 281·40		
diff. AP	= 83·60.		

Then, in the triangle APC, right-angled at P,

As AC	= 154·33	-	log. 2·1884504
To sin. ∠P	= 90°	- -	10·0000000
So AP	= 83·6	- -	1·9222063
To sin. ∠ACP	= 32° 48′	-	9·7337559
its comp. ∠A	= 57 12.		

And in the triangle BCP, right-angled at P,

As BC	= 309·86	-	log. 2.4911655
To sin. ∠P	= 90°	-	10·0000000
So BP	= 281·4	- -	2·4493241
To sin. ∠BCP	= 65° 15′	-	9·9581566
its comp. ∠B	= 24 45		
Also to ∠ACP	= 32 48		
add ∠BCP	= 65 15		
makes ∠ACB	= 98 3		

3. *Instrumentally.*—In the 1st proportion, Extend the compasses from 365 to 464 on the line of numbers, and that extent will reach, on the same line, from $155\frac{1}{2}$ to 197·8 nearly.—In the 2d proportion, Extend the compasses from $154\frac{1}{3}$ to 83·6 on the line of numbers, and that extent will reach, on the sines, from 90° to $32\frac{3}{4}$° nearly.—In the 3d proportion, Extend the compasses from 310 to $281\frac{1}{4}$ on the line of numbers; then that extent will reach, on the sines, from 90° to $65\frac{1}{4}$°.

Another method of resolving this case, and that at one operation, is as follows:

1. Add together the logarithm of half the sum of the three given sides and the logarithm of the difference between this half sum and the side opposite the angle sought, and find the complement of their sum. 2. Then, to this complement, increased by 10 in the index, add the logarithms of the differences between the said half sum and each of the other two sides, and the result, divided by 2, will give the tangent of half the required angle.

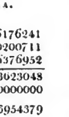
Thus, resuming the same example, to find the angle A, the work will be as under:

AB = 365·00		
AC = 154·33		
BC = 309·86 side op. required ∠A.		
Sum 829·19		
½ sum 414·595		log. 2·6176241
dif. 104·73		2·0200711
sum		4·6376952
log. complem. of do.		5·3623048
add		10·0000000
Differences between the ½ sum of sides and AB, AC.	49·595	1·6954379
	260·265	2·4154158
sum of these		19·4731585
tan. ½∠A = 28° 36′	½ sum	9·7365792
2		
∠A = 57 12 the same as before.		

The foregoing three cases include all the varieties of plane triangles that can happen, both of right and oblique-angled triangles. But beside these, there are some other theorems that are useful upon many occasions, or suited to some particular forms of triangles, which are often more expeditious in use than the foregoing general ones; one of which, for right-angled triangles, as the case for which it serves so often occurs, may be here inserted, and is as follows:

Case 4. When, in a right-angled triangle, there are given the angles and one leg, to find the other leg, or the hypothenuse. Then it will be,

As radius :
To given leg AB : :
So tang. adjacent ∠A :
To the opp. leg BC, and : :
So sec. of same ∠A :
To hypot. AC.



Ex. In the triangle ABC, right-angled at B,

Given the leg AB = 162
and the ∠A = 53° 7′ 48″ } to find BC and AC.
conseq. ∠C = 36 52 12

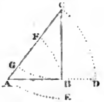
1. *Geometrically.*—Draw the leg AB = 162: Erect the indefinite perpendicular BC: Make the angle A = $53\frac{1}{8}$°, and the side AC will cut BC in C, and form the triangle ABC. Then, by measuring, there will be found AC = 270, and BC = 216.

2. *Arithmetically.*

As radius	= 10	log. 10·0000000
To AB	= 162	2·2095150
So tan. ∠A	= 53° 7′ 48″	10·1249372
To BC	= 216	2·3344522
So sec. ∠A	= 53° 7′ 48″	10·2218477
To AC	= 270	2·4313627

3. *Instrumentally.*—Extend the compasses from 45° at the end of the tangents (the radius) to the tangent of $50\frac{1}{8}$°; then that extent will reach, on the line of numbers, from 162 to 216, for BC. Again, extend the compasses from 36° 52′ to 90 on the sines; then that extent will reach, on the line of numbers, from 162 to 270 for AC.

Note, Another method, by making every side radius, is often added by the authors on trigonometry, which is thus: The given right-angled triangle being ABC, make first the hypothenuse AC radius, that is, with the extent of AC as a radius, and each of the centres A and C, describe arcs CD and AE; then it is evident that each leg will represent the sine of its opposite angle, viz, the leg BC the sine of the arc CD or of the angle A, and the leg AB the sine of the arc AE or of the angle C. Again, making either leg radius, the other leg will represent the tangent of its opposite angle, and the hypothenuse the secant of the same angle; thus, with radius AB and centre A describing the arc BF, BC represents the tangent of that arc, or of the angle A, and the hypothenuse AC the secant of the same; or with the radius BC and centre C describing the arc BG, the other leg AB is the tangent of that arc BG, or of the angle C, and the hypothenuse CA the secant of the same.



And then the general rule for all these cases is this, viz, that the sides bear to each other the same proportions as the parts or things which they represent. And this is called making every side radius.

For Plane Trigonometry considered analytically, see my Course of Mathematics, vol. 3, chap. 3.

Spherical TRIGONOMETRY, is the resolution and calculation of the sides and angles of spherical triangles, which are made by three intersecting arcs of great circles on a sphere. Here, any three of the six parts being given, even the three angles, the rest can be found; and the sides are measured or estimated by degrees, minutes, and seconds, as well as the angles.

Spherical Trigonometry is divided into right-angled and oblique-angled, or the resolution of right and oblique-angled spherical triangles. When the spherical triangle has a right angle, it is called a right-angled triangle, as well as in plane triangles; and when a triangle has one of its sides equal to a quadrant of a circle, it is called a quadrantal triangle.

For the resolution of spherical triangles, there are various theorems and proportions, which are similar to those in plane trigonometry, by substituting the sines of sides instead of the sides themselves, when the proportion respects sines; or tangents of the sides for the sides, when the proportion respects tangents, &c; some of the principal of which theorems are as follow:

Theor. 1. In any spherical triangle, the sines of the sides are proportional to the sines of their opposite angles.

Theor. 2. In any right-angled triangle,
As radius :
To sine of one side : :
So tang. of the adjacent angle :
To tang. of the opposite side.

Theor. 3. If a perpendicular be let fall from any angle, upon the base or opposite side of a spherical triangle; it will be,
As the sine of the sum of the two sides :
To the sine of their difference : :
So cotan. ½ sum angles at the vertex :
To tang. of half their difference.

Theor. 4.
As tang. half sum of the sides :
To tang. half their difference : :
So tang. ½ sum ∠s at the base :
To tang. half their difference.

Theor. 5.
As cotan. ½ sum of ∠s at the base :
To tang. half their difference : :
So tang. ½ sum of ∠s at the vertex :
To tang half their difference.

Theor. 6.
As tang. ½ sum segments of base :
To tang. half sum of the sides : :
So tang. half difference of the sides :
To tang. ½ diff. segments of base.

Theor. 7.
As sin. sum of ∠s at the base :
To sine of their difference : :
So tang. ½ sum segments of base :
To tang. of half their difference.

Theor. 8.
As sin. sum of segments of base :
To sine of their difference : :
So sin. sum of angles at the vertex :
To sine of their difference.

Theor. 9.
As sine of the base :
To sine of the vertical angle : :
So sin. of diff. segments of the base
To sin. diff. ∠s at vertex, when the perp. falls within : :
Or so sin. sum segments of base :
To sin. sum vertical ∠s, where the perp. falls without.

Theor. 10.
As cosin. half sum of the two sides :
To cosine of half their difference : :
So cotang. of half the included angle :
To tang. half sum of opposite angles.

Theor. 11.
As sin. of half sum of two sides :
To sine of half their difference : :
So cotang. half the included angle :
To tang. ½ diff. of the oppos. angles.

Theor. 12.
As cosin. half sum of two angles :
To cosine of half their difference : :
So tang. of half the included sides :
To tang. ½ sum of the opposite sides.

Theor. 13.
As sin. half sum of two angles :
To sine of half their difference : :
So tang. half the included side :
To tang. ½ diff. of the opposite sides.

Theor. 14. In a right-angled spherical triangle,
As sin. sum of hypot and one side :
To sin. of their difference : :
So radius squared
To square of tang. ½ contained angle.

Theor. 15. In any spherical triangle,
The product of the sines of two sides and of the cosine of the included angle, added to the product of the cosines of those sides, is equal to the cosine of the third side; the radius being 1.

Theor. 16. In any spherical triangle,
The product of the sines of two angles and of the cosine of the included side, minus the product of the cosines of those angles, is equal to the cosine of the third angle; the radius being 1.

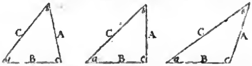
By some or other of these theorems may all the cases of spherical triangles be resolved, both right-angled and oblique: viz, the cases of right-angled triangles by the 1st and 2d theorems, and the oblique triangles by some of the other theorems.

In treatises on trigonometry are to be found many other theorems, as well as synopses or tables of all the cases, with the theorem that is peculiar or proper to each. See the Introduction to my Mathematical Tables, pa. 156 &c; or Robertson's Navigation, vol. 1, pa. 162. See also Napier's Catholic or Universal Rule in this Dictionary.

To the foregoing theorems may be added the following synopsis of rules for resolving all the cases of plane and spherical triangles, under the title of

Trigonometrical Rules.

1. In a right-lined triangle, whose sides are A, B, C, and their opposite angles *a*, *b*, *c*; having given any three of these, of which one is a side; to find the rest.



Put s for the sine, s′ the cosine, t the tangent, and t′ the cotangent of an arch or angle, to the radius *r*; also L for a logarithm, and L′ its arithmetical complement. Then

Case 1. When three sides A, B, C, are given.

Put $P = \frac{1}{2}(A + B + C)$ or semiperimeter.

Then $s.\ \frac{1}{2}c = r\sqrt{\frac{(P - A) \times (P - B)}{A \times B}}$.

And $s'.\ \frac{1}{2}c = r\sqrt{\frac{P \times (P - C)}{A \times B}}$.

$L.\ s.\ \frac{1}{2}c = \frac{1}{2}(L.\ (P - A) + L.\ (P - B) + L'A + L'B)$,
$L.'s.\ \frac{1}{2}c = \frac{1}{2}(L.\ P + L.\ (P - C) + L'A + L'B)$.

Note, When A = B, then

$s.\ \frac{1}{2}c = \frac{C}{A} \times \frac{r}{2}$. And $s'\ \frac{1}{2}c = r\sqrt{\frac{A^2 - \frac{1}{4}C^2}{A^2}}$.

Case 2. Given two sides A, B, and their included angle *c*.

Put $s = 90^\circ - \frac{1}{2}c$, and $t.\ d = \frac{A - B}{A + B} \times t.\ s$; then $a = s + d$; and $b = s - d$. And $C = \sqrt{(\frac{4AB + s^2 \frac{1}{2}c}{rr} + (A - B)^2)}$.

Or in logarithms, putting $L.\ Q = 2\ L.\ (A - B)$, and

$\text{L. R} = \text{L. } 2\text{A} + \text{L. } 2\text{B} + 2\text{L. s. } \tfrac{1}{2}c - 20$, we shall have $\text{L. C} = \tfrac{1}{2}\text{ L. } (\text{Q} + \text{R})$.

If the angle c be right, or $= 90°$; then

$$\text{t. } a = \frac{\text{A}}{\text{B}}r;\ \text{t. } b = \frac{\text{B}}{\text{A}}r;$$

$$\text{C} = \frac{r}{\text{s. } a}\text{A}, \text{ or } = \frac{r}{\text{s. } b}\text{B}, \text{ or } = \sqrt{(\text{A}^2 + \text{B}^2)}.$$

If $\text{A} = \text{B}$; we shall have $a = b = 90° - \tfrac{1}{2}c$, and | $\text{C} = \frac{\text{s. } \frac{1}{2}c}{r} \times 2\text{A}$.

Case 3. When a side and its opposite angle are among the terms given; then

$\frac{\text{A}}{\text{s. } a} = \frac{\text{B}}{\text{s. } b} = \frac{\text{C}}{\text{s. } c}$; from which equations any term wanted may be found.

When an angle, as a, is 90°, and A and C are given; then

$$\text{B} = \sqrt{(\text{A}^2 - \text{C}^2)} = \sqrt{(\text{A} + \text{C}) \times (\text{A} - \text{C})}.$$

And $\text{L. B} = \tfrac{1}{2}(\text{L. } (\text{A} + \text{C}) + \text{L. } (\text{A} - \text{C}))$.

Note, When two sides A, B, and an angle a opposite to one of them, are given; if A be less than B, then b, c, C have each two values; otherwise, only one value.

II. In a spherical triangle, whose three sides are A, B, C, and their opposite angles a, b, c; any three of these six terms being given, to find the rest.

Case 1. Given the three sides A, B, C.

Calling 2P the perim. or $\text{P} = \tfrac{1}{2}(\text{A} + \text{B} + \text{C})$.

Then $\text{s.} \tfrac{1}{2}c = r\sqrt{\frac{\text{s.}(\text{P} - \text{A}) \times \text{s.}(\text{P} - \text{B})}{\text{s.A} \times \text{s.B}}}$

And $\text{s}'\tfrac{1}{2}c = r\sqrt{\frac{\text{s.P} \times \text{s.}(\text{P} - \text{C})}{\text{s.A} \times \text{s.B}}}$.

$\text{L.s.}\tfrac{1}{2}c = \tfrac{1}{2}(\text{L.s.}(\text{P} - \text{A}) + \text{L.s.}(\text{P} - \text{C}) + \text{L}'\text{s.A} + \text{L}'\text{s.B})$

$\text{L.s}'\tfrac{1}{2}c = \tfrac{1}{2}(\text{L.s.P} + \text{L.s.}(\text{P} - \text{C}) + \text{L}'\text{s.A} + \text{L}'\text{s.B})$.

And the same for the other angles.

Case 2. Given the three angles.

Put $2p = a + b + c$. Then

$\text{s.}\tfrac{1}{2}\text{C} = r\sqrt{\frac{\text{s}'p \times \text{s}'(p - c)}{\text{s.}a \times \text{s.}b}}$. And

$\text{s}'\tfrac{1}{2}\text{C} = r\sqrt{\frac{\text{s}'(p - a) \times \text{s}'(p - b)}{\text{s.}a \times \text{s.}b}}$.

$\text{L.s.}\tfrac{1}{2}\text{C} = \tfrac{1}{2}(\text{L.s}'p + \text{L.s}'(p - c) + \text{L}'\text{s.}a + \text{L}'\text{s.B})$.

$\text{L.s}'\tfrac{1}{2}\text{C} = \tfrac{1}{2}(\text{L.s}'(p - a) + \text{L.s}'(p - b) + \text{L}'\text{s.}a + \text{L.s.}'b)$

And the same for the other sides.

Note. The sign $\succ$ signifies greater than, and $\prec$ less; also $\backsim$ the difference.

Case 3. Given A, B, and included angle c.

To find an angle a opposite the side A,
let $r : \text{s}'c :: \text{t. A} : \text{t. M}$, like or unlike A,
as c is $\succ$ or $\prec 90°$; also $\text{N} = \text{B} \backsim \text{M}$:
then $\text{s. N} : \text{s. M} :: \text{t. } c : \text{t. } a$, like or unlike
c as M is $\succ$ or $\prec$ B.

Or let $\text{s}'\tfrac{1}{2}(\text{A} + \text{B}) : \text{s}'\tfrac{1}{2}(\text{A} \backsim \text{B}) :: \text{t}'\tfrac{1}{2}c : \text{t. M}$,
which is $\succ$ or $\prec 90°$ as A + B is $\succ$ or $\prec 180°$;
and $\text{s.}\tfrac{1}{2}(\text{A} + \text{B}) : \text{s.}(\text{A} \backsim \text{B}) :: \text{t}'\tfrac{1}{2}c : \text{t. N}$, $\succ 90°$.
then $a = \text{M} + \text{N}$; and $b = \text{M} - \text{N}$.

Again let $r : \text{s}'c :: \text{t. A} : \text{t. M}$, like or unlike A as c is $\succ$ or $\prec 90°$; and $\text{N} = \text{B} \backsim \text{M}$.

Then $\text{s}'\text{M} : \text{s}'\text{N} :: \text{s}'\text{A}, \text{s}'\text{C}$, like or unlike N as c is $\succ$ or $\prec 90°$. Or,

$$\text{s.}\tfrac{1}{2}\text{C} = \sqrt{\frac{\text{s.A} \times \text{s.B} \times \text{s}^2\tfrac{1}{2}c}{rr} + \text{s}^2\tfrac{1}{2}(\text{A} \backsim \text{B})}.$$

In logarithms, put $\text{L. Q} = 2\text{L.s.}\tfrac{1}{2}(\text{A} \backsim \text{B})$; and $\text{L. R} = \text{L. s. A} + \text{L. s. B} + 2\text{L. s. } \tfrac{1}{2}c - 20$; then $\text{L.s.}\tfrac{1}{2}\text{C} = \tfrac{1}{2}\text{L.}(\text{Q} + \text{R})$.

Case 4. Given a, b, and included side C.

First, let $r : \text{s}'\text{C} :: \text{t. } a : \text{t}'m$, like or unlike a as C is $\succ$ or $\prec 90°$; also $n = b \backsim m$.

Then $\text{s}'n : \text{s}'m :: \text{t. C} : \text{t. A}$, like or unlike n as a is $\succ$ or $\prec 90°$.

Or, let $\text{s}'(\tfrac{1}{2}a + b) : \text{s}'\tfrac{1}{2}(a \backsim b) :: \text{t.}\tfrac{1}{2}\text{C} : \text{t. M}$, $\succ$ or $\prec 90°$ as $a + b$ is $\succ$ or $\prec 180°$;
and $\text{s}'\tfrac{1}{2}(a + b) : \text{s}\tfrac{1}{2}(a \backsim b) :: \text{t. }\tfrac{1}{2}\text{C} : \text{t N}$, $\succ 90°$;
then $\text{A} = \text{M} \pm \text{N}$; and $\text{B} = \text{M} \mp \text{N}$.

Again, let $r : \text{s}'\text{C} :: \text{t. } a : \text{t}'m$, like or unlike a as C is $\succ$ or $\prec 90°$;
and $n = b \backsim m$:
then $\text{s.}m. : \text{s.}n. :: \text{s}'a : \text{s}'c$, like or unlike a as m is $\succ$ or $\prec b$.

Case 5. Given A, B, and an opposite angle a.

1st. $\text{s. A} : \text{s. } a. :: \text{s. B} : \text{s. } b$, $\succ$ or $\prec 90°$.

2nd. Let $r : \text{s}'\text{B} :: \text{t. } a : \text{t}'m$, like or unlike B as a is $\succ$ or $\prec 90°$;
and $\text{t. A} : \text{t. B} :: \text{s}'m : \text{s}'n$, like or unlike A as a is $\succ$ or $\prec 90°$:
then $c = m \pm n$, two values also.

3dly. Let $r : \text{s}'a :: \text{t. B} : \text{t. M}$, like or unlike B as a is $\succ$ or $\prec 90°$;
and $\text{s}'\text{B} : \text{s}'\text{A} :: \text{s}'\text{M} : \text{s}'\text{N}$, like or unlike A as a is $\succ$ or $\prec 90°$:
then $\text{C} = \text{M} \pm \text{N}$, two values also.

But if A be equal to B, or to its supplement, or between B and its supplement; then is b like to B: also c is $= m \mp n$, and $\text{C} = \text{M} \pm \text{N}$, as B is like or unlike a.

Case 6. Given a, b, and an opposite side A.

1st. $\text{s. } a. : \text{s. A} :: \text{s. } b : \text{s. B}$, $\succ$ or $\prec 90°$.

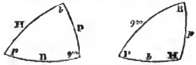
2nd. Let $r : \text{s}'b :: \text{t. A}$: to t. M, like or unlike b as A is $\succ$ or $\prec 90°$;
and $\text{t. } a : \text{t. } b. :: \text{s. M} : \text{s. N}$, $\succ$ or $\prec 90°$:
then $\text{C} = \text{M} \pm \text{N}$, as a is like or unlike b.

3dly. Let $r : \text{s}'\text{A} :: \text{t. } b : \text{t}'m$, like or unlike b as A $\succ$ or $\prec 90°$;
and $\text{s}'b : \text{s}'a :: \text{s. } m. : \text{s. } n$, $\succ$ or $\prec 90°$:
then $c = m \pm n$, as a is like or unlike b.

But if A be equal to B, or to its supplement, or between B and its supplement; then B is unlike b, and only the less values of N, n, are possible.

Note, When two sides A, B, and their opposite angles a, b, are known; the third side C, and its opposite angle c, are readily found thus:

$$\text{s. }\tfrac{1}{2}(a \backsim b) : \text{s. }\tfrac{1}{2}(a + b) :: \text{t. }\tfrac{1}{2}(\text{A} \backsim \text{B}) : \text{t. }\tfrac{1}{2}\text{C}.$$
$$\text{s. }\tfrac{1}{2}(\text{A} \backsim \text{B}) : \text{s. }\tfrac{1}{2}(\text{A} + \text{B}) :: \text{t. }\tfrac{1}{2}(a \backsim b) : \text{t. }\tfrac{1}{2}c.$$



III. In a right-angled spherical triangle, where H is the hypothenuse, or side opposite the right angle, B, P the other two sides, and b, p their opposite angles; any two of these five terms being given, to find the rest; the cases, with their solutions, are as in the following table.

The same table will also serve for the quadrantal triangle, or that which has one side $= 90°$, H being the angle opposite that side, B, P the other two angles, and b, p their opposite sides: observing, instead of H, to take its supplement: and mutually change the terms *like* and *unlike* for each other where H is concerned.

Case	Given	Req^d.	SOLUTIONS.
1	H B	b	s.H. : r :: s.B : s.b, and is like B
		p	r : t′H :: t B : s′p }, > or < 90° as H is like or unlike B
		P	s′B : r :: s′H : s′P }
2	H b	B	r : s H :: s.b : s.B, like b
		P	r : s′b :: t.H : t.P }, > or < 90° as H is like or unlike b
		p	r : s′H :: t.b : t′p }
3	B b	H	s.b : r :: s.B : s.H }, each > or < 90°; both values true
		P	r : t.B :: t′b : s.P }
		P	s′B : r :: s′b : s.p }
4	B p	H	r : t′B :: s′p : t′H, > or < 90° as B is like or unlike p
		b	r : s′B :: s.p : s′b, like B
		P	r : s.B :: t p : t P, like p
5	B P	H	r : s′B :: s′P : s′H, > or < 90° as B is like or unlike P
		b	r : s P :: t′H : t′b, like B
		p	r : s.B :: t′P : t′p. like P
6	b p	H	r : t′b :: t′p : s′H, > or < 90° as b is like or unlike p
		B	s.p : r :: s′b : s′B like b
		P	s.b : r :: s′p : s′P like p

The following propositions and remarks, concerning spherical triangles, (selected and communicated by the reverend Nevil Maskelyne, D. D. astronomer royal, F. R. S.) will also render the calculations of them perspicuous, and free from ambiguity.

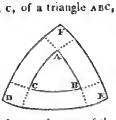
" 1. A spherical triangle is equilateral, isoscelar, or scalene, according as it has its three angles all equal, or two of them equal, or all three unequal; and *vice versa*.

2. The greatest side is always opposite the greatest angle, and the smallest side opposite the smallest angle.

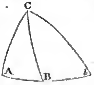
3. Any two sides taken together, are greater than the third.

4. If the three angles are all acute, or all right, or all obtuse; the three sides will be, accordingly, all less than 90°, or equal to 90°, or greater than 90°; and *vice versa*.

5. If from the three angles A, B, C, of a triangle ABC, as poles, there be described, upon the surface of the sphere, three arches of a great circle DE, DF, FE, forming by their intersections a new spherical triangle DEF; each side of the new triangle will be the supplement of the angle at its pole; and each angle of the same triangle, will be the supplement of the side opposite to it in the triangle ABC.



6. In any triangle ABC, or AbC, right-angled in A, 1st, The angles at the hypothenuse are always of the same kind as their opposite sides; 2dly, The hypothenuse is less or greater than a quadrant, according as the sides including the right-angle are of the same or different kinds; that is to say, according as these same sides are either both acute or both obtuse, or as one is acute and the other obtuse. And, *vice versa*, 1st, The sides including the right angle, are always of the same kind as their opposite angles: 2dly, The sides including the right angle will be of the same or different kinds, according as the hypothenuse is less or more than 90°; but one at least of them will be of 90°, if the hypothenuse is so."



Analytical TRIGONOMETRY. See my Course of Mathematics, last vol.

TRILATERAL, three-sided, a term applied to all figures of three sides, or triangles.

TRILLION, in Arithmetic, the number of a million of billions, or a million of million of millions.

TRIMMERS, in Architecture, pieces of timber framed at right angles to the joists, against the ways for chimneys to support the hearths, and the well-holes for stairs.

TRINE *Dimension*, or *threefold dimension*, includes length, breadth, and thickness. The trine dimension is peculiar to bodies or solids.

TRINITY *Sunday*, is the next after Whitsunday; so called, because on that day was anciently held a festival (as it still continues to be in the Romish church) in honor of the Holy Trinity.—The observance of this festival was first enjoined by the 6th canon of the council of Arles, in 1260; and John the 22d, who distinguished himself so much by his opinion concerning the beatific vision, it is said, fixed the office for this festival in 1334.

TRINODA, or TRINODIA *Terræ*, in some ancient writers, denotes the quantity of 3 perches of land.

TRINOMIAL, in Algebra, is a quantity, or a root, consisting of three parts or terms, connected together by the signs + or −: as $a + b - c$, or $x + y + z$.

TRIO, in Music, a part of a concert in which three persons sing; or rather a musical composition consisting of 3 parts.—Trios are the finest kind of musical composition, and please most in concerts.

TRIONES, in Astronomy, a kind of constellation, or assemblage of 7 stars in the Ursa Major, popularly called Charles's Wain.—From the Septem Triones the north pole takes the denomination Septentrio.

TRIPARTITION, is a division by 3, or the taking of the 3d part of any number or quantity.

TRIPLE, threefold. See RATIO and SUBTRIPLE.

TRIPLE, in Music, is one of the species of measure or time, and is taken from hence, that the whole, or half measure, is divisible into 3 equal parts, and is beaten accordingly.

TRIPLICATE *Ratio*, is the ratio which cubes, or any similar solids, bear to each other; and is the cube of the simple ratio, or this twice multiplied by itself. Thus 1 to 8 is the triplicate ratio of 1 to 2, and 1 to 27 triplicate of 1 to 3.

TRIS-DIAPASON, or *Triple Diapason Chord*, in Music, is what is otherwise called a triple eighth.

TRISECTION, the dividing a thing into three equal parts. The term is chiefly used in geometry, for the division of an angle into three equal parts. The trisection of an angle geometrically, is one of those great problems whose solution has been so much sought for by mathematicians, for 2000 years past; being, in this respect, on a footing with the famous one concerning the quadrature of the circle, and the duplicature of the cube.

The ancients trisected an angle by means of the conic sections, and the book of inclinations; and Pappus enumerates several ways of doing it, in the 4th book of his Mathematical Collections, prop. 31, 32, 33, 34, 35, &c. He further observes, that the problem of trisecting an angle, is a solid problem, or a problem of the 3d degree, being expressed by the resolution of a cubic equation, in which way it has been resolved by Vieta, and others of the moderns. See his angular sections, with those of other authors, and the trisection in particular by cubic equations, as in Guisne's Application of Algebra to Geometry, in l'Hospital's Conic Sections, and in Emerson's Trigonometry, book 1, sec. 4. The cubic equation by which the problem of trisection is resolved, is as follows: Let $2c$ denote the chord of a given arc, or angle, and x the chord of the 3d part of the same, to the radius 1; then is $x^3 - 3x = -2c$, by the resolution of which cubic equation is found the value of x, or the chord of the 3d part of the given arc or angle, whose chord is c; and the resolution of this equation, by Cardan's rule, gives the chord

$$x = \sqrt[3]{(-c + \sqrt{(c^2 - 1)})} + \frac{1}{\sqrt[3]{(-c + \sqrt{(c^2 - 1)})}}.$$

$$\text{or } x = \sqrt[3]{(-c + \sqrt{(c^2 - 1)})} + \sqrt[3]{(-c - \sqrt{(c^2 - 1)})}.$$

TRISPAST, or TRISPASTON, in Mechanics, a machine with 3 pulleys, or an assemblage of 3 pulleys, for raising great weights; being a lower species of the polyspaston.

TRITE, in Music, the 3d musical chord in the system of the ancients.

TRITONE, in Music, a false concord, consisting of three tones, or a greater third, and a greater tone. Its ratio or proportion in numbers, is that of 45 to 32.

TROCHILE, in Architecture, is that hollow ring, or cavity, which runs round a column next to the tore.

TROCHLEA, in Mechanics, one of the mechanic powers, more usually called the pulley.

TROCHOID, in the Higher Geometry, a curve described by a point in any part of the radius of a wheel, during its rotatory and progressive motions. This is the same curve as what is more usually called the cycloid, where the construction and properties of it are shown.

TRONE *Weight*, the most ancient of the different weights used in Scotland.

TRONE *Pound*, in Scotland, contains 20 Scotch ounces. Or because it is usual to allow one to the score, the trone pound is commonly 21 ounces.

TRONE *Stone*, in Scotland, according to Sir John Skene, contains $19\frac{1}{2}$ pounds.

TROPHY, in Architecture, an ornament which represents the trunk of a tree, charged or encompassed all around with arms or military weapons, both offensive and defensive.

TROPICAL, something relating to the tropics. As, TROPICAL-*Winds*. See WIND, and TRADE-*Winds*.

TROPICAL *Year*, the space of time during which the sun passes round from a tropic, till his return to it again. See YEAR.

TROPICS, in Astronomy, two fixed circles of the sphere, drawn parallel to the equator, through the solstitial points, or at such distance from the equator, as is equal to the sun's greatest recess or declination, or to the obliquity of the ecliptic.

That on the north side of the equator, passes through the first point of Cancer, and is therefore called the Tropic of Cancer. And the other on the south side, passing through the first point of Capricorn, is called the Tropic of Capricorn.

To determine the distance between the two tropics, and thence the sun's greatest declination, or the obliquity of the ecliptic; observe the sun's meridian altitude, both in the summer and winter solstice, and subtract the latter from the former, so shall the remainder be the distance between the two tropics; and the half of this the quantity of the greatest declination, or the obliquity of the ecliptic; the medium of which is now 23° 27′ 46″ nearly.

TROPICS, in Geography, are two lesser circles of the globe, drawn parallel to the equator through the beginnings of Cancer and Capricorn, being in the planes of the celestial tropics, and consequently at 23° 28′ distance nearly, either way from the equator.

TROY-*Weight*, anciently called trone-weight, is supposed to be taken from a weight of the same name in France, and that from the name of the town of Troyes there. The original of all weights used in England, was a corn or grain of wheat gathered out of the middle of the ear; and, when well dried, 32 of them were to make one pennyweight, 20 pennyweights 1 ounce, and 12 ounces 1 pound troy. Vide statutes of 51 Hen. III; 31 Ed. I. and 12 Hen. VII. But afterward it was thought sufficient to divide the said pennyweight into 24 equal parts, called grains, being the least weight now in common use; so that the divisions of troy weight now are these:

24 grains	=	1 pennyweight	*dwt.*
20 pennyweights	=	1 ounce	*oz.*
12 ounces	=	1 pound	*lb.*

By troy-weight are weighed jewels, gold, silver, and all liquors.

TRUCKS, among Gunners, are the small wooden wheels fixed on the axletrees of gun carriages, especially those for ship service, to move them about by.

TRUE *Conjunction*. See *True* CONJUNCTION.

TRUE *Place of a Planet or Star*, is a point in the heavens shown by a right line drawn from the centre of the earth, through the centre of the star or planet.

TRUMPET, *Listening or Hearing*, is an instrument invented by Joseph Landini, to assist the hearing of persons dull of that faculty, or to assist us to hear persons who speak at a great distance. Instruments of this kind are formed of tubes, with a wide mouth, and terminating in a small canal, which is applied to the ear. The form of these instruments evidently shows how they conduce to assist the hearing; for the greater quantity of the weak and languid pulses of the air being received and collected by the large end of the tube, are reflected to the small end, where they are collected and condensed; thence entering the ear in this condensed state, they strike the tympanum with a greater force than they could naturally have done from the ear alone. Hence it appears, that a speaking trumpet may be applied to the purpose of a hearing trumpet, by turning the wide end towards the sound, and the narrow end to the ear.

Speaking TRUMPET, is a tube of a considerable length, from 6 to 15 feet, used for speaking with to make the voice be heard to a greater distance. This tube, which is made of tin, is straight throughout its length, but opening to a large aperture outwards, and the other end terminating in a proper shape and size to receive both the lips in the act of speaking, the speaker pushing his voice or the sound outwards, by which means it may be heard at the distance of a mile or more.

The invention of this trumpet is held to be modern, and has been ascribed to Sir Samuel Moreland, who called it the tuba stentorophonica; and in a work of the same name, published at London in 1671, that author gave an account of it, and of several experiments made with it. With one of these instruments, of 5½ feet long, 21 inches diameter at the greater end, and 2 inches at the smaller, tried at Deal Castle, the speaker was heard to the distance of 3 miles, the wind blowing from the shore.

But it seems that Kircher has a better title to the invention; for it is certain that he had such an instrument before ever Moreland thought of his. That author, in his Phonurgia Nova, published in 1673, says, that the tromba, published last year in England, he invented 24 years before, and published in his Mesurgia. He adds, that Jac. Albanus Ghibbisius and Fr. Eschinardus ascribe it to him; and that G. Schottus testifies of him, that he had such an instrument in his chamber in the Roman college, with which he could call to, and receive answers from the porter.

But, considering how famous the tube or horn of Alexander the Great was, it is rather strange that the moderns should pretend to the invention. With his stentorophonic horn or tube he used to speak to his army, and make himself be distinctly heard, it is said, 100 stadia or furlongs. A figure of this tube is preserved in the Vatican; and it is nearly the same as that now in use. See STENTOROPHONIC.

The principle of this instrument is obvious; for as sound is stronger in proportion to the density of the air, it follows that the voice, in passing through a tube or trumpet, must be greatly augmented by the constant reflection and agitation of the air through the length of the tube, by which it is condensed, and its action on the external air greatly increased at its exit from the tube. It has been found, that a man speaking through a tube of 4 feet long, may be understood at the distance of 500 geometrical paces; with a tube 16⅔ feet, at the distance of 1800 paces; and with a tube 24 feet long, at more than 2500 paces.

Though some advantage in heightening the sound, both in speaking and hearing, be derived from the shape of the tube, and the width of the outer end, yet the effect depends chiefly on its length. As to the form of it, some have asserted that the best figure is that which is formed by the revolution of a parabola about its axis; the mouth-piece being placed in the focus of the parabola, and consequently the sonorous rays reflected parallel to the axis of the tube. But Mr. Martin observes, that this parallel reflection is by no means essential to increasing the sound: on the contrary, it prevents the infinite number of reflections and reciprocations of sound, in which, according to Newton, its augmentation chiefly consists; the augmentation of the impetus of the pulses of air being proportional to the number of repercussions from the sides of the tube, and therefore to its length, and to such a figure as is most productive of them. Hence he infers, that the parabolic trumpet is the most unfit of any for this purpose; and he endeavours to show, that the logarithmic or logistic curve gives the best form, viz, by a revolution about its axis. Martin's Philos. Brit. vol. 2, pa. 248, 3d edit.

But Cassegrain is of opinion that an hyperbola, having the axis of the tube for an asymptote, is the best figure for this instrument. Musschenb. Intr. ad Phil. Nat. tom. 2, pa. 926, 4to. For other constructions of speaking-trumpets, by Mr. Conyers, see Philos. Trans. No. 141, for 1678.

TRUNCATED *Pyramid* or *Cone*, is the frustum of one, being the part remaining at the bottom, after the top is cut off by a plane parallel to the base. See FRUSTUM.

TRUNNIONS, of a piece of ordnance, are those knobs or short cylinders of metal on the sides, by which it rests on the cheeks of the carriage.

TRUNNION-*Ring*, is the ring about a cannon, next before the trunnions.

TSCHIRNHAUSEN (ERENFROY WALTER), an ingenious mathematician, lord of Killingswald and of Stolzenberg in Lusatia, where he was born in 1651. After having served as a volunteer in the army of Holland in 1672, he travelled into most parts of Europe, as England, Germany, Italy, France, &c. He went to Paris for the third time in 1682; where he communicated to the Academy of Sciences, the discovery of the curves, called from him, Tschirnhausen's Caustics; and the Academy in consequence elected the inventor one of its foreign members. On returning to Italy, he was desirous of perfecting the science of optics; for which purpose he established two glass-works, whence resulted many new improvements in dioptrics and physics, particularly the noted burning-glass which he presented to the regent. It was to him too that Saxony owed its porcelane manufactory. Content with the enjoyment of literary fame, Tschirnhausen refused all other honours that were offered him. Learning was his sole delight. He searched out men of talents, and gave them encouragement. He was often at the expence of printing the useful works of other men, for the benefit of the public; and died, beloved and regretted, the 11th of September 1708.

Tschirnhausen wrote, De Medicina Mentis et Corporis, printed at Amsterdam in 1687. And the following memoirs were printed in the volumes of the Academy of Sciences:—1. Observations on Burning Glasses of 3 or 4 feet diameter; vol. 1699.—2. Observations on the Glass of a Telescope, convex on both sides, of 32 feet focal distance; 1700.—3. On the Radii of Curvature, with the finding of Tangents, Quadratures, and Rectifications of many curves; 1701.—4. On the Tangents of Mechanical Curves; 1702.—5. On a Method of Quadratures; 1702.

TUBE, a pipe, conduit, or canal; being a hollow cylinder, either of metal, wood, glass, or other matter, for the conveyance of air, or water, &c. The term is chiefly applied to those used in physics, astronomy, anatomy, &c. On other ordinary occasions, we more usually say pipe.

In the memoirs of the French Academy of Sciences, Varignon has given a treatise on the proportions for the diameters of tubes, to give any particular quantities of water. The result of his paper gives these two analogies, viz. that the diminutions of the velocity of water, occasioned by its friction against the sides of tubes, are as the diameters; the tubes being supposed equally long: and the quantities of water issuing out at the tubes, are as the square roots of their diameters, deducting out of them the quantity that each is diminished.

Tube, in Astronomy, is sometimes used for telescope; but more properly for that part of it into which the lenses are fitted, and by which they are directed and used.

TUESDAY, the 3d day of the week, so called from Tuisco, one of the Saxon Gods, similar to Mars; for which reason the astronomical mark for this day of the week, is ♂.

TUMBREL, is a kind of carriage with two wheels, used either in husbandry for dung, or in artillery to carry the tools of the pioneers, &c, and sometimes likewise the money of an army.

TUN, is a measure for liquids, as wine, oil, &c. The English tun contains 2 pipes, or 4 hogsheads, or 252 gallons.

TUNE, or Tone, in Music, is that property of sounds by which they come under the relation of acute and grave. If two or more sounds be compared together in this relation, they are either equal or unequal in the degree of tune: such as are equal, are called unisons. The unequal constitute what are called intervals, which are the differences of tone between sounds.

Sonorous bodies are found to differ in tone: 1st, According to the different kinds of matter; thus the sound of a piece of gold, is much graver than that of a piece of silver of the same shape and dimensions. 2d, According to the different quantities of the same matter in bodies of the same figure; as a solid sphere of brass of 1 foot diameter, sounds acuter than a sphere of brass of 2 feet diameter.

But the measures of tone are only to be sought in the relations of the motions that are the cause of sound, which are most discernible in the vibration of chords. Now, in general, we find that in two chords, all things being equal, excepting the tension, the thickness, or the length, the tones are different; which difference can only be in the velocity of their vibratory motions, by which they perform a different number of vibrations in the same time; as it is known that all the small vibrations of the same chord are performed in equal times. Now the frequenter or quicker those vibrations are, the more acute is the tone; and the slower and fewer they are in the same time, by so much the more grave is the tone. So that any given note of a tune is made by one certain measure of velocity of vibrations, that is, such a certain number of vibrations of a chord or string, in such a certain part of time, constitutes a determinate tone.

This theory is strongly supported by the best and latest writers on music, Holder, Malcolm, Smith, &c, both from reason and experience. Dr. Wallis, who owns it very reasonable, adds, that it is evident the degrees of acuteness are reciprocally as the lengths of the chords; though, he says, he will not positively affirm that the degrees of acuteness answer the number of vibrations, as their only true cause: but his diffidence arises from hence, that he doubts whether the thing has been sufficiently confirmed by experiment.

TUNNAGE. See Tonnage.

TURN, is used for a circular motion; in which sense it agrees with revolution.

Turn, in Clock or Watch-work, particularly denotes the revolution of a wheel or pinion. In calculation, the number of turns which the pinion has, is denoted in common arithmetic thus, 5) 60 (12, where the pinion 5, playing in a wheel of 60, moves round 12 times in one turn of the wheel. Now by knowing the number of turns which any pinion makes in one turn of the wheel it works in, is easily found how many turns a wheel or pinion has at a greater distance; as the contrat-wheel, crown-wheel, &c, by multiplying together the quotients, and the number produced is the number of turns, as in the example here annexed: the first of these

5) 55 (11
5) 45 (9
5) 40 (8

three numbers has 11 turns, the next 9, and the last 8: by multiplying 11 by 9, it produces 99; that is, in one turn of the wheel 55, there are 99 turns of the second pinion 5, or the wheel 45, which runs concentrical or on the same arbor with the second pinion 5: and again multiplying 99 by the last quotient 8, it produces 792, which is the number of turns the third pinion 5 has. See Clock-*work*, and Pinion.

TURNING *to windward*, in Sea-Language, denotes that operation in sailing when a ship endeavours to make a progress against the direction of the wind, by a compound course, inclined to the place of her destination.—This method of navigation is otherwise called plying to windward.

TUSCAN *Order*, in Architecture, is the first, the simplest, and the strongest or most massive of any. Its column has 7 diameters in height; and its capital, base, and entablement, have no ornaments, and but few mouldings.

TWELFTH-*Day*, the festival of the Epiphany, or the manifestation of Christ to the Gentiles, so called, as being the twelfth day, exclusive, from the nativity or Christmas-day; of course it falls always on the 6th day of January.

TWILIGHT, in Astronomy, is that faint light which is perceived before sun-rising, and after sun-setting. The twilight is occasioned by the earth's atmosphere refracting the rays of the sun, and reflecting them among its particles.

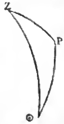
The depression of the sun below the horizon, at the beginning of the morning, and end of the evening twilight, has been variously stated, at different seasons, and by different observers: by Alhazen it was observed to be 19°; by Tycho 17°; by Rothman 24°; by Stevinus 18°; by Cassini 15°; by Riccioli, at the time of the equinox in the morning 16°, in the evening 20¼°; in the summer solstice in the morning 21° 25′, and in the winter 17° 15′. Whence it appears that the cause of the twilight is variable; but, on a medium, about 18° of the sun's depression will serve tolerably well for our latitude, for the beginning and end of twilight, and according to which Dr. Long, (in his Astronomy, vol. 1, pa. 258) gives the following table, of the duration of twilight, in different latitudes, and for several different declinations of the sun.

Latitude.	0	10	20	30	40	45	50	52½	55	60	65	70	75	80	85	90
☉ Enters	h m	h m	h m	h m	h m	h m	h m	h m	h m	h m	h m	h m	h m	h m	h m	h m
♋	1 18	1 21	1 28	1 41	2 8	2 39	w n	w n	w n	w n	w n	c d	c d	c d	c d	c d
♊ ♌	1 16	1 19	1 25	1 36	1 58	2 19	3 3	w n	w n	w n	w n	c d	c d	c d	c d	c d
♉ ♍	1 13	1 15	1 20	1 28	1 43	1 55	2 12	2 25	2 41	3 55	w n	w n	w n	c d	c d	c d
♈ ♎	1 12	1 13	1 17	1 24	1 35	1 44	1 55	2 2	2 10	2 33	3 8	4 18	w n	w n	w n	w n
♓ ♏	1 13	1 14	1 18	1 24	1 35	1 43	1 54	2 0	2 8	2 27	2 56	8 41	5 2	17 32	w n	w n
♒, ♐	1 16	1 17	1 21	1 28	1 40	1 49	2 1	2 8	2 18	2 43	3 26	11. 38	11 14	10 32	8 38	c n
♑	1 18	1 19	1 23	1 30	1 43	1 53	2 6	2 15	2 20	2 57	4 4	10 24	9 30	7 46	c n	c n

Where *c d* signify that it is then continual day, *c n* continual night, and *w n* that the twilight lasts the whole night.

Prob.—To find the Beginning or End of Twilight.

In this problem, there are given the sides of an oblique spherical triangle, to find an angle; viz, given the side ZP the co-latitude of the place; P☉ the co-declination, or polar distance; and Z☉ the zenith distance, which is always equal to 108°, viz, 90° from the zenith to the horizon, and 18° more for the sun's distance below the horizon. For example, suppose the place London in latitude 51° 32′, and the time the 1st of May, when the sun's declination is 15° 12′ north.



Here then ZP = 38° 28′ the complement of 51° 32′ and P☉ = 74° 48′, the complement of 15° 12′. Then the calculation is as follows.

P☉ = 74° 48′
PZ = 38 28
P☉ − PZ = 36 20 = D
Z☉ = 108 00
Z☉ + D = 144 20 | 72° 10′ = ½(Z☉ + D)
Z☉ − D = 71 40 | 35 50 = ½(Z☉ − D)

Then,

Co-ar. sin. polar dist.	= 74° 48′	0·01547
Co-ar. sin. colat.	= 38 28	0·20617
Sine ½(Z☉ + D)	= 72 10	9·97861
Sine ½(Z☉ − D)	= 35 50	9·76747
Sum of these four logs.		19.96772
Half sum gives	74° 28½′	9·98386

Which doubled gives 148 57 for the angle ZPO.

This 148° 57′ reduced to time, at the rate of 15° per hour, gives 9h 55m 48s, either before or after noon; that is, the twilight begins at 2h 4m 12s in the morning, and ends at 9h 55m 48s in the evening on the given day at London.

To find the time of shortest twilight at any given place, say, as radius to the sine of the latitude, so is the tangent of T to the sine of the sun's declination at the time required.—The declination of the sun and the latitude of the place must be of contrary kinds.—Hence, at about 51 or 52 degrees north latitude, the twilight will be shortest at about the 2d or 3d of March, and the 11th or 12th of October.

TWINKLING *of the Stars*, denotes that tremulous motion which is observed in the light proceeding from the fixed stars.—This twinkling in the stars has been variously accounted for. Alhazen, a Moorish philosopher of the 12th century, considers refraction as the cause of this phenomenon. Vitello, in his Optics, (composed before the year 1270) pa. 449, ascribes the twinkling of the stars to the motion of the air, in which the light is refracted; and he observes, in confirmation of this hypothesis, that they twinkle still more when they are viewed in water put into motion.

Dr. Hooke (Microgr. pa. 231, &c) ascribes this phenomenon to the inconstant and unequal refraction of the rays of light, occasioned by the tremulous motion of the air and interspersed vapours, in consequence of variable degrees of heat and cold in the air, producing corresponding variations in its density, and also of the action of the wind, which must cause the successive rays to fall upon the eye in different directions, and consequently on different parts of the retina at different times, and also to hit and miss the pupil alternately; and this also is the reason, he says, why the limbs of the sun, moon, and planets appear to wave or dance.

These tremors of the air are manifest to the eye by the undulating motion of shadows cast from high towers; and by looking at objects through the smoke of a chimney, or through steams of hot water, or at objects situated beyond hot sands, especially if the air be moved transversely over them. But when stars are seen through telescopes that have large apertures, they twinkle but little, and sometimes not at all. For, as Newton has observed, (Opt. pa. 98) the rays of light which pass through different parts of the aperture, tremble each of them apart, and by means of their various and contrary tremors, fall at one and the same time upon different points in the bottom of the eye, and their quivering motions are too quick and confused to be separately perceived. And all these illuminated points constitute one broad lucid point, composed of those many trembling points confusedly and insensibly mixed with one another by very short and swift tremors, and so cause the star to appear broader than it is, and without any motion of the whole.

Dr. Jurin, in his Essay on Distinct and Indistinct Vision, has recourse to Newton's hypothesis of fits of easy refraction and reflection for explaining the twinkling of the stars: thus, he says, if the middle part of the image of a star be changed from light to dark, and the adjacent ring at the same time be changed from dark to light, as must happen from the least motion of the eye towards or from the star, this will occasion such an appearance as twinkling.

Mr. Michell (Philos. Trans. vol. 57, pa. 262) supposes that the arrival of fewer or more rays at one time, especially from the smaller or more remote fixed stars, may make such an unequal impression on the eye, as may at least have some share in producing this effect: since it may be supposed that even a single particle of light is sufficient to make a sensible impression on the organs of sight; so that very few particles arriving at the eye in a second of time, perhaps not more than three or four may be sufficient to make an object constantly visible. See Light.

Hence, he says, it is not improbable that the number of the particles of light which enter the eye in a second of time, even from Sirius himself, may not exceed 3 or 4 thousand, and from stars of the 2d magnitude they may probably not exceed 100. Now the apparent increase and diminution of the light, which we observe in the twinkling of the stars, seem to be repeated at intervals not very unequal, perhaps about 4 or 5 times in a second. He therefore thought it reasonable to suppose, that the inequalities which will naturally arise from the chance of the rays coming sometimes a little denser, and sometimes a little rarer, in so small a number of them, as must fall upon the eye in the 4th or 5th part of a second, may be sufficient to account for this appearance.

Since these observations were published however, Mr. Michell (as we are informed by Dr. Priestley in his Hist. of Light, pa. 495) has entertained some suspicion, that the unequal density of light does not contribute to this effect in so great a degree as he had imagined; especially as he has observed that even Venus does sometimes twinkle. This he once observed her to do remarkably when she was about 6 degrees high, though Jupiter, which was then about 16 degrees high, and was sensibly less luminous, did not twinkle at all. If, notwithstanding the great number of rays which doubtless come to the eye from such a surface as this planet presents, its appearance be liable to be affected in this manner, it must be owing to such undulations in the atmosphere, as will probably render the effect of every other cause altogether insensible.

Musschenbroek suspects (Introd. ad. Phil. Nat. vol. 2, sect. 1741, pa. 707) that the twinkling of the stars arises from some affection of the eye, as well as the state of the atmosphere. For, says he, in Holland, when the weather is frosty, and the sky very clear, the stars twinkle most manifestly to the naked eye, though not in telescopes; and since he does not suppose there is any great exhalation, or dancing of the vapour, at that time, he questions whether the vivacity of the light, affecting the eye, may not be concerned in the phenomenon.

But this philosopher might have satisfied himself with respect to this hypothesis, by looking at the stars near the zenith, when the light traverses but a small part of the atmosphere, and therefore might be expected to affect the eye most sensibly. For he would have found that they do not twinkle near so much as they do near the horizon, when much more of their light is intercepted by the atmosphere.

Some astronomers have lately endeavoured to explain the twinkling of the fixed stars, by the extreme minuteness of their apparent diameter; so that they suppose the sight of them is intercepted by every mote that floats in the air. To this purpose Dr. Long observes (Astron. vol. 1, pa. 170), that our air near the earth is so full of various kinds of particles, which are in continual motion, that some one or other of them is perpetually passing between us and any star we look at, which makes us every moment alternately see it and lose sight of it: and this twinkling of the stars, he says, is greatest in those that are nearest the horizon, because they are viewed through a great quantity of thick air, where the intercepting particles are most numerous; whereas stars that are near the zenith do not twinkle so much, because we do not look at them through so much thick air, and therefore the intercepting particles, being fewer, come less frequently before them. With respect to the planets, it is observed that, because they are much nearer to us than the stars, they have a sensible apparent magnitude, so that they are not covered by the small particles floating in the atmosphere, and therefore do not twinkle, but shine with a steady light.

The fallacy of this hypothesis appears from the observation of Mr. Michell, that no object can hide a star from us that is not large enough to exceed the apparent diameter of the star, by the diameter of the pupil of the eye; so that if a star were even a mathematical point, or of no diameter, the interposing object must still be equal in size to the pupil of the eye; and indeed it must be large enough to hide the star from both eyes at the same time.

The principal cause therefore of the twinkling of the stars, is now acknowledged to be the unequal refraction of light, in consequence of inequalities and undulations in the atmosphere.

Besides a variation in the quantity of light, it may here be added, that a momentary change of colour has likewise been observed in some of the fixed stars. Mr. Melville (Edinb. Essays, vol. 2, pa. 81) asserts, that when one looks stedfastly at Sirius, or any bright star, not much elevated above the horizon, its colour appears not to be constantly white, but as tinctured, at every twinkling, with red and blue. Mr. Melville could not entirely satisfy himself as to the cause of this phenomenon; observing that the separation of the colours by the refractive power of the atmosphere, is probably too small to be perceived. Mr. Michell's hypothesis above-mentioned, though not adequate to the explication of the twinkling of the stars, may pretty well account for this circumstance. For the red and blue rays being much fewer than those of the intermediate colours, and therefore much more liable to inequalities from the common effect of chance, a small excess or defect in either of them will make a very sensible difference in the colour of the stars.

TYCHONIC *System*, or *Hypothesis*, is an order or arrangement of the heavenly bodies, of an intermediate nature between the Copernican and Ptolemaic; and is so called from its inventor Tycho Brahé. See System.

TYMPAN, or Tympanum, in Architecture, is the area of a pediment, being that part which is on a level with the naked of the frize. Or it is the space included between the three cornices of a triangular pediment, or the two cornices of a circular one.

Tympan is also used for that part of a pedestal called the trunk or dye.

Tympan, among joiners, is also applied to the pannels of doors.

Tympan *of an Arch*, is a triangular space or table in the corners of sides of an arch, usually hollowed and enriched, sometimes with branches of laurel, olive-tree, or oak; or with trophies, &c; sometimes with flying figures, as fame, &c; or sitting figures, as those representing the cardinal virtues.

Tympan, in Mechanics, is a kind of wheel placed round an axis, or cylindrical beam, on the top of which are two levers, or fixed staves, for more easily turning the axis about, in order to raise a weight. The tympanum is much the same with the peritrochium; but that the cylinder of the axis of the peritrochium is much shorter and less than the cylinder of the tympanum.

TYMPANUM of a machine, is also used for a hollow wheel, in which people or animals walk, to turn it; such as that of some cranes, calenders, &c.

TYR, in the Ethiopian Calendar, the name of the 5th month of the Ethiopian year. It commences on the 25th of December of the Julian year.

TYSHAS, among the Ethiopians, the name of the 4th month of their year, commencing the 27th of November in the Julian year.

U AND V

V Is a numeral letter, in the Roman numeration, denoting 5 or five. And with a dash over the top thus $\bar{V}$, it denoted 5000.

VACUUM, in Physics, a space empty or devoid of all matter.—Whether there be any such thing in nature as an absolute vacuum; or whether the universe be completely full, and there be an absolute plenum; is a question that has been agitated by the philosophers of all ages.

The ancients, in their controversies, distinguished two kinds; a Vacuum coacervatum, and a Vacuum interspersum, or disseminatum.

VACUUM *Coacervatum*, is conceived as a considerably large space destitute of matter; such, for instance, as there would be, should God annihilate all the air, and other bodies, within the walls of a chamber.—The existence of such a vacuum is maintained by the Pythagoreans, Epicureans, and the Atomists or Corpuscularians; most of whom assert, that such a vacuum actually exists without the limits of the sensible world. But the modern Corpuscularians, who hold a vacuum coacervatum, deny that appellation; as conceiving that such a vacuum must be infinite, eternal, and uncreated.

According then to the later philosophers, there is no vacuum coacervatum without the bounds of the sensible world; nor would there be any other vacuum, provided God should annihilate divers contiguous bodies, than what amounts to a mere privation, or nothing; the dimensions of such a space, which the ancients held to be real, being by these held to be mere negations; that is, in such a place there is so much length, breadth, and depth wanting, as a body must have to fill it. To suppose then, that when all the matter in a chamber is annihilated, there should yet be real dimensions, is to suppose, say they, corporeal dimensions without body; which is absurd.

The Cartesians however deny any vacuum coacervatum at all, and assert that if God should immediately annihilate all the matter, for example in a chamber, and prevent the ingress of any other matter, the consequence would be, that the walls would become contiguous, and include no space at all. They add, that if there be no matter in a chamber, the walls cannot be conceived otherwise than as contiguous; those things being said to be contiguous, between which there is not any thing intermediate: but if there be no body between, there is, say they, no extension between; extension and body being the same thing: and if there be no extension between, then the walls are contiguous, and where is the vacuum?——But this reasoning, or rather quibbling, is founded on the mistake, that body and extension are the same thing.

VACUUM Disseminatum, or Interspersum, is that supposed to be naturally interspersed in and among bodies, in the interstices between different bodies, and in the pores of the same body.—It is this kind of vacuum which is chiefly contested among the modern philosophers; the Corpuscularians strenuously asserting it; and the Peripatetics and Cartesians as tenaciously denying it. See CARTESIAN and LEIBNITZIAN.

The great argument urged by the Peripatetics against a vacuum interspersum, is, that there are divers bodies frequently seen to move contrary to their own nature and inclination; and that for no other apparent reason, but to avoid a vacuum: whence they conclude, that nature abhors a vacuum; and give us a new class of motions ascribed to the fuga vacui or nature's flying a vacuum. Such, they say, is the rise of water in a syringe, on the drawing up of the piston; and such is the ascent of water in pumps, and the swelling of the flesh in a cupping glass, &c.—But since the weight, elasticity, &c, of the air have been ascertained by sure experiments, those motions and effects are universally, and justly, ascribed to the gravity and pressure of the atmosphere.

The Cartesians deny, not only the actual existence, but even the possibility of a vacuum; and that on this principle, that extension being the essence of matter, or body, wherever extension is, there is matter; but mere space, or vacuity, is supposed to be extended; therefore it is material. Whoever asserts an empty space, say they, conceives dimensions in that space, i. e. he conceives an extended substance in it; and therefore he denies a vacuum, at the same time that he admits it.—But Descartes, if we may believe some accounts, rejected a vacuum from a complaisance to the taste which prevailed in his time, against his own first sentiments; and among his familiar friends he used to call his system his philosophical romance.

On the other hand, the corpuscular authors prove, not only the possibility, but the actual existence, of a vacuum, from divers considerations; particularly from that of motion in general; and that of the planets, comets, &c, in particular; as also from the fall of bodies; from the vibration of pendulums; from rarefaction and condensation; from the different specific gravities of bodies; and also from the divisibility of matter into parts.

1. First, there could be no linear or progressive motion without a vacuum; for if all space were full of matter, no body could be moved out of its place, for want of another place unoccupied, to move into. And this argument was stated even by Lucretius.

2. The motions of the planets and comets also confirm a vacuum. Thus, Newton argues, "that there is no such

fluid medium as æther," (to fill up the porous parts of all sensible bodies, and so make a plenum,) "seems probable; because the planets and comets proceed with so regular and lasting a motion, through the celestial spaces; for hence it appears that those celestial spaces are void of all sensible resistance, and consequently of all sensible matter. Consequently if the celestial regions were as dense as water, or as quicksilver, they would resist almost as much as water or quicksilver; but if they were perfectly dense, without any interspersed vacuity, though the matter were ever so fluid and subtile, they would resist more than quicksilver does: a perfectly solid globe, in such a medium, would lose above half its motion, in moving 3 lengths of its diameter; and a globe not perfectly solid, such as the bodies of the planets and comets are, would be stopped still sooner. Therefore, that the motion of the planets and comets may be regular, and lasting, it is necessary that the celestial spaces be void of all matter; except perhaps some few and much rarefied effluvia of the planets and comets, and the passing rays of light."

3. The same great author also deduces a vacuum from the consideration of the weights of bodies; thus: "All bodies about the earth gravitate towards it; and the weights of all bodies, equally distant from the earth's centre, are as the quantities of matter in those bodies. If the æther therefore, or any other subtile matter, were altogether destitute of gravity, or did gravitate less than in proportion to the quantity of its matter; because (as Aristotle, Descartes, and others, argue) it differs from other bodies only in the form of matter; the same body might, by the change of its form, gradually be converted into a body of the same constitution with those which gravitate most in proportion to the quantity of matter: and, on the other hand, the heaviest bodies might gradually lose their gravity, by gradually changing their form; and so the weights would depend upon the forms of bodies, and might be changed with them; which is contrary to all experiment."

4. The descent of bodies also proves, that all space is not equally full; for the same author proceeds, "If all spaces were equally full, the specific gravity of that fluid with which the region of the air would, in that case, be filled, would not be less than the specific gravity of quicksilver or gold, or any other the most dense body; and therefore neither gold, nor any other body, could descend in it. For bodies do not descend in a fluid, unless that fluid be specifically lighter than the body. But by the air-pump we can exhaust a vessel, till even a bit of down shall fall with a velocity equal to that of gold in the open air; and therefore the medium through which this feather falls, must be much rarer than that through which the gold falls in the other case. The quantity of matter therefore in a given space may be diminished by rarefaction: and why may it not be diminished ad infinitum? Add, that we conceive the solid particles of all bodies to be of the same density; and that they are only rarefiable by means of their pores; and hence a vacuum evidently follows."

5. "That there is a vacuum, is evident too from the vibrations of pendulums: for since those bodies, in places out of which the air is exhausted, meet with no resistance to retard their motion, or shorten their vibrations; it is obvious that there is no sensible matter in those spaces, or in the occult pores of those bodies."

6. That there are interspersed vacuities, appears from matter's being actually divided into parts, and from the figures of those parts; for, on supposition of an absolute plenum, we do not conceive how any part of matter could be actually divided from that next adjoining, any more than it is possible to divide actually the parts of absolute space from one another: for by the actual division of the parts of a continuum from each other, we conceive nothing else understood, but the placing of those parts at a distance from one another, which in the continuum were at no distance asunder: but such divisions between the parts of matter must imply vacuities between them.

7. As for the figures of the parts of bodies, on the supposition of a plenum, they must either be all rectilinear, or all concavo-convex; otherwise they would not adequately fill space; which we do not find to be true in fact.

8. The denying a vacuum supposes what it is impossible for any one to prove to be true, viz, that the material world has no limits.

However, we are told by some, that it is impossible to conceive a vacuum. But this surely must proceed from their having imbibed Descartes's doctrine, that the essence of body is constituted by extension; as it would be contradictory to suppose space without extension. To suppose that there are fluids penetrating all bodies and replenishing space, which neither resist nor act on bodies, merely in order to avoid admitting a vacuum, is feigning two kinds of matter without any necessity or foundation; or is tacitly giving up the question.

Since then the essence of matter does not consist in extension, but in solidity, or impenetrability, the universe may be said to consist of solid bodies moving in a vacuum; nor need we at all fear, lest the phenomena of nature, most of which are plausibly accounted for from a plenum, should become inexplicable when the plenitude is set aside. The principal ones, such as the tides; the suspension of the mercury in the barometer; the motion of the heavenly bodies, and of light, &c, are more easily and satisfactorily accounted for from other principles.

VACUUM *Boileanum*, is used to express that approach to a real vacuum, which we arrive at by means of the air-pump. Thus, any thing put in a receiver so exhausted, is said to be put in vacuo: and thus most of the experiments with the air-pump are said to be performed in vacuo, or in vacuo Boileano.

Some of the principal phenomena observed of bodies in vacuo, are; that the heaviest and lightest bodies, as gold and a feather, fall with equal velocity:—that fruits, as grapes, cherries, peaches, apples, &c, kept for any time in vacuo, retain their nature, freshness, colour, &c, and those withered in the open air recover their plumpness in vacuo:—all light and fire become immediately extinct in vacuo:—little or no sound is heard from a bell rung in vacuo:—a bladder half full of air, will distend the bladder, and lift up 40 pound weight in vacuo:—most animals soon expire in vacuo.

By experiments made in 1704, Dr. Derham found that animals which have two ventricles, and no foramen ovale, as birds, dogs, cats, mice, &c, die in less than half a minute; counting from the first exsuction: a mole died in one minute; a bat lived 7 or 8. Insects, as wasps, bees, grasshoppers, &c, seemed dead in two minutes; but after being left in vacuo 24 hours, they came to life again in the open air: snails continued 24 hours in vacuo, without appearing much affected.—Seeds planted in vacuo do not grow: Small beer dies, and loses all its taste, in vacuo: and air rushing through mercury into a vacuum, throws the mercury in a kind of shower upon the receiver, and produces a great light in a dark room.

The air-pump can never produce a perfect vacuum: as is evident from its structure, and the manner of its working: in effect, every exsuction only takes away a part of the air; so that there is still some left after any finite number of exsuctions. For the air-pump has no longer any effect but while the spring of the air remaining in the receiver is able to lift up the valves; and when the rarefaction is come to that degree, you can arrive no nearer to a vacuum; unless perhaps the air valves can be opened mechanically, independent of the spring of the air, as it is said they are in some newly improved air-pumps.

Torricellian VACUUM, is that made in the barometer tube, between the upper end and the top of the mercury. This is probably never a perfect and entire vacuum; as all fluids are found to yield or to rise in elastic vapours, on the removal of the pressure of the atmosphere. See TORRICELLIAN, and BAROMETER.

VALVE, in Hydraulics, Pneumatics, &c, is a kind of lid or cover to a tube or vessel, contrived to open one way; but which, the more forcibly it is pressed the other way, the closer it shuts the aperture: so that it either admits the entrance of a fluid into the tube, or vessel, and prevents its return; or permits it to escape, and prevents its re-entrance.

Valves are of great use in the air-pump, and other wind machines: in which they are usually made of pieces of bladder. In hydraulic engines, as the emboli of pumps, they are mostly of strong leather, of a round figure, and fitted to shut the apertures of the barrels or pipes. Sometimes they are made of two round pieces of leather enclosed between two others of brass; having divers perforations, which are covered with another piece of brass, moveable upwards and downwards, on a kind of axis, which goes through the middle of them all. Sometimes they are made of brass, covered over with leather, and furnished with a fine spring, which gives way upon a force applied against it; but on the ceasing of that, returns the valve over the aperture. See PUMP. See also Desaguliers' Exper. Philos. vol. 2, pa. 156, and pa. 180.

VANE, in a ship, &c, a thin slip of some kind of matter, placed on high in the open air, turning easily round on an axis or spindle, and veered about by the wind, to show its direction or course.

VANES, in Mathematical or Philosophical Instruments, are sights made to slide and move upon cross-staves, fore-staves, quadrants, &c.

VAPOUR, in Meteorology, a watery exhalation raised up either by the heat of the sun, or any other heat, as fire, &c. Vapour is considered as a thin vesicle of water, or other humid matter, filled or inflated with air; which, being rarefied to a certain degree by the action of heat, ascends to some height in the atmosphere, where it is suspended, till it returns in form of rain, snow, or the like. An assemblage of a number of particles or vesicles of vapour, constitutes what is called a cloud.

Some use the term vapour indifferently, for all fumes emitted, either from moist bodies, as fluids of any kind; or from dry bodies, as sulphur, &c. But Newton, and other authors, better distinguish between humid and dry fumes, calling the latter exhalations.

For the manner in which vapours are raised, and again precipitated, see CLOUD, DEW, RAIN, BAROMETER, and particularly EVAPORATION.

It may here be added, with respect to the principles of solution adopted to account for evaporation, and largely illustrated under that article, that Dr. Halley, about the beginning of the 18th century, seems to have been acquainted with the solvent power of air on water; for he says, that supposing the earth to be covered with water, and the sun to move diurnally round it, the air would of itself imbibe a certain quantity of aqueous vapours, and retain them like salts dissolved in water; and that the air warmed by the sun would sustain a greater proportion of vapours, as warm water will hold more dissolved salts; which would be discharged in dews, similar to the precipitation of salts on the cooling of liquors. Philos. Trans. vol. 3.

Mr. Eeles, in 1755, endeavoured to account for the ascent of vapour and exhalation, and their suspension in the atmosphere, by means of the electric fire. The sun, he acknowledges, is the great agent in detaching vapour and exhalations from their masses, whether he acts immediately by himself, or by his rendering the electric fire more active in its vibrations: but their subsequent ascent he attributes entirely to their being rendered specifically lighter than the lower air, by their conjunction with electrical fire: each particle of vapour, with the electrical fluid that surrounds it, occupying a greater space than the same weight of air. Mr. Eeles also endeavours to show, that the ascent and descent of vapour, attended by this fire, are the cause of all the winds, and that they furnish a satisfactory solution of the general phenomena of the weather and barometer. Philos. Trans. vol. 49, pa. 124.

Dr. Darwin, in 1757, published remarks on the theory of Mr. Eeles, with a view of confuting it; and attempting to account for the ascent of vapours, by considering the power of expansion which the constituent parts of some bodies acquire by heat, and also that some bodies have a greater affinity to heat, or acquire it sooner, and retain it longer, than others. On these principles, he thinks, it is easily understood how water, whose parts appear from the æolipile to be capable of immeasurable expansion, should by heat alone become specifically lighter than the common atmosphere. A small degree of heat is sufficient to detach or raise the vapour of water from the mass to which it belongs; and the rays of the sun communicate heat only to those bodies by which they are refracted, reflected, or obstructed; whence, by their impulse, a motion or vibration is caused in the parts of such bodies. Hence he infers, that the sphericles of vapour will, by refracting the solar rays, acquire a constant heat, though the surrounding atmosphere remain cold. If it be asked, how clouds are supported in the absence of the sun? it must be remembered, that large masses of vapour must for a considerable time retain much of the heat they have acquired in the day; at the same time reflecting how small a quantity of heat was necessary to raise them, and that doubtless even a less will be sufficient to support them; as from the diminished pressure of the atmosphere at a given height, a less power may be able to continue them in their present state of rarefaction; and lastly, that clouds of particular shapes will be sustained or elevated by the motion they acquire from winds. Philos. Trans. vol. 50, pa. 246.

The quantity of vapour raised from the sea by the warmth of the sun, must be far greater than is commonly imagined. Dr. Halley has attempted to estimate it. For the result of his calculations, see EVAPORATION.

For the Effect of Vapour in the Formation of Springs, &c, see SPRING, and RIVER.

VARENIUS (BERNARD), a learned Dutch geographer and physician, of the 17th century, who was author of the best mathematical treatise on Geography, intitled, Geographia Universalis, in qua affectiones generalis Telluris explicantur. This excellent work has been translated into all languages, and was honoured by an edition, with improvements, by Sir Isaac Newton, for the use of his academical students at Cambridge.

VARIABLE, in Geometry and Analytics, is a term applied by mathematicians, to such quantities as are considered in a variable or changeable state, either increasing or decreasing. Thus, the abscisses and ordinates of an ellipsis, or other curve line, are variable quantities; because these vary or change their magnitude together, the one at the same time with the other. But some quantities may be variable by themselves alone, or while those connected with them are constant: as the abscisses of a parallelogram, whose ordinates may be considered as all equal, and therefore constant. Also the diameter of a circle, and the parameter of a conic section, are constant, while their abscisses are variable.

Variable quantities are usually denoted by the last letters of the alphabet, z, y, x, &c: while the constant ones are denoted by the leading letters, a, b, c, &c. Some authors, instead of variable and constant quantities, use the terms fluent and stable quantities. The indefinitely small quantity by which a variable quantity is continually increased or decreased, in very small portions of time, is called the differential, or increment or decrement of that quantity. And the rate of its increase or decrease at any point, is called its fluxion; while the variable quantity itself is called the fluent. And the calculation of these, is the subject of the new Methodus Differentialis, or Doctrine of Fluxions.

VARIABLE MOTION, in Mechanics, is that motion of a body when subject to the continual action of a force which changes, or is different at every instant. We have instances of variable motion, in the unbending of springs: though the velocity continues to be augmented, yet the degrees by which the augmentation proceeds are diminishing. It is the same with regard to the degrees by which the motion of a ship arrives at uniformity: the action of the wind on the sails diminishes in proportion as the vessel acquires greater velocity, because the action of the wind varies as the difference between its velocity and that of the sail on which it acts.

For an illustration of the different natures of constant and variable accelerating motions, see the art. *Acceleration.*

VARIATION, *of Quantities*, in Algebra. See CHANGES, and COMBINATION.

Calculus of VARIATIONS, is that by which, having given an expression or function containing two or more variable quantities, whose relation is expressed by a determinate law, we find what that function becomes when the law itself is supposed to experience any variation indefinitely small, occasioned by the variation of one or of several of the terms which express that law. The origin of this calculus is imputed to the circumstance of certain problems concerning the maxima and minima of quantities having been proposed by John Bernoulli, to the mathematicians of Europe. Such a problem was that in which it was required to find, of all curves passing through two fixed points, and situated in the same vertical plane, that along which a body would descend from the highest to the lowest point in the least time possible.

The first geometricians, remarking that nothing was obtained by putting the differential of the time $\frac{dz}{\sqrt{x}} = o$, found that they could obtain a solution by making the time a minimum for two successive elements of the curve: thus, if x, x', x'' were three vertical abscissas, and y, y', y'', the corresponding ordinates, the time would be expressed by

$$\sqrt{\frac{(x'-x)^2+(y'-y)^2}{x}} + \sqrt{\frac{(x''-x')^2+(y''-y')^2}{x'}},$$

the differential of which being taken, and put $= o$, gave a resulting equation $\frac{dy}{\sqrt{c} \times \sqrt{(dx^2+dy^2)}} = b$, a constant quantity; and hence proved the curve to be a cycloid. —Euler, with far greater analytical knowledge than John Bernoulli, next treated these problems in a general manner, in his tract entitled, "Methodus inveniendas lineas curvas maximi minimive proprietate gaudentes; sive solutio problematis isoperimetricalatissimo sensu accepti." M. Lagrange afterwards gave greater generality to this calculus, by making variable not only y, dy, d^2y, &c, but also x.

The explanation of M. Lacroix affords as clear an idea of the calculus of variations as any that we are acquainted with.

"Suppose," says he, "the variable quantities at first connected together by an equation, or by any other dependence, to change by reason of the form of the equation, or of the relation that results from the dependence established between them ceasing to be the same; this circumstance cannot be expressed in a more general manner, than by regarding the increments of x and y as absolutely independent of each other; since, in effect, this hypothesis not designating any particular relation between x and y, comprehends all. It follows thence, that the calculus of variations can only be employed for expressions, to which the differential calculus has already been applied; and it differs from the last only by the independence which it supposes between the variable quantities, which before were considered as connected by constant relations. The following example will illustrate this notion. The expression $\frac{ydx}{dy}$, which belongs to the subtangent of a curve, represents a determinate function of x, when y is considered as a function whose composition in terms of x is known: and if this last changes, the first changes also. There will be perhaps some difficulty in conceiving how we can submit to calculation the variability of a function which is only the abstract dependence in which several quantities are with regard to each other: but this difficulty is removed, by considering that the connection between the quantities y and x changes if the first be made to vary independently of the second. Thus, in the example before us, if we suppose x to remain the same, and y and $\frac{dy}{dx}$ to change, the relation between x and y must necessarily have changed also, since these quantities are the immediate consequences of that relation: $\frac{dy}{dx}$, in the form $\frac{ydx}{dy}$, may alone be made to vary, since it depends only on one value of y: but, if an expression affected by the sign $\int$ (denoting the integral of that expression) be considered, y and $\frac{dy}{dx}$ must be made to vary at the same time; for it follows from the theory for the formation of integrals, that the value of a like function depends on the consecutive values of y, which are deduced from those of $\frac{dy}{dx}$.

"It is evident that, to take under this point of view the differential of any expression whatever, it is sufficient to make y, dy, d^2y, &c, vary without altering x; but in treating this latter quantity as variable as the first, we arrive at results more general and symmetrical than what are otherwise obtained, and which lead to very interesting remarks on the nature of the differential forms. For these reasons, we shall adopt in this chapter the method of making x, dy, d^2y vary. That the symbols of this new species of differentiation, in which x and y are considered as independent, may not be confounded with the symbols of the first, in which one of the variable quantities is regarded as a function of the other, we shall employ, after the manner of Lagrange, the characteristic δ; and we shall suppose, with him, that when y changes only by virtue of the change of x, which becomes $x + dx$, its differential is dy: but that when the relation of y and x varies, these two quantities become respectively $x + \delta x$, $y + \delta y$; and we note by the name of variations, the increments δx and δy.

"Hence it follows that, as $du = \frac{du}{dx} dx + \frac{du}{dy} dy$, ($u$ being a function of x and y) so $\delta u = \frac{\delta u}{\delta x} \delta x + \frac{\delta u}{\delta y} \delta y$.

"In applying this to the example $\frac{ydx}{dy}$ we must regard $\frac{dx}{dy}$ as a function of x and y; whence it results that $\delta\frac{ydx}{dy} = \frac{dx\delta y}{dy} + y\delta(\frac{dx}{dy})$, and $\delta(\frac{dx}{dy}) = \frac{dy\delta dx - dx\delta dy}{dy^2} = \frac{dyd\delta x - dxd\delta y}{dy^2}$, for $\delta dx = d\delta x$, $\delta dy = d\delta y$ — "

M. Lacroix then proves $\delta dx = d\delta x$, &c. After the methods for finding the variations of any function whatever, is given the application of the calculus to the problems of maxima and minima.

VARIATION, in Astronomy.—The Variation of the Moon, called by Bulliald, the Reflection of her Light, is the third inequality observed in the moon's motion; by which, when out of the quadratures, her true place differs from her place twice equated. See PLACE, EQUATION, &c.—Newton makes the moon's variation to arise partly from the form of her orbit, which is an ellipsis; and partly from the inequality of the spaces, which the moon describes in equal times, by a radius drawn to the earth.

To find the Greatest Variation. Observe the moon's longitude in the octants; and to the time of observation compute the moon's place twice equated; then the difference between the computed and observed place, is the greatest variation.

Tycho makes the greatest variation 40′ 30″; and Kepler makes it 51′ 49″.—But Newton makes the greatest variation, at a mean distance between the sun and the earth, to be 35′ 10″: at the other distances, the greatest variation is in a ratio compounded of the duplicate ratio of the times of the moon's synodical revolution directly, and the triplicate ratio of the distance of the sun from the earth inversely. And therefore in the sun's apogee, the greatest variation is 33′ 14″, and in his perigee 37′ 11″; provided that the eccentricity of the sun be to the transverse semidiameter of the orbis magnus, as $16\frac{7}{8}$ to 1000. Or, taking the mean motions of the moon from the sun, as they are stated in Dr. Halley's tables, then the greatest variation at the mean distance of the earth from the sun will be 35′ 7″, in the apogee of the sun 33′ 27″, and in his perigee 36′ 51″. Philos. Nat. Princ. pr. 29, lib. 3.

VARIATION *of Curvature*, is the rate at which is varied the curvature of any curve, except that of the circle, which is constant.

VARIATION, in Geography, Navigation, &c, a term applied to the deviation of the magnetic needle, or compass, from the true north point, either towards the east or west; called also the declination. Or the variation of the compass is properly defined, the angle which a magnetic needle freely suspended makes with the meridian line on an horizontal plane; or an arch of the horizon, comprehended between the true and the magnetic meridians. In the sea-language, the variation is usually called northeasting, or north-westing.

All magnetic bodies are found to range themselves, in some sort, according to the meridian; but they seldom agree precisely with it; in one place they decline, from the north toward the east, in another toward the west; and that too differently at different times.

The variation of the compass could not long remain a secret, after the invention of the compass itself: accordingly Ferdinand, the son of Columbus, in his life written in Spanish, and printed in Italian at Venice in 1571, asserts, that his father observed it on the 14th of September 1492; though others seem to attribute the discovery of it to Sebastian Cabot, a Venetian, employed in the service of our king Henry VII, about the year 1500.—It now appears however, that this variation or declination of the needle was known even some centuries earlier, though it does not appear that the use of the needle itself in navigation was then known. For it seems there is in the library of the university of Leyden, a small manuscript tract on the magnet, in Latin, written by one Peter Adsiger, bearing date the 8th of August 1269; in which the declination of the needle is particularly mentioned. Mr. Cavallo has printed the chief part of this letter in the Supplement to his Treatise on Magnetism, with a translation; and it is to be wished he had printed the whole of so curious a paper. The curiosity of this letter, says Mr. Cavallo, consists in its containing almost all that is at present known on the subject, at least the most remarkable parts of it, mixed however with a good deal of absurdity. The laws of magnetic attraction, and of the communication of that power to iron, the directive property of the natural magnet, as well as of the iron that has been touched by it, and even the declination of the magnetic needle, are clearly and unequivocally mentioned in it.

As this variation differs in different places, Gonzales d'Oviedi found there was none at the Azores; whence some geographers thought fit in their maps to make the first meridian pass through one of these islands; it not being then known that the variation altered in time. See

MAGNET; also Gilbert de Magnete, Lond. 1600, pa. 4 and 5; or Purchas's Pilgrims, Lond. 1625, book 2, sect. 1.

Various are the hypotheses that have been framed to account for this extraordinary phenomenon: we shall only notice some of the later, and more probable: just premising, that Robert Norman, the inventor of the dipping-needle, disputes against Cortes's notion, that the variation was caused by a point in the heavens; contending that it should be sought for in the earth, and proposes how to discover its place.

The first is that of Gilbert (De Magnete, lib. 4, pa. 151 &c), which is followed by Cabeus, &c. This notion is, that it is the earth, or land, that draws the needle out of its meridian direction: hence they argue, that the needle varied more or less, as it was more or less distant from any great continent; and consequently that if it were placed in the middle of an ocean, equally distant from equal tracts of land on each side, eastward and westward, it would not decline either to the one or the other, but point exactly north and south. Thus, say they, in the Azores islands, which are equally distant from Africa on the east, and America on the west, there is no variation: but as you sail from thence towards Africa, the needle begins to decline toward the east, and that still more and more till you reach the shore. Proceed still further eastward, the declination gradually diminishes again, by reason of the land left behind on the west, which continues to draw the needle. The same also obtains till you arrive at a place where the tracts of land on each side are equal; and there again the variation will be nothing. But the misfortune is, the law does not hold universally; for multitudes of observations of the variation, in different parts, made and collected by Dr. Halley, overturn the whole theory.

Others therefore have recourse to the frame and compages of the earth, considered as interspersed with rocks and shelves, which being generally found to run towards the polar regions, the needle comes to have a general tendency that way; but it seldom happens that their direction is exactly in the meridian, and the needle has consequently, for the most part, some variation.

Others maintain that divers parts of the earth have different degrees of the magnetic virtue, as some are more intermixed with heterogeneous matters, which prevent the free action or effect of it, than others are.

Others again ascribe all to magnetic rocks and iron mines, which, affording more of the magnetic matter than other parts, attract or draw the needle more.

Lastly, others imagine that earthquakes, or high tides, have disturbed and dislocated several considerable parts of the earth, and so changed the magnetic axis of the globe, which was originally the same with the axis of the earth itself.

But none of these theories can be the true one; for still that great phenomenon, the variation of the variation, i. e. the continual change of the declination, in one and the same place, is not accountable for, on any of these foundations, nor is it even consistent with them.

Doctor Hooke communicated to the Royal Society, in 1674, a theory of the variation; the substance of which is, that the magnet has its peculiar pole, distant 10 degrees from the pole of the earth, about which it moves, so as to make a revolution in 370 years: whence the variation, he says, has altered of late about 10 or 11 minutes every year, and will probably so continue to do for some time, when it will begin to proceed slower and slower, till at length it become stationary and retrograde, and so return back again. Birch's Hist. of the Royal Society, vol. 3, pa. 131.

Dr. Halley has given a new system, the result of numerous observations, and even of a number of voyages made at the public expence on this account. The light which this author has thrown upon this obscure part of natural history, is very great, and of important consequence in navigation, &c. In this system he has reduced the several variations in divers places to a precise rule, or order, which before appeared quite precarious and arbitrary. His theory will therefore deserve a more ample detail. The observations it is built upon, as laid down in the Philos. Trans. No. 148, or Abr. vol. 2, pa. 624, are as follow:

Observed Variations of the Needle in divers places, and at divers times.

On these observed variations Dr. Halley makes several remarks, as to the variation in different parts of the world at the time of his writing, eastward and westward, and the situation and direction of the lines or places of no variation: from the whole he deduces the following theory.

Dr. Halley's Theory of the Variation of the Magnetic Needle.—That the whole globe of the earth is one great magnet, having four magnetical poles, or points of attraction; near each pole of the equator two; and that in those parts of the world which lie nearly adjacent to any one of these magnetic poles, the needle is governed by it; the nearest pole being always predominant over the more remote.

The pole which at present is nearest to us, he conjectures to lie in or near the meridian of the Land's-end of England, and not above 7° from the north pole: by this pole, the variations in all Europe and Tartary, and the North Sea, are chiefly governed; though still with some regard to the other northern pole, whose situation is in the meridian passing about the middle of California, and about 15° from the north pole of the world, to which the needle has chiefly respect in all North America, and in the two oceans on either side of it, from the Azores westward to Japan, and farther.

The two southern magnetic poles, he imagines, are rather more distant from the south pole of the world; the one being about 16° from it, on a meridian 20° to the westward of the Magellanic Streights, or 95° west from London: this pole commands the needle in all South America, in the Pacific Ocean, and the greatest part of the Ethiopic Ocean. The other magnetic pole seems to have the greatest power, and the largest dominion of all, as it is the most remote from the pole of the world, being little less than 20° distant from it, in the meridian which passes through New Holland, and the island Celebes, about 120° east from London: this pole is predominant in the south part of Africa, in Arabia, and the Red Sea, in Persia, India, and its islands, and all over the Indian sea, from the Cape of Good Hope eastward, to the middle of the Great South Sea that divides Asia from America.

Such, he observes, seems to be the present disposition of the magnetic virtue throughout the whole globe of the earth. It is then shown how this hypothesis accounts for all the variations that have been observed of late, and how it answers to the several remarks drawn from the table. It is there inferred that from the whole it appears, that the direction of the needle, in the temperate and frigid zones, depends chiefly on the counterpoise of the forces of two magnetic poles of the same nature: as also why, under the same meridian, the variation should be in one place 29½ degrees west, and in another 20½ degrees east.

In the torrid zone, and particularly about the equator, respect must be had to all the four poles, and their positions must be well considered, otherwise it will not be easy to determine what the variation should be, the nearest pole being always strongest; yet so however as to be sometimes counterbalanced by the united forces of two more remote ones. Thus, in sailing from St. Helena, by the isle of Ascension, to the equator, on the north-west course, the variation is very little easterly, and unalterably the same in that whole track; because the South-American pole (which is much the nearest in the aforesaid places), requiring a great easterly variation, is counterpoised by the contrary attraction of the North-American and the Asiatic south poles; each of which singly is, in these parts, weaker than the American south pole; and on the north-west course the distance from this latter is very little varied; and as you recede from the Asiatic south-pole, the balance is still preserved by an access toward the North-American pole. In this case no notice is taken of the European north pole; its meridian being a little removed from the meridians of these places, and of itself requiring the same variations which are here found.

After the same manner may the variations in other places about the equator be accounted for, upon Dr. Halley's hypothesis.—But still this will do nothing as to accounting for the continual variation or change of the declination, in the same place.

To observe the Variation of the Needle.—Draw a meridian line, as directed under MERIDIAN; then a stile being erected in the middle of it, place a needle upon it, and draw the right line which it hangs over. Thus will the quantity of the variation appear.

Or thus: As the former method of finding the variation cannot be applied at sea, others have been devised, the principal of which are as follow. Suspend a thread and plummet over the compass, till the shadow pass through the centre of the card; observe the rhumb, or point of the compass which the shadow touches when it is the shortest. For the shadow is then a meridian line; and consequently the variation is determined.

Or thus: Observe the point of the compass on which the sun, or some star, rises and sets; bisect the arch intercepted between the rising and setting points, and the line of bisection will be the meridian line; consequently the variation is had as before. The same may also be obtained from two equal altitudes of the same star, observed either by day or night. Or thus: Observe the rhumb upon which the sun or star rises and sets; and from the latitude of the place find the eastern or western amplitude: for the difference between the amplitude, and the distance of the rhumb observed, from the eastern rhumb of the card, is the variation sought.

Or thus: Observe the altitude of the sun, or some star s, whose declination is known; and note the rhumb in the compass to which it then corresponds. Then in the triangle ZPS, are known three sides, viz, PZ the co-latitude, PS the co-declination, and ZS the co-altitude; the angle PZS is thence found by spherical trigonometry; the supplement to which, viz AZS, is the azimuth from the south. Then the difference between the azimuth and the observed distance of the rhumb from the south, is the variation sought. See *Azimuth* COMPASS.

The use of the variation is to correct the courses a ship has steered by the compass, which must always be done before they are worked, or calculated.

VARIATION *of the Variation*, is a gradual and continual change in the variation, observed in any place, by which the quantity of the variation is found to be different at different times.

This variation, according to Henry Bond (in his Longitude Found, Lond. 1670, pa. 6), "was first found to decrease by Mr. John Mair; 2dly, by Mr. Edmund Gunter: 3dly, by Mr. Henry Gellibrand; 4thly, by myself (Henry Bond) in 1640; and lastly, by Dr. Robert Hooke, and others, in 1665;" which they found out by comparing together observations made at the same place, at different times. The discovery was soon known abroad; for Kircher, in his treatise entitled Magnes, first printed at Rome in 1641, says that our countryman Mr. John Greaves had informed him of it, and then he gives a letter of Mersenne's, containing a distinct account of it.

This continual change in the variation, is gradual and universal, as appears by numerous observations. Thus, the variation was, at Paris,

in 1550	-	8°	0′E
in 1640	-	3	0 E
in 1660	-	0	0
in 1681	-	2	2 W
in 1759	-	18	10 W
in 1760	-	18	20 W
in 1794	-	21	54 W
in 1798	-	22	15 W
in 1799	-	22	0 W
in 1800	-	22	12 W
in 1801	-	22	1 W
in 1802	-	21	45 W
in 1803	-	21	59 W
in 1804	-	22	15 W
in 1810	-	22	16 W

the variation towards the conclusion appearing obviously to vacillate about a limit. M. de la Lande (Exposition du Calcul Astronomique) observes, that the variation has changed, at Paris, 26° 20′ in the space of 150 years, allowing that in 1610 the variation was 8° E: and since 1740 the needle, which was always used by Maraldi, is more than 3° advanced toward the west, beyond what it was at that period: which is a change after the rate nearly of 9¼′ per year.

At Cape d'Agulhas, in 1600, it had no variation; (whence the Portuguese gave it that name);

in 1622	it was	2°	W
in 1675	-	8	W
in 1692	-	11	W

which is a change of nearly 8′ per year.

At St. Helena, the variation,

in 1600	was	8°	0′E
in 1623	-	6	0 E
in 1677	-	0	40 E
in 1692	-	1	0 W

which is a change of nearly 5½′ per year.

At Cape Comorin, the variation,

in 1620	was	14°	20′W
in 1680	-	8	44 W
in 1688	-	7	30 W

which is a change of nearly 6¼′ per year.

At London, the variation,

in 1580	was	11°	15′E
in 1622	-	6	0 E
in 1634	-	4	5 E
in 1657	-	0	0
in 1672	-	2	30 W
in 1692	-	6	0 W
in 1723	-	14	17 W
in 1747	-	17	40 W
in 1780	-	22	41 W
in 1812	-	24	16 W

which till 1780, is a change after the rate of 10′ per year. But in the 32 years, from 1780 to 1812, the change was only 1° 35′, being only at the rate of 3′ a year. See Philos. Trans. No. 148 and No. 383, and also vol. 45, pa. 280, and vol. 66, pa. 393. On the subject of the variation, see also Norman's New Attractive 1614; Burrows's Discovery of the Variation 1581; Bond's Longitude Found 1676; &c.

Mr. Thomas Harding, in the Transactions of the Royal Irish Academy, vol. 4, has given observations on the variation of the magnetic needle, at Dublin, which are rather extraordinary. He says the change in the variation at that place is uniform; that from the year 1657, in which the variation was nothing (the same as at London in that year), it has been going on at the medium rate of 12′ 20″ annually, and was in May 1791, 27° 23′ west; exceeding that at London now by 3 or 4 degrees. He brings proof of his assertion of the uniformity of the variation, from different authentic records, and states the operations by which it is calculated. He concludes with recommending accuracy in marking the existing variation when maps are made, as not only conducing to the exact definition of boundaries, but as laying the best foundation for a discovery of the longitude by sea or land.

Theory of the Variation of the Variation.—According to Dr. Halley's theory, this change in the variation of the compass, is supposed owing to the difference of velocity in the motions of the internal and external parts of the globe. From the observations that have been cited, it seems to follow, that all the magnetical poles have a motion westward, but yet not exactly about the axis of the earth, for then the variations would continue the same in the same parallel of latitude, contrary to experience.

From the disagreement of such a supposition with experiments therefore, the learned author of the theory invented the following hypothesis: The external parts of the globe he considers as the shell, and the internal as a nucleus, or inner globe; and between the two he conceives a fluid medium. That inner earth having the same common centre and axis of diurnal rotation, may revolve with our earth every 24 hours: only the outer sphere having its turbinating motion somewhat swifter or slower than the internal ball; and a very minute difference in length of time, by many repetitions, becoming sensible; the internal parts will gradually recede from the external, and they will appear to move, either eastward or westward, by the difference of their motions.

Now, supposing such an internal sphere, having such a motion, the two great difficulties in the former hypothesis are easily solved; for if this exterior shell of earth be a magnet, having its pole at a distance from the poles of diurnal rotation; and if the internal nucleus be likewise a magnet, having its poles in two other places, distant also from the axis; and these latter, by a slow gradual motion, change their place in respect of the external, a reasonable account may then be given of the four magnetical poles before mentioned, and also of the changes of the needle's variation.

The author thinks that two of these poles are fixed, and the other two moveable; viz, that the fixed poles are the poles of the external cortex or shell of the earth; and the other the poles of the magnetical nucleus, included and moveable within the former. From the observations he infers, that the motion is westward, and consequently that the nucleus has not precisely attained the same velocity with the exterior parts in their diurnal rotation; but so very nearly equals it, that in 365 revolutions the difference is scarcely sensible.

That there is any difference of this kind, arises from hence, that the impulse by which the diurnal motion was impressed on the earth, was given to the external parts, and from thence in time communicated to the internal; but so as not yet perfectly to equal the velocity of the first motion impressed on the superficial parts of the globe, and still preserved by them.

As to the precise period, observations are wanting to determine it, though the author thinks we may reasonably conjecture that the American pole has moved westward 46° in 90 years, and that its whole period is performed in about 700 years.

Mr. Whiston, in his New Laws of Magnetism, raises several objections against this theory. See MAGNETISM.

M. Euler too, the son of the celebrated mathematician of that name, has controverted and censured Dr. Halley's theory. He thinks, that two magnetic poles, placed on the surface of the earth, will sufficiently account for the variation: and he then endeavours to show, how we may determine the declination of the needle, at any time, and on every part of the globe, from this hypothesis.

Euler first examines the case in which the two magnetic poles are diametrically opposite; 2d, he places them in the two opposite meridians, but at unequal distances from the poles of the world; 3d, he places them in the same meridians; finally, he considers them situated in two different meridians. These four cases may become equally important; because if it is determined that there are only two magnetic poles, and that these poles change their situations, it may some time hereafter be discovered that they pass through all the different positions.

Since the needle of the compass ought always to be in the plane which passes through the place of observation and two magnetic poles, the problem is reduced to the discovery of the angle contained between this plane and the plane of the meridian. M. Euler, after having examined the different cases, finds that they also express the earth's magnetism, represented in the chart published by Messrs. Mountaine and Dodson in 1744, particularly throughout Europe and North America, if the following principles are established; viz, Between the arctic pole and the magnetic pole 14° 53';—between the antarctic pole and the other magnetic pole 29° 23';—the angle at the north pole, formed by the meridians passing through the two magnetic poles 53° 18';—The longitude of the meridian which passes over the northern magnetic pole 250'.

As the observations which have been collected, with regard to the variation, are for the most part loose and inaccurate, it is impossible to represent them all with precision; and the great variations observed in the Indian ocean seem to require, says Euler, that the first three quantities should be 14, 35, and 65 degrees.—See Cavallo's Treatise on Magnetism, pa. 117.

In the memoir of Messrs. Biot and Humboldt, "On the variations of the terrestrial magnetism in different latitudes," the position of the magnetic equator is determined from direct observations. The inclination of the plane of this circle to the astronomical equator, is stated to be 10° 58' 56", its occidental node on that equator being at 120° 2' 5" longitude west from Paris, the other node at 59° 57' 55" east of Paris. The points where the axis of the magnetic equator pierces the earth's surface, are, the northern point at 79° 1' 4" north lat. and 30° 2' 5" west long. from Paris; the southern point is situated in the same latitude south, and 149° 57' 55" east long. from Paris.

Variation of the Needle by Heat and Cold, otherwise called the *Diurnal* or *Daily Variation*.—There is a small variation of the variation of the magnetic needle, amounting only to a few minutes of a degree in the same place, at different hours of the same day, which is only discoverable by nice observations. Mr. George Graham made several observations of this kind in the years 1722 and 1723, professing himself altogether ignorant of the cause of the phenomena he observed. Philos. Trans. No. 383.

About the year 1750, Mr. Wargentin, secretary of the Swedish Academy of Sciences, took notice both of the regular diurnal variation of the needle, and also of its being disturbed at the time of the aurora borealis, as recorded in the Philos. Trans. vol. 47, pa. 126.

About the year 1756, Mr. Canton commenced a series of observations, amounting to near 4000, with an excellent variation-compass, of about 9 inches diameter. The number of days on which these observations were made, was 603, and the diurnal variation on 574 of them was regular, so as that the absolute variation of the needle westward was increasing from about 8 or 9 o'clock in the morning, till about 1 or 2 in the afternoon, when the needle became stationary for some time; after that, the absolute variation westward was decreasing, and the needle came back again to its former situation, or nearly so, in the night, or by the next morning. The diurnal variation is irregular when the needle moves slowly eastward in the latter part of the morning, or westward in the latter part of the afternoon; also when it moves much either way after night, or suddenly both ways in a short time. These irregularities seldom happen more than once or twice in a month, and are always accompanied, as far as Mr. Canton observed, with an aurora borealis.

Mr. Canton lays down and evinces, by experiment, the following principle, viz, that the attractive power of the magnet (whether natural or artificial) will decrease while the magnet is heating, and increase while it is cooling. He then proceeds to account for both the regular and irregular variation. It is evident, he says, that the magnetic parts of the earth in the north, on the east side and on the west side of the magnetic meridian, equally attract the north end of the needle. If then the eastern magnetic parts be heated faster by the sun in the morning, than the western parts, the needle will move westward, and the absolute variation will increase: when the attracting parts of the earth on each side of the magnetic meridian have their heat increasing equally, the needle will be stationary, and the absolute variation will then be greatest: but when the western magnetic parts are either heating faster or cooling slower than the eastern, the needle will move eastward, or the absolute variation will decrease; and when the eastern and western magnetic parts are cooling equally fast, the needle will again be stationary, and the absolute variation will then be a minimum.

By this theory, the diurnal variation in the summer ought to exceed that in winter; and accordingly it is found by observation, that the diurnal variation in the months of June and July is almost double of that in December and January.

The irregular diurnal variation must arise from some other cause than that of heat communicated by the sun; and here Mr. Canton has recourse to subterranean heat, which is generated without any regularity as to time, and which will, when it happens in the north, affect the attractive power of the magnetic parts of the earth on the north end of the needle. That the air nearest the earth will be most warmed by the heat of it, is obvious; and this has been often noticed in the morning, before day, by means of thermometers at different distances from the ground. Philos. Trans. vol. 48, pa. 526.

Mr. Canton has annexed to his paper on this subject, a complete year's observations; from which it appears, that the diurnal variation increases from January to June, and decreases from June to December. Philos. Trans. an. 1759, pa. 398. Abridg. vol. 11, pa. 421.

It has also been observed, that different needles, especially if touched with different loadstones, will differ a few minutes in their variation. See Poleni Epist. Phil. Trans. No. 421.

Dr. Lorimer (in the Supp. to Cavallo's Magnetism) adduces some ingenious observations on this subject. It must be allowed, says he, according to the observations of several ingenious gentlemen, that the collective magnetism of this earth arises from the magnetism of all the ferruginous bodies contained in it, and that the magnetic poles should therefore be considered as the centres of the powers of those magnetic substances. These poles must therefore change their places according as the magnetism of such substances is affected; and if with Mr. Canton we allow, that the general cause of the diurnal variation arises from the sun's heat in the forenoon and afternoon of the same day, it will naturally occur, that the same cause, being continued, may be sufficient to produce the general variation of the magnetic needle for any number of years. For we must consider, that ever since any attentive observations have been made on this subject, the natural direction of the magnetic needle in Europe has been constantly moving from east to west, and that in other parts of the world it has continued its motion with equal constancy.

As we must therefore admit, says Dr. Lorimer, that the heat in the different seasons depends chiefly on the sun, and that the months of July and August are commonly the hottest, while January and February are the coldest months of the year; and that the temperature of the other months falls into the respective intermediate degrees; so we must consider the influence of heat upon magnetism to operate in the like manner, viz, that for a short time it scarcely manifests itself; yet in the course of a century, the constancy and regularity of it becomes sufficiently apparent. It would therefore be idle to suppose, that such an influence could be derived from an uncertain or fortuitous cause. But if it be allowed to depend on the constancy of the sun's motion, and this appears to be a cause sufficient to explain the phenomena, we should (agreeably to Newton's first law of philosophizing) look no farther.

As we therefore consider, says he, the magnetic powers of the earth to be concentrated in the magnetic poles, and that there is a diurnal variation of the magnetic needle, these poles must perform a small diurnal revolution proportional to such variation, and return again to the same point nearly. Suppose then that the sun in his diurnal revolution passes along the northern tropic, or along any parallel of latitude between it and the equator; when he comes to that meridian in which the magnetic pole is situated, he will be much nearer to it, than in any other; and in the opposite meridian he will of course be the farthest from it. As the influence of the sun's heat will therefore act most powerfully at the least, and less forcibly at the greatest distance, the magnetic pole will consequently describe a figure something of the elliptical kind; and as it is well known that the greatest heat of the day is some time after the sun has passed the meridian, the longest axis of this elliptical figure will lie north-easterly in the northern, and south-easterly in the southern hemisphere. Again, as the influence of the sun's heat will not from those quarters have so much power, the magnetic poles cannot be moved back to the very same point from which they set out; but to one which will be a little more northerly and easterly, or more southerly and easterly, according to the hemispheres in which they are situated. The figures therefore which they describe, may more properly be termed elliptoidal spirals.

In this manner the variation of the magnetic needle in the northern hemisphere may be accounted for. But with respect to the southern hemisphere we must recollect, that though the lines of declination in the northern hemisphere have constantly moved from west to east, yet in the southern hemisphere, it is equally certain that they have moved from east to west, ever since any observations have been made on the subject. Hence then the lines of magnetic declination, or Halleyan curves, as they are now commonly called, appear to have a contrary motion in the southern hemisphere, to what they have in the northern; though both the magnetic poles of the earth move in the same direction, that is from west to east.

In the northern hemisphere there was a line of no variation, which had east variation on its eastern side, and west variation on its western side. This line evidently moved from west to east during the two last centuries; the lines of east variation moving before it, while the lines of west variation followed it with a proportional pace. These lines first passed the Azores or Western Islands, then the meridian of London, and after a certain number of years still later, they passed the meridian of Paris. But in the southern hemisphere there was another line of no variation, which had east variation on its western side, and west variation on its eastern; the lines of east variation moving before it, while those of the west variation followed it. This line of no variation first passed the Cape des Aiguilles, and then the Cape of Good Hope; the lines of 5°, 10°, 15°, and 20° west variation following it, the same as was the case in the northern hemisphere, but in the contrary direction.

We may just farther mention the idea of Dr. Gowin Knight, which was, that this earth had originally received its magnetism, or rather that its magnetical powers had been brought into action, by a shock, which entered near the southern tropic, and passed out at the northern one. His meaning appears to have been, that this was the course of the magnetic fluid, and that the magnetic poles were at first diametrically opposite to each other. Though, according to Mr. Canton's doctrine, they would not have long continued so; for from the intense heat of the sun in the torrid zone, according to the principles already explained, the north pole must have soon retired to the north-eastward, and the south pole to the south-eastward. It is also curious to observe, that on account of the southern hemisphere being colder upon the whole than the northern hemisphere, the magnetic poles would have moved with unequal pace: that is, the north magnetic pole would have moved farther in any given time to the north-east, than the south magnetic pole could have moved to the south-east. And, according to the opinions of the most ingenious authors on this subject, it is generally allowed, that at this time the north magnetic pole is considerably nearer to the north pole of the earth, than the south magnetic pole is to the south pole of the earth.

It may farther be added, that several ingenious sea officers are of opinion, that in the western parts of the English Channel the variation of the magnetic needle has already begun to decrease; having in no part of it ever amounted to 25°. There are however other persons who assert that the variation is still increasing in the Channel, and as far westward as the 15th degree of longitude and 51° of latitude, at which place they say that it amounts to about 30°.

Of the Variation Chart. Doctor Halley having collected a multitude of observations made on the variation of the needle in many parts of the world, was hence enabled to draw, on a Mercator's chart, certain lines, showing the variation of the compass in all those places over which they passed, in the year 1700, when he published the first chart of this kind, called the Variation Chart.

From the construction of this chart it appears, that the longitude of any of those places may be found by it, when the latitude and the variation in that place are known. Thus, having found the variation of the compass, draw a a parallel of latitude on the chart through the latitude found by observation; and the point where it cuts the curved line, whose variation is the same with that observed, will be the ship's place. A similar project of thus finding the longitude, from the known latitude and inclination or dip of the needle, was before proposed by Henry Bond, in his treatise entitled, The Longitude Found, printed in 1676.

This method however is attended with two considerable inconveniences: 1st, That wherever the variation lines run east and west, or nearly so, this way of finding the longitude becomes imperfect, as their intersection with the parallel of latitude must be very indefinite: and among all the trading parts of the world, this imperfection is at present found chiefly on the western coasts of Europe, between the latitudes of 45° and 53°; and on the eastern shores of North America, with some parts of the Western Ocean and Hudson's Bay, lying between the said shores: but for the other parts of the world, a variation chart may be attended with considerable benefit. However, the variation curves, when they run east and west, may sometimes be applied to good purpose in correcting the latitude, when meridian observations cannot be had, as it often happens on the northern coasts of America, in the Western Ocean, and about Newfoundland; for if the variation can be obtained exactly, then the east and west curve, answering to the variation in the chart, will show the latitude.

2dly, As the deviation of the magnetical meridian, from the true one, is subject to continual alteration, therefore a chart to which the variation lines are fitted for any year, must in time become useless, unless new lines, showing the state of the variation at that time, be drawn on the chart: but as the change in the variation is very slow, therefore new variation charts published every 7 or 8 years, will answer the purpose tolerably well. And thus it has happened that Halley's variation chart has become useless, for want of encouragement to renew it from time to time.

However, in the year 1744, Mr. William Mountaine and Mr. James Dodson published a new variation chart, adapted for that year, which was well received; and several instances of its great utility having been communicated to them, they fitted the variation lines anew for the year 1756, and in the following year published the 3d variation chart, and also presented to the Royal Society a curious paper concerning the variation of the magnetic needle, with a set of tables annexed, containing the result of upwards of 50 thousand observations, in six periodical reviews, from the year 1700 to 1756 inclusive, and adapted to every 5 degrees of latitude and longitude in the more frequented oceans; which paper and tables were printed in the Transactions for the year 1757.

From these tables of observations, such extraordinary and whimsical irregularities occur in the variation, that we cannot think it wholly under the direction of one general and uniform law; but rather conclude, with Dr. Knight, in the 87th prop. of his Treatise upon Attraction and Repulsion, that it is influenced by various and different magnetic attractions, perhaps occasioned by the heterogeous compositions in the great magnet, the earth.

Many other observations on the variation of the magnetic needle, are to be found in several volumes of the Philos. Trans. See particularly vol. 48, pa. 875; vol. 50, pa. 329; vol. 56, pa. 220; and vol. 61, pa. 422.

VARIATION *Compass.* See COMPASS.

VARIATION *of Curvature*, in Geometry, is used for that inequality or change which takes place in the curvature of all curves except the circle, by which their curvature is more or less in different parts of them. And this variation constitutes the quality of the curvature of any line.

Newton makes the index of the inequality, or variation of curvature, to be the ratio of the fluxion of the radius of curvature to the fluxion of the curve itself: and Maclaurin, to avoid the perplexity that different notions, connected with the same terms, occasion to learners, has adopted the same definition: but he suggests, that this ratio gives rather the variation of the ray of curvature, and that it might have been proper to have measured the variation of curvature rather by the ratio of the fluxion of the curvature itself to the fluxion of the curve; so that, the curvature being inversely as the radius of curvature, and consequently its fluxion as the fluxion of the radius itself directly, and the square of the radius inversely, its variation would have been directly as the measure of it according to Newton's definition, and inversely as the square of the radius of curvature.

According to this notion, it would have been measured by the angle of contact contained by the curve and circle of curvature, in the same manner as the curvature itself is measured by the angle of contact contained by the curve and tangent. The reason of this remark may appear from this example: The variation of curvature, according to Newton's explication, is uniform in the logarithmic spiral, the fluxion of the radius of curvature in this figure being always in the same ratio to the fluxion of the curve; and yet, while the spiral is produced, though its curvature decreases, it never vanishes; which must appear a strange paradox to those who do not attend to the import of Newton's definition. Newton's Method of Fluxions and Inf. Series, pa. 76. Maclaurin's Flux. art. 386. Philos. Trans. No. 468, pa. 342.

The variation of curvature at any point of a conic section, is always as the tangent of the angle contained by the diameter that passes through the point of contact, and the perpendicular to the curve at the same point, or to the angle formed by the diameter of the section and of the circle of curvature. Hence the variation of curvature vanishes at the extremities of either axis, and is greatest when the acute angle, contained by the diameter passing through the point of contact and the tangent, is least.

When the conic section is a parabola, the variation is as the tangent of the angle, contained by the right line drawn from the point of contact to the focus, and the perpendicular to the curve. See Curvature.

From Newton's definition may be derived practical rules for the variation of curvature, as follows:

1. Find the radius of curvature, or rather its fluxion; then divide this fluxion by the fluxion of the curve, and the quotient will give the variation of curvature; exterminating the fluxions when necessary, by the equation of the curve, or perhaps by expressing their ratio by help of the tangent, or ordinate, or subnormal, &c.

2. Since $\frac{\dot z^3}{-\dot x\ddot y}$, or $\frac{\dot z^3}{-\ddot y}$ (putting $\dot x = 1$) denotes the radius of curvature of any curve z, whose absciss is x, and ordinate y; if the fluxion of this be divided by $\dot z$, and $\dot z$ and $\ddot z$ be exterminated, the general value of the variation will come out $\frac{-3\dot y\ddot y^2 + \dddot y(1+\dot y^2)}{\ddot y^2}$; then substituting the values of $\dot y$, $\ddot y$, $\dddot y$ (found from the equation of the curve) into this quantity, it will give the variation sought.

Ex. Let the curve be the parabola, whose equation is $ax = y^2$. Here then $2y\dot y = a\dot x = a$, and $\dot y = \frac{a}{2y}$; hence $\ddot y = \frac{-a\dot y}{2yy} = \frac{-aa}{4y^3}$, and $\dddot y = \frac{3aa\dot y}{2y^4} = \frac{3a^3}{8y^5}$. Therefore $\frac{-3\dot y\ddot y^2 + \dddot y(1+\dot y^2)}{\ddot y^2} = -3\dot y + \dddot y \times \frac{1+\dot y^2}{\ddot y^2} = \frac{-3a}{2y} + \frac{3a^3}{8y^5} \times (1 + \frac{aa}{4yy}) \times \frac{16y^6}{a^4} = \frac{6y}{a}$, the variation sought. Emerson's Flux. pa. 228.

VARIGNON (Peter), a celebrated French mathematician and priest, was born at Caen in 1654, and died 1722, at 68 years of age. He was the son of an architect in middling circumstances, but had a college education, being intended for the church. An accident threw a copy of Euclid's Elements in his way, which gave him a strong turn to that kind of learning. The study of geometry led him to the works of Descartes on the same science, and there he was struck with that new light which has, from thence, spread over the world.

At this time the abbé St. Pierre, who studied philosophy in the same college, became acquainted with him. A taste in common for rational subjects, whether physics or metaphysics, and continual disputations, formed the bonds of their friendship. They were mutually serviceable to each other in their studies. The abbé, to enjoy Varignon's company with greater ease, lodged him with himself; thus, growing still more sensible of his merit, he resolved to give him a fortune, that he might fully pursue his genius, and improve his talents; and, out of only 18 hundred livres a year, which he had himself, he conferred 300 of them on Varignon.

The abbé, persuaded that he could not do better than go to Paris to study philosophy, settled there in 1686, with M. Varignon, in the suburbs of St. Jacques. There each studied in his own way; the abbé applying himself to the study of men, manners, and the principles of government; whilst Varignon was wholly occupied with the mathematics. In these solitary suburbs he formed a connection with many other learned men; as Duhamel, Duverney, Delahire, &c. Duverney often asked his assistance in those parts of anatomy connected with mechanics: they examined together the positions of the muscles, and their directions; hence Varignon learned a good deal of anatomy from Duverney, which he repaid by the application of mathematical reasoning to that subject.

At length, in 1687, Varignon made himself known to the public by a treatise on New Mechanics, dedicated to the Academy of Sciences. His thoughts on this subject were, in effect, quite new. He discovered truths, and laid open their sources. In this work, he demonstrated the necessity of an equilibrium, in such cases where it happens, though the cause of it is not exactly known. This discovery Varignon made by the theory of compound motions, and is what this essay chiefly treats upon.

This new treatise on mechanics was greatly admired by the mathematicians, and procured the author two considerable places, the one of geometrician in the Academy of Sciences, the other of professor of mathematics in the College of Mazarine, to which he was the first person raised.

Varignon catched eagerly at the science of infinitesimals as soon as it appeared in the world, and became one of its most early cultivators. When that sublime and beautiful method was attacked in the Academy itself (for it could not escape the fate of all innovations), he became one of its most zealous defenders, and in its favour he put a violence upon his natural character, which abhorred all contention. He sometimes lamented, that this dispute had interrupted him in his enquiries into the integral calculation so far, that it would be difficult for him to resume his disquisition where he had left it off. He sacrificed infinitesimals to the interest of infinitesimals, and gave up the pleasure and glory of making a farther progress in them when called upon by duty to undertake their defence.

All the printed volumes of the Academy bear witness to his application and industry. His works are never detached pieces, but complete theories of the laws of motion, central forces, and the resistance of mediums to moving bodies. In these he makes such use of his rules, that nothing escapes him that has any connection with the subject he treats.

Geometrical certainty is by no means incompatible with obscurity and confusion, and those are sometimes so great, that it is surprising a mathematician should not lose his way in so dark and perplexing a labyrinth. The works of M. Varignon never occasion this disagreeable surprise, he makes it his chief care to place every thing in the clearest light; he does not, like some great geniuses, consult his ease by declining to take the trouble of being methodical, a trouble much greater than that of composition itself; he does not endeavour to acquire a reputation for profoundness, by leaving a great deal to be guessed by the reader.

Though Varignon's constitution did not seem easy to be impaired, assiduity and constant application brought upon him a severe disease in 1705. Great abilities are generally dangerous to the possessors. He was six months in danger, and three years in a languid state, which proceeded from his spirits being almost entirely exhausted. He said that sometimes, when delirious with a fever, he thought himself in the midst of a forest, where all the leaves of the trees were covered with algebraical calculations. Condemned by his physicians, his friends, and himself, to lay aside all study, he could not, when alone in his chamber, avoid taking up a book of mathematics, which he hid as soon as he heard any person coming. He again resumed the attitude and behaviour of a sick man, and seldom had occasion to counterfeit. Our author recovered from his disease; but the remembrance of what he had suffered did not make him more prudent for the future.

With regard to his character, Fontenelle observes, that it was at this time that a writing of his appeared, in which he censured Dr. Wallis for having advanced that there are certain spaces more than infinite, which that great geometrician ascribes to hyperbolas. He maintained, on the contrary, that they were finite. The criticism was softened with all the politeness and respect imaginable; but a criticism it was, though he had written it only for himself. He let M. Carré see it, when he was in a state that rendered him indifferent about things of that kind; and that gentleman, influenced only by the interest of the sciences, caused it to be printed in the memoirs of the Academy of Sciences, unknown to the author, who thus made an attack against his inclination.

Notwithstanding his great desire of peace, in the latter part of his life he was involved in a dispute. An Italian monk, well versed in mathematics, attacked him on the subject of tangents and the angle of contact in curves, such as they are conceived in the arithmetic of infinites; he answered by the last memoir he ever gave to the Academy, and the only one which turned on a dispute.

In the last two years of his life he was attacked with an asthmatic complaint. This disorder increased daily, and all remedies were ineffectual. He did not however cease from any of his customary business; so that, after having finished his lecture at the College of Mazarine, on the 22d of December 1722, he died suddenly the following night.

His character, says Fontenelle, was as simple as his superior understanding could require. He was not apt to be jealous of the fame of others: indeed he was at the head of the French mathematicians, and one of the best in Europe. It must be owned however, that when a new idea was offered to him, he was too hasty to object. The fire of his genius, the various insights into every subject, made too impetuous an opposition to those that were offered; so that it was not easy to obtain from him a favourable attention.

His works that were published separately, were,

1. Projet d'une Nouvelle Mechanique; 4to, Paris 1687.
2. Des Nouvelles Conjectures sur la Pesanteur.
3. Nouvelle Mechanique ou Statique, 2 tom. 4to, 1725.
4. Un Traité du Mouvement & de la Mesure des Eaux Courantes &c. 1725, in 4to.
5. Eclaircissement sur l'Analyse des Infiniment Petits, in 4to.
6. Des Cahiers de Mathématiques, ou Elémens de Mathématiques; in 1731.
7. Une Demonstration de la Possibilité de la Présence réelle du Corps de Jesus Christ dans l'Eucharistie; in a collection entitled, Pièces Fugitives sur l'Eucharistie, published in 1730; an extraordinary thing for a mathematician to undertake to demonstrate; which he does, as might be expected, not mathematically, but sophistically.

As to his memoirs in the volumes of the Academy of Sciences, they are far too numerous to be here particularized; they extend through almost all the volumes, down to his death in 1722.

VASA *Concordiæ*, in Hydraulics, are two vessels, so constructed, as that one of them, though full of wine, will not run a drop, unless the other, being full of water, run also. Their structure and apparatus may be seen in Wolfius, Element. Mathes. tom. 3, Hydraul.

VAUBAN (Sebastian le Prestre), a very great French engineer, was born in 1633. He displayed great abilities and skill in many sieges, and his services were rewarded with the first military honours. He was made governor of Lisle, commissary-general of the fortifications of France, and afterwards governor of the maritime parts of Flanders, and a marshal of France. He died in 1707, having brought fortification to a degree of perfection unknown before. His writings on these subjects are still in very high esteem.

VAULT, in Architecture, an arched roof, so contrived, as that the several stones of which it consists, by their disposition into the form of a curve, mutually sustain each other; as the arches of bridges, &c.

Vaults are to be preferred, on many occasions, to soffits, or flat ceilings, as they give a greater rise and elevation, and are also more firm and durable.

The ancients, Salmasius observes, had only three kinds of vaults: the first the fornix, made cradle-wise; the 2d, the testudo, tortoise-wise, or oven-wise; the 3d, the concha, made shell-wise. But the moderns subdivide these three kinds into a great many more, to which they give different names, according to their figures and use: some are circular, others elliptical, &c.

Again, the sweeps of some are larger, and others less portions of a sphere: all above hemispheres are called high, or surmounted vaults; all that are less than hemispheres, are low, or surbased vaults, &c.—In some the height is greater than the diameter; in others it is less: there are others again quite flat, only made with haunses; others oven-like, and others growing wider as they lengthen, like a trumpet.

Vaults are either single, double, cross, diagonal, horizontal, ascending, descending, angular, oblique, pendent, &c, &c. There are also Gothic vaults, with pendentives, &c.

Master VAULTS, are those which cover the principal parts of buildings; in contradistinction from the less, or subordinate vaults, which only cover some small part; as a passage, a gate, &c.

Double VAULT, is such a one as, being built over another, to make the exterior decoration range with the interior, leaves a space between the convexity of the one and the concavity of the other; as in the dome of St. Paul's at London, and that of St. Peter's at Rome.

VAULTS *with Compartiments*, are such whose sweep, or inner face, is enriched with pannels of sculpture, separated by platbands. These compartiments, which are of different figures, according to the vaults, and are usually gilt on a white ground, are made with stucco, on brick vaults; as in the church of St. Peter's at Rome; and with plaster, on timber vaults.

Theory of VAULTS—In a semicircular vault, or arch, being a hollow cylinder cut by a plane through its axis, standing on two imposts, and all the stones that compose it being cut and placed in such a manner, as that their joints, or beds, being prolonged, do all meet in the centre of the vault; it is evident that all the stones must be cut wedge-wise, or wider at top and above, than below; by virtue of which, they sustain each other, and mutually oppose the effort of their weight, which determines them to fall.

The stone in the middle of the vault, which is perpendicular to the horizon, and is called the key of the vault, is sustained on each side by the two contiguous stones, as by two inclined planes. The second stone, which is on the right or left of the key-stone, is sustained by a third; which, by virtue of the figure of the vault, is necessarily more inclined to the second, than the second is to the first; and consequently the second, in the effort it makes to fall, employs a less part of its weight than the first. For the same reason, all the stones, reckoning from the keystone, employ still a less and less part of their weight, to the last; which, resting on the horizontal plane, employs no part of its weight, or makes no effort to fall, as being entirely supported by the impost.

Now a great point to be aimed at in vaults, is, that all the several stones make an equal effort to fall: to effect this, it is evident that as each stone, reckoning from the key to the impost, employs a still less and less part of its whole weight; the first only employing, for example, one-half; the 2d, one-third; the 3d, one-fourth; &c; there is no other way to make these different parts equal, but by a proportionable augmentation of the whole; that is, the second stone must be heavier than the first, the third heavier than the second, and so on to the last, which should be vastly heavier.

Lahire demonstrates what that proportion is, in which the weights of the stones of a semicircular arch must be increased, to be in equilibrio, or to tend with equal forces to fall; which gives the firmest disposition that a vault can have. Before him, the architects had no certain rule to conduct themselves by; but did all at random. Reckoning the degrees of the quadrant of the circle, from the keystone to the impost, the length or weight of each stone must be so much greater, as it is farther from the key. Lahire's rule is, to augment the weight of each stone above that of the keystone, as much as the tangent of the arch to the stone exceeds the tangent of the arch of half the key. Now the tangent of the last stone becomes infinite, and consequently the weight should be so too; but as infinity has no place in practice, the rule amounts to this, that the last stone be loaded as much as possible, and the others in proportion, that they may the better resist the effort which the vault makes to separate them; which is called the shoot or drift of the vault.

M. Parent, and other authors, have since determined the curve, or figure, which the extrados or outside of a vault, whose intrados or inside is spherical, ought to have, that all the stones may be in equilibrio.

The above rule of Lahire's has since been found not accurate. See ARCH, and BRIDGE. See also my Treatise on the Principles of Bridges in my Tracts, and Emerson's Construction of Arches; also M. Berard's Statique des Voutes.

Key of a VAULT. See KEY, and VOUSSOIR.

Reins or *Fillings up of a* VAULT, are the sides which sustain it.

Pendentive of a VAULT. See PENDENTIVE.

Impost of a VAULT, is the stone upon which is laid the first voussoir, or arch-stone of the vault.

VEADAR, in Chronology, the 13th month of the Jewish ecclesiastical year, answering commonly to our March; this month is intercalated, to prevent the beginning of Nisan from being removed to the end of February.

VECTIS, in Mechanics, one of the simple mechanical powers, more usually called the Lever.

VECTOR, or *Radius Vector*, in Astronomy, is a line conceived to be drawn from any planet moving round a centre, or the focus of an ellipse, to that centre, or focus. It is so called, because it is that line by which the planet seems to be carried round its centre; and with which it describes areas proportional to the times.

VELOCITY, *Celerity*, or *Swiftness*, in Mechanics, is that affection of motion, by which a moving body passes over a certain space in a certain time. This is always proportional to the space moved over in a given time, when the velocity is uniform, or always the same during that time.

Velocity is either uniform or variable. Uniform, or equal velocity, is that with which a body passes over equal spaces in equal times. And it is variable, or unequal, when the spaces passed over in equal times are unequal; in which case it is either accelerated or retarded velocity; and this acceleration, or retardation, may also be equal or unequal, i.e. uniform or variable, &c. See ACCELERATION, and MOTION.

Velocity is also either absolute or relative. Absolute velocity is that we have hitherto been considering, in which the velocity of a body is considered simply in itself, or as passing over a certain space in a certain time. But relative or respective velocity, is that with which bodies approach to, or recede from one another, whether they both move, or one of them be at rest. Thus, if one body move with the absolute velocity of 2 feet per second, and another with that of 6 feet per second; then if they move directly towards each other, the relative velocity with which they approach is that of 8 feet per second; but if they move both the same way, so that the latter overtake the former, then the relative velocity with which that overtakes it, is only that of 4 feet per second, or only half of the former; and consequently it will require double the time of the former before they come in contact together.

VELOCITY *in a Right Line.*—When a body moves with a uniform velocity, the spaces passed over by it, in different times, are proportional to the times; also the spaces described by two different uniform velocities, in the same time, are proportional to the velocities; and consequently, when both times and velocities are unequal, the spaces described are in the compound ratio of the times and velocities. That is, $S \propto TV$, and $s \propto tv$; or $S : s :: TV : tv$. Hence also, $V : v :: \frac{S}{T} : \frac{s}{t}$, or the velocity is as the space directly and the time reciprocally.

But in uniformly accelerated motions; the last degree of velocity uniformly gained by a body in beginning from rest, is proportional to the time; and the space described from the beginning of the motion, is as the product of the time and velocity, or as the square of the velocity, or as the square of the time. That is, in uniformly accelerated motions, $v \propto t$, and $s \propto tv$ or $\propto v^2$ or $\propto t^2$. And, in fluxions, $\dot{s} = v\dot{t}$.

VELOCITY *of Bodies moving in Curves.*—According to Galileo's system of the descent of heavy bodies, which is now universally admitted among philosophers, the velocities of a body falling vertically are, at each moment of its fall, as the square roots of the heights from whence it has fallen; reckoning from the beginning of the descent. Hence he inferred, that if a body descend along an inclined plane, the velocities acquired at different times, will be in the same ratio: for since its velocity is all owing to its fall, and it only falls as much as there is perpendicular height in the inclined plane, the velocity should be still measured by that height, the same as if the descent were vertical.

The same principle led him also to conclude, that if a body fall through several contiguous inclined planes, making any angles with each other, much like a stick when broken, the velocity would still be regulated after the same manner, by the vertical heights of the different planes taken together, considering the last velocity as the same that the body would acquire by descending through the same perpendicular height.

This conclusion, it seems, continued to be acquiesced in, till the year 1672, when it was demonstrated to be false, by James Gregory, in a small piece of his, intitled Tentamina quædam Geometrica de Motu Penduli et Projectorum. This piece has been very little known, because it was only added to the end of an obscure and pseudonymous piece of his, then published, to expose the errors and vanity of Mr. Sinclar, professor of natural philosophy at Glasgow. This little jeu d'esprit of Gregory is entitled, "The great and new Art of Weighing Vanity: or a discovery of the Ignorance and Arrogance of the great and new Artist, in his Pseudo-Philosophical writings: by M. Patrick Mathers, Arch-Bedal to the University of St. Andrews." In the Tentamina, Gregory shows what the real velocity is, which a body acquires by descending down two contiguous inclined planes, forming an obtuse angle, and that it is different from the velocity a body acquires by descending perpendicularly through the same height; also that the velocity on quitting the first plane, is to that with which it enters the second, and in this latter direction, as radius to the cosine of the angle of inclination between the two planes.

This conclusion, however, Gregory observes, does not apply to the motions of descent down any curve lines, because the contiguous parts of curve lines do not form any angle between them, and consequently no part of the velocity is lost by passing from one part of the curve to the other; hence he infers, that the velocities acquired in descending down a continued curve line, are the same as by falling perpendicularly through the same height. This principle is then applied, by the author, to the motion of pendulums and projectiles.

Varignon too, in the year 1693, followed in the same track, showing that the velocity lost in passing from one right lined direction to another, becomes indefinitely small in the course of a curve line; and that therefore the doctrine of Galileo holds good for the descent of bodies down a curve line, viz, that the velocity at any point of the curve, is equal to that which would be acquired by falling through the same perpendicular altitude.

The nature of every curve is abundantly determined by the ratio of the ordinates to the corresponding abscisses; and the essence of curves in general may be conceived as consisting in this ratio, which may be varied in a thousand different ways. But this same ratio will be also that of two simple velocities, by whose joint effect a body may describe the curve in question; and consequently the essence of all curves, in general, is the same thing as the concourse or combination of all the forces which, taken two by two, may move the same body. Thus we have a most simple and general equation of all possible curves, and of all possible velocities. By means of this equation, as soon as the two simple velocities of a body are known, the curve resulting from them is immediately determined.

It may be observed, in particular, according to this equation, that an uniform velocity, combined with a velocity that always varies as the square roots of the heights, will produce the particular curve of a parabola, independent of the angle made by the directions of the two forces that give the velocities; and consequently a cannon ball, projected either horizontally or obliquely to the horizon, must always describe a parabola, were it not for the resistance of the air.

Circular VELOCITY. See CIRCULAR.

Initial VELOCITY, in Gunnery, denotes the velocity with which military projectiles issue from the mouth of the piece by which they are discharged. This, it is now known, is much more considerable than was formerly apprehended. For the method of estimating it, and the result of a variety of experiments, by Mr. Robins, and myself, &c, see the articles GUN, GUNNERY, PROJECTILE, RESISTANCE, and my Tracts, vols. 2 and 3.

Mr. Robins had hinted in his New Principles of Gunnery, at another method of measuring the initial velocities of military projectiles, viz, from the arc of vibration of the gun itself, in the act of expulsion, when it is suspended by an axis like a pendulum. And Mr. Thompson, in his experiments (Philos. Trans. vol. 71, pa. 229), has pursued the same idea at considerable length, in a number of experiments, from which he deduces a rule for computing the velocity, which is somewhat different from that of Mr. Robins, but which agrees very well with his own experiments.

This rule however being drawn only from the experiments with a musket barrel, and with a small charge of powder, and besides being different from that in the theory as proposed by Robins; it was suspected that it would not obtain when applied to cannon, or other large pieces of ordnance, of different and various lengths, and to larger charges of powder. For this reason, a great number of experiments, as related in my Tracts, were instituted with cannon of various lengths, and charged with many different quantities of powder; and the initial velocities of the shot were computed both from the vibration of a ballistic pendulum, and from the vibration of the gun itself; but the consequence was, that these two hardly ever agreed together, and in many cases they differed by almost 400 feet per second in the velocity. A brief abstract for a comparison between these two methods, is contained in the following tablet, viz,

Comparison of the Velocities by the Gun and Pendulum.

Gun. No.	2 Ounces.			4 Ounces.			8 Ounces.			16 Ounces.		
	Velocity by		Diff.	Velocity by		Diff.	Velocity by		Diff.	Velocity by		Diff.
	Gun.	Pend.		Gun.	Pend.		Gun.	Pend.		Gun.	Pend.	
1	830	780	50	1135	1100	35	1445	1430	15	1345	1377	−32
2	863	835	28	1203	1180	23	1521	1580	−59	1485	1656	−171
3	919	920	−1	1294	1300	−6	1631	1790	−159	1680	1998	−318
4	929	970	−41	1317	1370	−53	1669	1940	−271	1730	2106	−376

In this table, the first column shows the number of the gun, as they were of different lengths; viz, the length of number 1 was $30\frac{1}{5}$ inches, number 2 was $40\frac{1}{5}$ inches, number 3 was 60 inches, and number 4 was 83 inches, nearly. After the first column, the rest of the table is divided into four spaces, for the four charges, 2, 4, 8, 16 ounces of powder: and each of these is divided into three columns, in the first of the three is the velocity of the ball as determined from the vibration of the gun; in the second is the velocity as determined from the vibration of the pendulum; and in the third is the difference between the two, being so many feet per second, which is marked with the negative sign, or −, when the former velocity is too little, otherwise it is positive.

From the comparison contained in this table, it appears, in general, that the velocities, determined by the two different methods, do not agree together; and that therefore the method of determining the velocity of the ball from the recoil of the gun, is not generally true, though Mr. Robins and Mr. Thompson had suspected it to be so: and consequently that the effect of the inflamed powder on the recoil of the gun, is not exactly the same when it is fired without a ball, as when it is fired with one. It also appears, that this difference is no ways regular, neither in the different guns with the same charge of powder, nor in the same gun with different charges: that with very small charges, the velocity by the gun is greater than that by the pendulum; but that the latter always gains upon the former, as the charge is increased, and soon becomes equal to it; afterwards it proceeds to exceed it more and more: that the particular charge, at which the two velocities become equal, is different in the different guns; and that this charge is less, or the equality sooner takes place, as the gun is longer. And all this, whether we use the actual velocity with which the ball strikes the pendulum, or the same increased by the velocity lost by the resistance of the air, in its flight from the gun to the pendulum.

Virtual VELOCITY. See VIRTUAL *Velocity*.

VENA CONTRACTA, a term employed by Sir Isaac Newton to denote that section of a stream of fluid issuing from an orifice in the side or bottom of a vessel, at the distance of its diameter from the orifice. When a fluid issues from a vessel, the velocity through the orifice does not arise from a continual acceleration of descending particles by the force of gravity, as in the case of a body falling freely, but it is communicated by the whole pressure of the surrounding fluid; in consequence of which, the water rushing towards the orifice in all directions causes a contraction in the stream; and at a distance from the orifice equal to its diameter. Sir Isaac Newton measured the diameter of the section of the stream (which section he called by the above name), and found it to be to the diameter of the orifice as 21 to 25: hence, the area of the orifice: the area of the vena contracta (they being supposed to be similar) $: : 25^2 : 21^2$, which is very nearly as $\sqrt{2} : 1$; and as the velocity is inversely as the area of the section, the velocity at the vena contracta: the velocity at the orifice $: : \sqrt{2} : 1$. Also from the quantity of water, running out in a given time, and the area of the vena contracta, Sir Isaac also determined that the velocity at the vena contracta is that which a body acquires in falling down the altitude of the fluid above the orifice: hence the velocity at the orifice (being less than that at the vena contracta in the ratio of $\sqrt{2} : 1$) is that which a body would acquire in falling down half the altitude. See the art. WATER, *Motion of*.

VENTILATOR, a machine by which the noxious air of any close place, as an hospital, gaol, ship, chamber, &c, may be discharged and changed for fresh air.—The noxious qualities of bad air have been long known; and Dr. Hales and others have taken great pains to point out the mischiefs arising from foul air, and to prevent or remedy them. That philosopher proposed an easy and effectual one, by the use of his ventilators; the account of which was read before the Royal Society in May 1741; and a farther account of it may be seen in his Description of Ventilators, printed at London in 8vo, 1743; and still farther in part 2, pa. 32, printed in 1758; where the uses and applications of them are pointed out for ships, and prisons, &c. For what is said of the foul air of ships may be applied to that of gaols, mines, workhouses, hospitals, barracks, &c. In mines, ventilators may guard against the suffocations, and other terrible accidents arising from damps. The air of gaols has often proved infectious;

and we had a fatal proof of this, by the accident that happened some years since at the Old Bailey sessions. After that, ventilators were used in the prison, which were worked by a small windmill, placed on the top of Newgate; and the prison became more healthy.

Dr. Hales farther suggests, that ventilators might be of use in making salt; for which purpose there should be a stream of water to work them; or they might be worked by a windmill, and the brine should be in long narrow canals, covered with boards of canvas, about a foot above the surface of the brine, to confine the stream of air, so as to make it act on the surface of the brine, and carry off the water in vapours. Thus it might be reduced to a dry salt, with a saving of fuel, in winter and summer, or in rainy weather, or any state of the air whatever. Ventilators, he apprehends, might also serve for drying linen hung in low, long, narrow galleries, especially in damp or rainy weather, and also in drying woollen cloths, after they are fulled or dyed; and in this case, the ventilators might be worked by the fulling water-mill. Ventilators might also be a useful appendage to malt and hop kilns; and the same author is farther of opinion, that a ventilation of warm dry air from the adjoining stove, with a cautious hand, might be of service to trees and plants in greenhouses; where it is well known that air full of the rancid vapours which perspire from the plants, is very unfavourable to them, as well as the vapours from human bodies are to men: for fresh air is as necessary to the healthy state of vegetables, as it is to that of animals.—Ventilators are also of excellent use for drying corn, hops, and malt. —Gunpowder may be thoroughly dried, by blowing air up through it by means of ventilators; which is of great advantage to the strength of it. These ventilators, even the smaller ones, will also serve to purify most easily and effectually, the bad air of a ship's well, before a person is sent down into it, by blowing air through a trunk, reaching nearly to its bottom. And in a similar manner may stinking water, and ill-tasted milk, &c, be sweetened, viz, by passing a current of air through them, from bottom to top, which will carry the offensive particles along with it.

For these and other uses to which they might be applied, as well as for a particular account of the construction and disposition of ventilators in ships, hospitals, prisons, &c, and the benefits attending them, see Hales's Treatise on Ventilators, part 2 passim; and the Philos. Trans. vol. 49, pa. 332.

The method of drawing off air from ships by means of fire-pipes, which some have preferred to ventilators, was published by sir Robert Moray in the Philos. Trans. for 1665. These are metal pipes, about $2\frac{1}{2}$ inches diameter, one of which reaches from the fire-place to the well of the ship, and other three branches go to other parts of the ship; the stove hole and ash hole being closed up, the fire is supplied with air through these pipes. The defects of these, compared with ventilators, are particularly examined by Dr. Hales, ubi supra, pa. 113.

In the latter part of the year 1741, M. Triewald, military architect to the king of Sweden, informed the secretary to the Royal Society, that he had in the preceding spring invented a machine for the use of ships of war, to draw out the foul air from under their decks, which exhausted 36172 cubic feet of air in an hour, or at the rate of 21732 tuns in 24 hours. In 1742 he sent one of these to France, which was approved of by the Academy of Sciences at Paris, and the navy of France was ordered to be furnished with the like ventilators.

Mr. Erasmus King proposed to have ventilators worked by the fire engines, in mines. And Mr. Fitzgerald has suggested an improved method of doing this, which he has also illustrated by figures. See Philos. Trans. vol. 50, pa. 727.

There are various ways of ventilation, or changing the air of rooms. Mr. Tidd contrived to admit fresh air into a room, by taking out the middle upper sash pane of glass, and fixing in its place a frame box, with a round hole in its middle, about 6 or 7 inches diameter; in which holes are fixed, behind each other, a set of sails of very thin broad copper-plates, which spread over and cover the circular hole, so as to make the air which enters the room, and turning round these sails, to spread round in thin sheets sideways; and so not to incommode persons, by blowing directly upon them, as it would do if it were not hindered by the sails.

This method however is very unseemly and disagreeable in good rooms; and therefore, instead of it, the late ingenious Mr. John Whitehurst substituted another; which was, to open a small square or rectanglar hole in the party wall of the room, in the upper part near the cieling, at a corner or part distant from the fire; and before it he placed a thin piece of metal or pasteboard, &c, attached to the wall in its lower part just below the hole, but declining from it upwards, so as to give the air, that enters by the hole, a direction upwards against the cieling, along which it sweeps and disperses itself through the room, without blowing in a current against any person. This method is very useful to cure smoky chimneys, by thus admitting conveniently fresh air. A picture placed before the hole prevents the sight of it from disfiguring the room. This, and many other methods of ventilating, he meant to have published, and was occupied on, when death put an end to his useful labours. These have since been published, viz in 1794, 4to, by Dr. Willan.

VENUS, in Astronomy, one of the inferior planets, but the brightest, and to appearance the largest, of all the planets; and is designed by the mark ♀, supposed to be a rude representation of a female figure, with her trailing robe. Venus is easily distinguished from all the other planets, by her whiteness and brightness, in which she exceeds all the rest, even Jupiter himself, and which is so considerable, that in a dusky place she causes an object to project a sensible shadow, and she is often visible in the day-time. Her place in the system is the second from the sun, viz, between Mercury and the earth, and in magnitude is about equal to the earth, or rather a little larger according to Dr. Herschel's observations.

As Venus moves round the sun, in a circle beneath that of the earth, she is never seen in opposition to him, nor indeed very far from him; but seems to move backward and forward, passing him from side to side, to the distance of about 47 or 48 degrees, both ways, which is her greatest elongation. When she appears west of the sun, which is from her inferior conjunction to her superior, she rises before him, or is a morning star, and is called Phosphorus, or Lucifer, or the Morning Star; and when she is eastwards from the sun, which is from her superior conjunction to her inferior, she sets after him, or is an evening star, and is then called Hesperus, or Vesper, or the Evening Star: being each of those in its turn for 290 days.

The real diameter of Venus is nearly equal to that of the earth, being about 7900 miles; her apparent mean diameter seen from the sun, or her horizontal parallax, 30″; but as seen from the earth 18″·79 according to Dr. Herschel, or 16″·7 by M. Lalande; her distance from the sun 68 million of miles; her eccentricity $\frac{1}{141}$ths of the same, or 490,000 miles; the inclination of her orbit to the plane of the ecliptic 3° 23′; the points of their intersection or nodes are 14° of ♊ and ♐; the place of her aphelion = 10° 18′; her axis inclined to her orbit 75° 0′; her periodical course round the sun 224 days 17 hours; the diurnal rotation about her axis very uncertain, being according to Cassini only 23 hours, but according to the observations of Bianchini it is in 24 days 8 hours; though Dr. Herschel thinks it cannot be so much; and by M. Schroeter 23h. 21min. See also PLANETS.

Venus, when viewed through a telescope, is rarely seen to shine with a full face, but has phases and changes just like those of the moon, being increasing, decreasing, horned, gibbous, &c: her illuminated part being constantly turned toward the sun, or directed toward the east when she is a morning star, and toward the west when an evening star. These different phases of Venus were first discovered by Galileo; who thus fulfilled the prediction of Copernicus: for when this excellent astronomer revived the ancient Pythagorean system, asserting that the earth and planets move round the sun, it was objected that in such a case the phases of Venus should resemble those of the moon; to which Copernicus replied, that some time or other that resemblance would be found out. Galileo sent an account of the first discovery of these phases in a letter, written from Florence in 1611, to William de Medici, the duke of Tuscany's ambassador at Prague; desiring him to communicate it to Kepler. The letter is extant in the preface to Kepler's Dioptrics, and a translation of it in Smith's Optics, pa. 416. Having recited the observations he had made, he adds, "We have hence the most certain, sensible decision and demonstration of two grand questions, which to this day have been doubtful and disputed among the greatest masters of reason in the world. One is, that the planets in their own nature are opake bodies, attributing to Mercury what we have seen in Venus: and the other is, that Venus necessarily moves round the sun; as also Mercury and the other planets; a thing well believed indeed by Pythagoras, Copernicus, Kepler, and myself, but never yet proved, as now it is, by ocular inspection on Venus."

Cassini and Campani, in the years 1665 and 1666, both discovered spots in the face of Venus: from the appearances of which the former ascertained her motion about her axis; concluding that this revolution was performed in less than a day; or at least that the bright spot which he observed, finished its period either by revolution or libration in about 23 hours. And Lahire, in 1790, through a telescope of 16 feet, observed spots also in Venus; which he found to be larger than those in the moon.

The next observations of the same kind that occur, are those of signior Bianchini at Rome, in 1726, 1727, 1728, who, with Campani's glasses, discovered several dark spots in the disk of Venus, of which he gave an account and a representation in his book entitled Hesperi et Phosphori Nova Phenomena, published at Rome in 1728. From several successive observations Bianchini concludes, that a rotation of Venus about her axis was not completed in 23 hours, as Cassini imagined, but in 24⅓ days; that the north pole of this rotation faced the 20th degree of Aquarius, and was elevated 15 above the plane of the ecliptic, and that the axis kept parallel to itself, during the planet's revolution about the sun. Cassini the son, though he admits the accuracy of Bianchini's observations, disputes the conclusion drawn from them, and finally observes, that if we suppose the period of the rotation of Venus to be 23h. 20min. it agrees equally well with the observations both of his father and Bianchini; but if she revolve in 24d. 8h. then his father's observations must be rejected as of no consequence.

In the Philos. Trans. 1792, are published the results of a course of observations on the planet Venus, begun in the year 1780, by M. Schroeter, of Lilienthal, Bremen. From these observations, the author infers, that Venus has an atmosphere in some respects similar to that of our earth, but far exceeding that of the moon in density, or power to weaken the rays of the sun: that the diurnal period of this planet is probably much longer than that of other planets: that the moon also has an atmosphere, though less dense and high than that of Venus: and that the mountains of this planet are 5 or 6 times as high as those on the earth.

Dr. Herschel too, between the years 1777 and 1793, has made a long series of observations on this planet, accounts of which are given in the Philos. Trans. for 1793. The results of these observations are: that the planet revolves about its axis, but the time of it is uncertain: that the position of its axis is also very uncertain: that the planet's atmosphere is very considerable: that the planet has probably hills and inequalities on its surface, but he has not been able to see much of them, owing perhaps to the great density of its atmosphere: as to the mountains of Venus, no eye, he says, which is not considerably better than his, or assisted by much better instruments, will ever get a sight of them: and that the apparent diameter of Venus, at the mean distance from the earth, is 18″·79; whence it may be inferred, that this planet is somewhat larger than the earth, instead of being less, as former astronomers have imagined.

Sometimes Venus is seen in the disk of the sun, in form of a dark round spot. These appearances, called transits, happen but seldom, viz, when the earth is about her nodes at the time of her inferior conjunction. One of these transits was seen in England in 1639 by Mr. Horrox and Mr. Crabtree; and two in the last century, viz, the one June 6, 1761, and the other in June 1769. There will not happen another of them till the year 1874. See PARALLAX. Except such transits as these, Venus exhibits the same appearances to us regularly every 8 years; her conjunctions, elongations, and times of rising and setting, being very nearly the same, on the same days, as before.

In 1672 and 1686, Cassini, with a telescope of 34 feet, thought he saw a satellite move round this planet, at the distance of about ⅗ of Venus's diameter. It had the same phases as Venus, but without any well-defined form; and its diameter scarce exceeded ¼ of the diameter of Venus. Dr. Gregory (Astron. lib. 6, prop. 5) thinks it more than probable that this was a satellite; and supposes that the reason why it is not more frequently seen, is the unfitness of its surface to reflect the rays of the sun's light; as is the case of the spots in the moon; for if the whole disk of the moon were composed of such, he thinks she could not be seen so far as to Venus.

Mr. Short, in 1740, with a reflecting telescope of 16½ inches focus, perceived a small star near Venus: with another telescope of the same focus, magnifying 50 or 60 times, and fitted with a micrometer, he found its distance from Venus about 10′; and with a magnifying power of 240, he observed the star assume the same phases with Venus; its diameter seemed to be about ¼, or somewhat less, of the diameter of Venus; its light not so bright and vivid, but exceeding sharp and well defined. He viewed it for the space of an hour; but never had the good fortune to see it after the first morning. Philos. Trans. No. 459. pa. 646.

M. Montaign, of Limoges in France, preparing for observing the transit of 1761, discovered in the preceding month of May a small star, about the distance of 20′ from Venus, the diameter of it being about ¼ of that of the planet. Others have also thought they saw a like appearance. And indeed it must be acknowledged, that Venus may have a satellite, though it be difficult for us to see it. Its enlightened side can never be fully turned towards us, but when Venus is beyond the sun; in which case Venus herself appears little larger than an ordinary star, and therefore her satellite may be too small to be perceived at such a distance. When she is between us and the sun, her moon has its dark side turned towards us; and when Venus is at her greatest elongation, there is but half the enlightened side of the moon turned toward us, and even then it may be too far distant to be seen by us. But it was presumed, that the two transits of 1761, and 1769, would afford opportunity for determining this point; and yet we do not find, though many observers directed their attention to this object, that any satellite was then seen in the sun's disk; unless we except two persons, viz, an anonymous writer in the London Chronicle of May 18, who says that he saw the satellite of Venus on the sun the day of the transit, at St. Neot's in Huntingdonshire; that it moved in a track parallel to that of Venus, but nearer the ecliptic; that Venus quitted the sun's disk at 31 minutes after 8, and the satellite at 6 minutes after 9; and M. Montaign at Limoges, whose account of his observations is in the Memoirs of the Academy of Paris, whence the following certificate is extracted:—Certificate. "We having examined, by order of the Academy, the remarks of M. Baudouin on a new observation of the satellite of Venus, made at Limoges the 11th of May by M. Montaign. This fourth observation, of great importance for the theory of the satellite, has shown that its revolution must be longer than appeared by the first three observations. M. Baudouin believes it may be fixed at 12 days; as to its distance, it appears to him to be 50 semidiameters of Venus; whence he infers that the mass of Venus is equal to that of the earth. This mass of Venus is a very essential element to astronomy, as it enters into many computations, and produces different phenomena: &c.

Signed L'Abbé De La Caille,
De La Lande."

VERBERATION, in Physics, a term used to express the cause of sound, which arises from a verberation of the air, when struck, in divers manners, by the several parts of the sonorous body first put into a vibratory motion.

VERNAL, something belonging to the spring season: as vernal signs, vernal equinox, &c.

VERNIER, is a scale, or a division, well adapted for the graduation of mathematical instruments, so called from its inventor Peter Vernier, a gentleman of Franche Comté, who published the discovery in a small tract, entitled La Construction, l'Usage, et les Proprietez du Quadrant Nouveau de Mathematique &c, printed at Brussels in 1631. This was an improvement on the method of division proposed by Jacobus Curtius, printed by Tycho in Clavius's Astrolabe, in 1593. Vernier's method of division, or dividing plate, has been very commonly, though erroneously, called by the name of Nonius; the method of Nonius being very different from that of Vernier, and much less convenient.

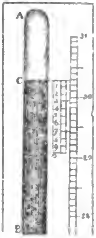
When the relative unit of any line is so divided into many small equal parts, those parts may be too numerous to be introduced, or if introduced, they may be too close to one another to be readily counted or estimated; for which reason there have been various methods contrived for estimating the aliquot parts of the small divisions, into which the relative unit of a line may be commodiously divided; and among those methods, Vernier's has been most justly preferred to all others. For a curious history of this, and other inventions of a similar nature, see Robins's Math. Tracts, vol. 2, pa. 265, &c.

This improved method of subdividing scaler divisions, was first published by Peter Vernier, a person of distinction in Franche Comté, in a very small tract, entitled, The Construction, the Use, and the Properties of a New Mathematical Quadrant, &c. In his dedication, having shown its preference to what has been done in the affair by Nunez and Clavius, he adds, Mine having all these advantages over the others, it is not without reason that I call it new and of my own invention.

In the preface also he claims it as his own invention, and says, by it a quadrant of 3 inches is rendered capable of determining minutes. In his book he shows how to apply it to instruments of different dimensions. His contrivance is a moveable arch divided into equal parts, one *less* in number than the divisions of the portion of the limb corresponding to it.

Vernier's scale then, is a small moveable arch, or scale, sliding along the limb of a quadrant, or any other graduated scale, and divided into equal parts, that are one less in number, than the divisions of the portion of the limb corresponding to it. So, if we want to subdivide the graduations on any scale into (for ex.) 10 equal parts; we must make the vernier equal in length to 11 of those graduations of the scale, but dividing the same length of the vernier itself only into 10 equal parts; for then it is evident that each division on the vernier will be $\frac{1}{10}$th part longer than the gradations on the instrument, or that the division of the former is equal to $\frac{1}{10}$ of the degree on the latter, as that gains 1 in 10 upon this.

Thus let AB be a part of the upper end of a barometer tube, the quicksilver standing at the point C; from 28 to 31 is a part of the scale of inches, viz, from 28 inches to 31 inches, divided into 10ths of inches; and the middle piece, from 1 to 10, is the vernier, that slides up and down in a groove, and having 10 of its divisions equal to 11-10ths of the inches, for the purpose of subdividing every 10th of the inch into 10 parts, or, the inches into centesms or 100th parts. In practice, the method of counting is by observing (when the vernier is set with its index at top, pointing exactly against the upper surface of the mercury in the tube) which division of the vernier it is that exactly, or nearest, coincides with a division in the scale of 10ths of inches, for that will show the number of 100ths, over the 10ths of inches next below the index at top. So, in the annexed figure, the top of the vernier is between 2 and 3 tenths above the 30 inches of the barometer; and because the 8th division of the vernier is seen to coincide with a division of the scale, this shows that it is 8 centesms more: so that the height of the quicksilver altogether, is 30·28, that is, 30 inches, and 28 hundredths, or 2 tenths and 8 hundredths.



If the scale were not inches and 10ths, but degrees of a quadrant, &c, then the 8 would be $\frac{8}{10}$ths of a degree, or 48'; or if every division on the scale be 10 minutes, then the vernier will subdivide it into single minutes, and the 8 will then be 8 minutes. And so for any other case.

By altering the number of divisions, either in the degrees or in the vernier, or in both, an angle can be observed to many different degrees of accuracy. Thus, if a degree on a quadrant be divided into 12 parts, each being 5 minutes, and the length of the vernier be 21 such parts, or $1\frac{3}{4}$°, and divided into 20 parts, then

$$\frac{1}{12} \times \frac{1}{20} = \frac{1^\circ}{240} = \frac{1'}{4} = 15'',$$

is the smallest division the vernier will measure to; Or, if the length of the vernier be $2\frac{7}{12}$°, and divided into 30 parts, then

$$\frac{1}{12} \times \frac{1}{30} = \frac{1^\circ}{360} = \frac{1'}{6} = 10'',$$

is the smallest part in this case: Also

$$\frac{1}{12} \times \frac{1}{50} = \frac{1^\circ}{600} = \frac{1'}{10} = 6'',$$

is the smallest part when the vernier extends $4\frac{1}{4}$°. See Robertson's Navigation, book 5, pa. 279.

But though the vernier was thus originally divided into one *less* than the correspondent length on the scale, yet a practice has gradually come into use, of dividing it into one part *more* than those of the scale; so that it is now more usual to practise this latter way, than the former.

M. Delambre, in his Abrégé d'Astronomie, 1813, pa. 48, says, The general formula is, to take $n-1$ parts of the limb, and to divide them into n parts on the vernier, or the formula is $\frac{n-1}{n}$; then the vernier gives the $\frac{1}{n}$ part of the division of the limb. This, says he, I call the *Direct Vernier*, because the numeration on it proceeds in the same way as on the limb. There is another, which I call the *Retrograde*, because the numeration on it reads the contrary way: this is rather less common; and its formula is $\frac{n+1}{n}$; but the principle is the same, as well as the use.

For the method of applying the vernier to a quadrant, see *Hadley's* QUADRANT. And for the application of this instrument to a telescope, and the principles of its construction, see Smith's Optics, book 3, sect. 801.

VERSED *Sine*, of an arch, is the part of the diameter intercepted between the sine and the commencement of the arc; and it is equal to the difference between the radius and the cosine. See *Versed* SINE. And for *coversed sine*, see COVERSED *Sine*.

VERTEX *of an Angle*, is the angular point, or the point where the legs or sides of the angle meet.

VERTEX *of a Figure*, is the uppermost point, or the vertex of the angle opposite to the base.

VERTEX *of a Curve*, is the extremity of the axis or diameter, or it is the point where the diameter meets the curve; which is also the vertex of the diameter.

VERTEX *of a Glass*, in Optics, the same as its pole.

VERTEX is also used, in Astronomy, for the point of the heavens vertically or perpendicularly over our heads, also called the zenith.

VERTEX, *Path of the*. See PATH.

VERTICAL, something relating to the vertex or highest point. As,

VERTICAL *Point*, in Astronomy, is the same with vertex, or zenith.—Hence a star is said to be vertical, when it happens to be in that point which is perpendicularly over any place.

VERTICAL *Circle*, is a great circle of the sphere, passing through the zenith and nadir of a place.—The vertical circles are also called azimuths. The meridian of any place is a vertical circle, viz, that particular one which passes through the north or south point of the horizon.—All the vertical circles intersect one another in the zenith and nadir.

The use of the vertical circles is to estimate or measure the height of the stars &c, and their distances from the zenith, which is reckoned on these circles; and to find their eastern and western amplitude, by observing how many degrees the vertical, in which the star rises or sets, is distant from the meridian.

Prime VERTICAL, is that verticle circle, or azimuth, which passes through the poles of the meridian; or which is perpendicular to the meridian, and passes through the equinoctial points.

Prime VERTICALS, in Dialling. See PRIME *Verticals*.

VERTICAL *of the Sun*, is the vertical which passes through the centre of the sun at any moment of time.—Its use is, in dialling, to find the declination of the plane on which the dial is to be drawn, which is done by observing how many degrees that vertical is distant from the meridian, after marking the point or line of the shadow on the plane at any times.

VERTICAL *Dial*. See *Vertical* DIAL.

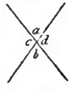
VERTICAL *Line*, in Dialling, is a line in any plane perpendicular to the horizon.—This is best found and drawn on an erect and reclining plane, by steadily holding up a string and plummet, and then marking two points of the shadow of the thread on the plane, a good distance from each other; and drawing a line through these marks.

VERTICAL *Line*, in Conics, is a line drawn on the vertical plane, and through the vertex of the cone.

VERTICAL *Line*, in Perspective. See *Vertical* LINE.

VERTICAL *Plane*, in Conics, is a plane passing through the vertex of a cone, and parallel to any conic section.

VERTICAL *Plane*, in Perspective. See PLANE and PERSPECTIVE.



VERTICAL *Angles*, or *Opposite Angles*, in Geometry, are such as have their legs or sides continuations of each other, and which consequently have the same vertex or angular point. So the angles *a* and *b* are vertical angles; as also the angles *c* and *d*. Vertical angles are equal to each other.

VERTICITY, is that property of the magnet or loadstone, or of a needle, &c touched with it, by which it turns or directs itself to some peculiar point, as to its pole.—The attraction of the magnet was known long before its verticity.

VERU, a comet, according to some writers resembling a spit, being nearly the same as the lonchites, only its head is rounder, and its train longer and sharper pointed.

VESPER, in Astronomy, called also Hesperus, and the Evening Star, is the planet Venus, when she is eastward of the sun, and consequently sets after him, and shines as an evening star.

VESPERTINE, in Astronomy, is when a planet is descending to the west after sun-set, or shines as an evening star.

VESTA, one of the small planetary bodies revolving between the planets Mars and Jupiter. It was discovered by M. Olbers the 29th of March, 1807, and is the nearest to Mars of the 4 small planets. See my Recreations, vol. 3, pa. 144.

VESTIBULE, in Architecture, a kind of entrance into a large building; being an open place before the hall, or at the bottom of the staircase.

VIA LACTEA, in Astronomy, the milky way, or Galaxy. See GALAXY.

VIA SOLIS, or *Sun's Way*, is used among astronomers, for the ecliptic line, or path in which the sun seems always to move.

VIBRATION, in Mechanics, a regular reciprocal motion of a body, as, for example, a pendulum, which being freely suspended, vibrates or swings from side to side of the vertical line. Mechanical authors, instead of vibration, often use the term oscillation, especially when speaking of a body that thus swings by means of its own gravity or weight.

The vibratinns of the same pendulum are all isochronal; that is, they are performed in an equal time, at least in the same latitude; for in lower latitudes they are found to be slower than in higher ones. See PENDULUM. In our latitude, a pendulum 39⅛ inches long, vibrates seconds, making 60 vibrations in a minute.

The vibrations of a longer pendulum take up a longer time than those of a shorter one, and that in the subduplicate ratio of the lengths, or the ratio of the square roots of the lengths. Thus, if one pendulum be 40 inches in length, and another only 10 inches, the former will be double the time of the latter in making a vibration; for $\sqrt{40} : \sqrt{10} :: \sqrt{4} : \sqrt{1}$, that is as 2 to 1. And because the number of vibrations, made in any given time, is reciprocally as the duration of one vibration, therefore the number of such vibrations is in the reciprocal subduplicate ratio of the lengths of the pendulums.

M. Mouton, a priest of Lyons, wrote a treatise, expressly to show, that by means of the number of vibrations of a given pendulum, in a certain time, may be established an universal measure throughout the whole world; and may fix the several measures that are in use among us, in such a manner, as that they might be recovered again, if at any time they should chance to be lost, as is the case of most of the ancient measures, which we now only know by conjecture.

The VIBRATIONS *of a Stretched Chord*, or *String*, arise from its elasticity; which power being in this case similar to gravity, as acting uniformly, the vibrations of a chord follow the same laws as those of pendulums. Consequently the vibrations of the same chord equally stretched, though they be of unequal lengths, are isochronal, or are performed in equal times; and the squares of the times of vibration are to one another inversely as their tensions, or powers by which they are stretched.

The vibrations of a spring too are proportional to the powers by which it is bent. These follow the same laws as those of the chord and peudulum; and consequently are isochronal; which is the foundation of spring watches.

VIBRATIONS are also used in Physics, &c, and for several other regular alternate motions. Sensation, for instance, is supposed to be performed by means of the vibratory motion of the contents of the nerves, begun by external objects, and propagated to the brain. This doctrine has been particularly illustrated by Dr. Hartley, who has extended it farther than any other writer, in establishing a new theory of our mental operations. The same ingenious author also applies the doctrine of vibrations to the explanation of muscular motion, which he thinks is performed in the same general manner as sensation and the perception of ideas. See his Observations on Man, vol. 1.

The several kinds and rays of light, Newton conceives to make vibrations of divers magnitudes; which, according to those magnitudes, excite sensations of several colours; much after the same manner as vibrations of air, according to their several magnitudes, excite sensations of several sounds. See the article COLOUR.

Heat, according to the same author, is only an accident of light, occasioned by the rays putting a fine, subtile, ethereal medium, which pervades all bodies, into a vibratory motion, which gives us that sensation. See HEAT. From the vibrations or pulses of the same medium, he accounts for the alternate fits of easy reflection and ready transmission of the rays.—In the Philosophical Transactions it is observed, that the butterfly, into which the silkworm is transformed, makes 130 vibrations or motions of its wings, in one coition.

VIETA (FRANCIS), a very celebrated French mathematician, was born in 1540 at Fontenai, or Fontenai-le-Comté, in Lower Poitou, a province of France. He was master of requests at Paris, where he died in 1603, being the 63d year of his age. Among other branches of learning in which he excelled, he was one of the most respectable mathematicians of the 16th century, or indeed of any age. His writings abound with marks of great originality, and the finest genius, as well as intense application. Indeed such was the vigour of his perseverance, that he has sometimes remained in his study for three days together, without eating or sleeping. His inventions and improvements in all parts of the mathematics were very considerable. He was in a manner the inventor and introducer of specious algebra, in which letters are used instead of numbers, as well as of many beautiful theorems in that science full explanation of which may be found under the article ALGEBRA, and still more in my Tracts, vol. 2. He made also considerable improvements in geometry and trigonometry. His angular sections are a very ingenious and masterly performance: by these he was enabled to resolve the problem of Adrian Roman, proposed to all mathematicians, amounting to an equation of the 45th degree. Romanus was so struck with his sagacity, that he immediately quitted his residence of Wirtsbourg in Franconia, and came to France to visit him, and solicit his friendship. His Apollonius Gallus, being a restoration of Apollonius's tract on Tangencies, and many other geometrical pieces to be found in his works, give proofs of the finest taste and genius for true geometrical speculations.—He gave some masterly tracts on trigonometry, both plane and spherical, which may be found in the collection of his works, published at Leyden in 1646, by Schooten, besides another large and separate volume in folio, published in the author's life-time at Paris in 1579, containing extensive trigonometrical tables, with the construction and use of the same, which are particularly described in the introduction to my Logarithms, pa. 4 &c. To this complete treatise on trigonometry, plane and spherical, are subjoined several miscellaneous problems and observations, such as, the quadrature of the circle, the duplication of the cube, &c. Computations are here given of the ratio of the diameter of a circle to the circumference, and of the length of the sine of 1 minute, both to a great many places of figures; by which he found that the sine of 1 minute is between 2908881959

and 2908882056;

also the diameter of a circle being 1000 &c, that the perimeter of the inscribed and circumscribed polygon of 393216 sides, will be as follows, viz, the

perimeter of the inscribed polygon 31415926535

perim. of the circumscribed polygon 31415926537

and that therefore the circumference of the circle lies between these two numbers.

Vieta having observed that there were many faults in the Gregorian Calendar, as it then existed, he composed a new form of it, to which he added perpetual canons, and an explication of it, with remarks and objections against Clavius, whom he accused of having deformed the true Lelian reformation, by not rightly understanding it.

Besides those, it seems a work greatly esteemed, and the loss of which cannot be sufficiently deplored, was his Harmonicon Cœleste, which, being communicated to father Mersenne, was, by some perfidious acquaintance of that honest-minded person, surreptitiously taken from him, and irrecoverably lost, or suppressed, to the great detriment of the literary world. There were also, it is said, other works of an astronomical kind, that have been buried in the ruins of time.

Vieta was also a profound decipherer, an accomplishment that proved very useful to his country. As the different parts of the Spanish monarchy lay very distant from one another, when they had occasion to communicate any secret designs, they wrote them in ciphers and unknown characters, during the disorders of the league: the cipher was composed of more than 500 different characters, which yielded their hidden contents to the penetrating genius of Vieta alone. His skill so disconcerted the Spanish councils for two years, that they published it at Rome, and other parts of Europe, that the French king had only discovered their ciphers by means of magic.

VINCULUM, in Algebra, a mark or character, either drawn over, or including, or some other way accompanying, a factor, divisor, dividend, &c, when it is compounded of several letters, quantities, or terms, to connect them together as one quantity, and show that they are to be multiplied, or divided, &c, together.

Vieta, I think, first used the bar or line over the quantities, for a vinculum, thus $\overline{a + b}$; and Albert Girard the parenthesis thus $(a + b)$; the former way being now chiefly used by the English, and the latter by most other Europeans. Thus $\overline{a + b} \times c$, or $(a + b) \times c$, denotes the product of c and the sum $a + b$ considered as one quantity. Also $\sqrt{a + b}$, or $\sqrt{}(a + b)$, denotes the square root of the sum $a + b$. Sometimes the mark : is set before a compound factor, as a vinculum, especially when it is very long, or an infinite series; thus $3a \times : 1 - 2x + 3x^2 - 4x^3 + 5x^5$ &c.

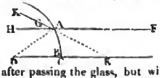
VINDEMIATRIX, or VINDEMIATOR, a fixed star of the third magnitude, in the northern wing of the constellation Virgo.

VIRGO, in Astronomy, one of the signs or constellations of the zodiac, which the sun enters about the 21st or 22d of August; being one of the 48 old constellations, and is mentioned by the astronomers of all ages and nations, whose works have reached us. Anciently the figure was that of a girl, almost naked, with an ear of corn in her hand, evidently to denote the time of harvest among the people who invented this sign, whoever they were. But the Greeks much altered the figure, with clothes, wings, &c, and variously explained the origin of it by their own fables; thus, they tell us that the virgin, now exalted into the skies, was, while on earth, that Justitia, the daughter of Astræus and Ancora, who lived in the golden age, and taught mankind their duty; but who, when their crimes increased, was obliged to leave the earth, and take her place in the heavens. Again, Hesiod gives the celestial maid another origin, and says she was the daughter of Jupiter and Themis. There are also others who depart from both these accounts, and make her to have been Erigone, the daughter of Icarius; while others make her Parthene, the daughter of Apollo, who placed her there; and others, from the ear of corn, make it a representation of Ceres; and others, from the obscurity of her head, of Fortune.

The ancients, as they gave each of the 12 months of the year to the care of some one of the 12 principal deities, so they also threw into the protection of each of these one of the 12 signs of the zodiac. Hence Virgo, from the ear of corn in her hand, naturally fell to the lot of Ceres, and we accordingly find it called Signum Cereris.

The stars in the constellation Virgo, in Ptolemy's catalogue, are 32; in Tycho's 33; in Hevelius's 50; and in the Britannic 110.

VIRTUAL *Focus*, in Optics, is a point in the axis of a glass, where the continuation of a refracted ray meets it.



Thus, let D be the centre, and DBE the axis of the glass AB; upon which falls the ray FA. Now this ray will not proceed straight forward, as AH, after passing the glass, but will take the course as AK, being deflected from the perpendicular AD. If then the refracted ray KA be produced, by

AE, to the axis at E, this point E Mr. Molineux calls the Virtual focus, or point of divergence.

VIRTUAL *Velocity*, of a point urged by any force, denotes the element of the space which it would describe in the direction of the power, when the system is supposed to have suffered an indefinitely small derangement.

The principle of virtual velocities, in mechanics, is much used by the foreign mathematicians, and is thus enunciated: If any system whatever, of bodies or points, be urged on powers in equilibrio, and there be given to this system any small motion, by virtue of which every point describes an indefinitely small space; then the sum of the products of each power multiplied by the space, which the point where it is applied would describe, according to the direction of the same power, will be always equal to zero or nothing; regarding as positive the small spaces described in the direction of the powers; and as negative, those described in the opposite sense.—This principle is due to Galileo. For its history and demonstration, Lagrange, Mecanique, pa. 8. See also Fournier's demonstration in 5° Caheir du Journal de l'Ecole Polytechnique.

VIS, a Latin word, signifying force or power; adopted by writers on physics, to express divers kinds of natural powers or faculties.

The term vis is either active or passive: the vis activa is the power of producing motion; the vis passiva is that of receiving or losing it. The vis activa is again subdivided into vis viva and vis mortua.

VIS *Absoluta*, or *Absolute Force*, is that kind of centripetal force which is measured by the motion that would be generated by it in a given body, at a given distance, and depends on the efficacy of the cause producing it.

VIS *Acceleratrix*, or *Accelerating Force*, is that centripetal force which produces an accelerated motion, and is proportional to the velocity which it generates in a given time; or it is as the motive or absolute force directly, and as the quantity of matter moved inversely.

VIS *Impressa* is defined by Newton to be the action exercised on any body to change its state, either of rest or uniform motion in a right line.—This force consists altogether in the action; and has no place in the body after the action is ceased: for the body perseveres in every new state by the vis inertiæ alone. This vis impressa may arise from various causes; as from percussion, pression, and centripetal force.

VIS *Inertiæ*. See INERTIA.

The vis inertiæ, the same great author elsewhere observes, is a passive principle, by which bodies persist in their motion or rest, and receive motion, in proportion to the force impressing it, and resist as much as they are resisted. See RESISTANCE.

VIS *Insita*, or *Innate Force* of matter, is a power of resisting, by which every body, as much as in it lies, endeavours to persevere in its present state, whether of rest or of motion uniformly forward in a right line. This force is always proportional to the quantity of matter in the body, and differs in nothing from the vis inertiæ, but in our manner of conceiving it.

VIS *Centripeta*. See CENTRIPETAL *Force*.

VIS *Motrix*, or *Moving Force* of a centripetal body, is the tendency of the whole body towards the centre, resulting from the tendency of all the parts, and is proportional to the motion which it generates in a given time; so that the vis motrix is to the vis acceleratrix, as the motion is to the celerity: and as the quantity of motion in a body is estimated by the product of the velocity into the quantity of matter, so the vis motrix arises from the vis acceleratrix multiplied by the quantity of matter. The followers of Leibnitz use the term vis motrix for the force of a body in motion, in the same sense as the Newtonians use the term vis inertiæ; this latter they allow to be inherent in a body at rest; but the former, or vis motrix, a force inherent in the same body only while in motion, which actually carries it from place to place, by acting upon it always with the same intensity in every physical part of the line which it describes.

VIS *Mortua*, and VIS *Viva*, in Mechanics, are terms used by Leibnitz and his followers for force, which they distinguish into two kinds, vis mortua, and vis viva; understanding by the former any kind of pressure, or an endeavour to move, not sufficient to produce actual motion, unless its action on a body be continued for some time; and by the latter, that force or power of acting which resides in a body in motion.

VISIBLE, something that is an object of vision or sight, or the property of a thing seen.—The Cartesians say that light alone is the proper object of vision. But according to Newton, colour alone is the proper object of sight; colour being that property of light by which the light itself is visible, and by which the images of opake bodies are painted on the retina.

As to the Situation and Place of Visible Objects:—Philosophers in general had formerly taken for granted, that the place to which the eye refers any visible object, seen by reflection or refraction, is that in which the visual ray meets a perpendicular from the object upon the reflecting or the refracting plane. That this is the case with respect to plane mirrors is universally acknowledged; and some experiments with mirrors of other forms seem to favour the same conclusion, and thus afford reason for extending the analogy to all cases of vision. If a right line be held perpendicularly over a convex or concave mirror, its image seems to make one line with it. The same is the case with a perpendicular right line held within water; for the part which is within the water appears to be a continuation of that which is without. But Dr. Barrow called in question this method of judging of the place of an object, and so opened a new field of inquiry and debate in this branch of science. This, with other optical investigations, he published in his Optical Lectures, first printed in 1674. According to him, we refer every point of an object to the place from which the pencils of light issue, or from which they would have issued, if no reflecting or refracting substance intervened. Pursuing this principle, Dr. Barrow proceeded to investigate the place in which the rays issuing from each of the points of an object, and that reach the eye after one reflection or refraction, meet; and he found that when the refracting surface was plane, and the refraction was made from a denser medium into a rarer, those rays would always meet in a place between the eye and a perpendicular to the point of incidence. If a convex mirror be used, the case will be the same; but if the mirror be plane, the rays will meet in the perpendicular, and beyond it if it be concave. The same author also determined, according to these principles, what form the image of a right line will take when it is presented in different manners to a spherical mirror, or when it is seen through a refracting medium.

Dr. Barrow however notices an objection against the maxim above-mentioned, concerning the supposed place of visible objects, and candidly owns that he was not able to give a satisfactory solution of it. The objection is this: Let an object be placed beyond the focus of a convex lens, and if the eye be close to the lens, it will appear confused, but very near to its true place. If the eye be a little withdrawn, the confusion will increase, and the object will seem to come nearer; and when the eye is very near the focus, the confusion will be very great, and the object will appear to be close to the eye. But in this experiment the eye receives no rays but those that are converging; and the point from which they issue is so far from being nearer than the object, that it is beyond it; notwithstanding which, the object is conceived to be much closer than it is, though no very distinct idea can be formed of its precise distance.

The first person who took much notice of Dr. Barrow's hypothesis, and the difficulty attending it, was Dr. Berkeley, who (in his Essay on a New Theory of Vision, pa. 30) observes, that the circle formed on the retina, by the rays which do not come to a focus, produce the same confusion in the eye, whether they cross one another before they reach the retina, or tend to it afterwards; and therefore that the judgment concerning distance will be the same in both cases, without any regard to the place from which the rays originally issued; so that in this case, by receding from the lens, as the confusion increases, which always accompanies the nearness of an object, the mind will judge that the object comes nearer. See *Apparent* DISTANCE.

M. Bouguer (in his Traité d'Optique, pa. 104) adopts Barrow's general maxim, in supposing that we refer objects to the place from which the pencils of rays seemingly converge at their entrance into the pupil. But when rays issue from below the surface of a vessel of water, or any other refracting medium, he finds that there are always two different places of this seeming convergence: one of them of the rays that issue from it in the same vertical circle, and therefore fall with different degrees of obliquity on the surface of the refracting medium; and another, of those that fall upon the surface with the same degree of obliquity, entering the eye laterally with respect to one another. He says, sometimes one of these images is attended to by the mind, and sometimes the other; and different images may be observed by different persons. And he adds, that an object plunged in water affords an example of this duplicity of images.

G. W. Krafft has ably supported Barrow's opinion, that the place of any point seen by reflection from the surface of any medium, is that in which rays issuing from it, infinitely near to one another, would meet; and considering the case of a distant object viewed in a concave mirror, by an eye very near it, when the image, according to Euclid and other writers, would be between the eye and the object, and Barrow's rule cannot be applied, he says that in this case the speculum may be considered as a plane, the effect being the same, only that the image is more obscure. Com. Petrepol. vol. 12, pa. 252, 256. See Priestley's Hist. of Light &c, pa. 89, 688.

From the principle above illustrated, several remarkable phenomena of vision may be accounted for: as—That if the distance between two visible objects be an angle that is insensible, the distant bodies will appear as if contiguous: whence, a continuous body being the result of several contiguous ones, if the distances between several visibles subtend insensible angles, they will appear one continuous body; which gives a pretty illustration of the notion of a continuum.—Hence also parallel lines, and long vistas, consisting of parallel rows of trees, seem to converge more and more the farther they are extended from the eye; and the roofs and floors of long extended alleys seem, the former to descend, and the latter to ascend, and approach each other; because the apparent magnitudes of their perpendicular intervals are perpetually diminishing, while at the same time we mistake their distance.

As to the different Distances of Visible Objects.—The mind perceives the distance of visible objects, 1st, From the different configurations of the eye, and the manner in which the rays strike the eye, and in which the image is impressed upon it. For the eye disposes itself differently, according to the different distances it is to see; viz, for remote objects the pupil is dilated, and the crystalline brought nearer the retina, and the whole eye is made more globous; on the contrary, for near objects, the pupil is contracted, the crystalline thrust forwards, and the eye lengthened. The mode of performing this, however, has greatly divided the opinions of philosophers. See Priestley's Hist. of Light &c, pa. 638—652, where the several opinions of Descartes, Kepler, Lahire, Leroi, Porterfield, Jurin, Musschenbroek, &c, are stated and examined.

Again, the distance of visible objects is judged of by the angle the object makes; from the distinct or confused representation of the objects; and from the briskness or feebleness, or the rarity or density of the rays.

To this it is owing, 1st, That objects which appear obscure or confused, are judged to be more remote; a principle which the painters make use of to cause some of their figures to appear farther distant than others on the same plane. 2d. Hence also, rooms whose walls are whitened, appear the smaller; that fields covered with snow, or white flowers, seem less than when clothed with grass; that mountains covered with snow, in the night time, appear the nearer, and that opaque bodies appear the more remote in the twilight.

The Magnitude of Visible Objects.—The quantity or magnitude of visible objects, is known chiefly by the angle contained between two rays drawn from the two extremes of the object to the centre of the eye. An object appears so large as is the angle it subtends; or bodies seen under a greater angle appear greater; and those under a less angle, less, &c. Hence the same object appears greater or less as it is nearer the eye or farther off. And this is called the apparent magnitude.

But to judge of the real magnitude of an object, we must consider the distance; for since a near and a remote object may appear under equal angles, though the magnitudes be different, the distance must necessarily be estimated, because the magnitude is great or small according as the distance is great or small. So that the real magnitude is in the compound ratio of the distance and the apparent magnitude; at least when the subtended angle, or apparent magnitude, is very small; otherwise, the real magnitude will be in a ratio compounded of the distance and the sine of the apparent magnitude, nearly, or nearer still its tangent.

Hence, objects seen under the same angle, have their magnitudes in the same ratio as their distances. The chord of an arc of a circle appears of equal magnitude from every point in the circumference, though one point be vastly nearer than another. Or if the eye be fixed in any point in the circumference, and a right line be moved round so as its extremes be always in the periphery, it will appear of the same magnitude in every position. And the reason is, because the angle it subtends is always of the same magnitude. And hence also, the eye being placed in any angle of a regular polygon, the sides of it will all appear of equal magnitude; being all equal chords of a circle described about it.

If the magnitude of an object directly opposite to the eye be equal to its distance from the eye, the whole object will be distinctly seen, or taken in by the eye, but nothing more. And the nearer you approach an object, the less part you see of it.—The least angle under which an ordinary object becomes visible, is about one minute of a degree.

Of the Figure of Visible Objects.—This is estimated chiefly from our opinion of the situation of the several parts of the object. This opinion of the situation, &c, enables the mind to apprehend an external object under this or that figure, more justly than any similitude of the images in the retina with the object can; the images being often elliptical, oblong, &c, when the objects they exhibit to the mind, are circles, or squares, &c.

The laws of vision with regard to the figures of visible objects are, 1. That if the centre of the eye be exactly in the direction of a right line, the line will appear only as a point. 2. If the eye be placed in the direction of a surface, it will appear only as a line. 3. If a body be opposed directly towards the eye, so as only one plane of the surface can radiate on it, the body will appear as a surface. 4. A remote arch, viewed by an eye in the same plane with it, will appear as a right line. 5. A sphere, viewed at a distance, appears a circle. 6. Angular figures, at a distance, appear round. 7. If the eye look obliquely on the centre of a regular figure, or a circle, the true figure will not be seen; but the circle will appear oval, &c.

VISIBLE *Horizon, Place, &c.* See the substantives.

VISION, is the act of seeing, or of perceiving external objects by the organ of sight. When an object is so disposed, that the rays of light, coming from all parts of it, enter the pupil of the eye, and present its image on the retina, that object is then seen. This is proved by experiment; for if the eye of any animal be taken out, and the skin and fat be carefully stript off from the back part of it, till only the thin membrane, which is called the retina, remains to terminate it behind, and any object be placed before the front of the eye, the picture of that object will be seen figured as with a pencil on that membrane. There are thousands of experiments which prove that this is the mechanical effect of vision, or seeing, but none of them appear so conveniently as this, which is made with the very eye itself of an animal; an eye of an ox newly killed shows this happily, and with very little trouble. It will indeed appear singular in this, that the object is inverted, in the picture thus drawn of it, in the eye; and the case is the same in the eye of a living person.

Various other opinions however have been held concerning the means of vision among philosophers.

The Platonists and Stoics held vision to be effected by the emission of rays out of the eyes; conceiving that there was a kind of light thus darted out; which, with the light of the external air, taking hold as it were of the objects, rendered them visible; and thus returning back again to the eye, altered and new modified by the contact of the object, made an impression on the pupil, which gave the sensation of the object.

Our illustrious countryman, Roger Bacon, also assents to the opinion that visual rays proceed from the eye; giving this reason for it, that every thing in nature is qualified to discharge its proper functions by its own powers, in the same manner as the sun, and other celestial bodies. Opus Majus, pa. 289.

The Epicureans held, that vision is performed by the emanation of corporeal species or images from objects; or a kind of atomical effluvia continually flying off from the intimate parts of objects, to the eye.

The Peripatetics hold, with Epicurus, that vision is produced by the reception of species; but they differ from him in the circumstances; for they will have the species (which they call intentionales) to be incorporeal. It is true, Aristotle's doctrine of vision, delivered in his chapter De Aspectu, amounts to no more than this, that objects must have some intermediate body, that by this they may move the organ of sight. To which he adds, in another place, that when we perceive bodies, it is their species, not their matter, that we receive; as a seal makes an impression on wax, without the wax receiving any thing of the seal.

But this vague and obscure account the Peripatetics have thought proper to improve. Accordingly, what their master calls species, the disciples, understanding of real proper species, assert, that every visible object expresses a perfect image of itself in the air contiguous to it; and this image another, somewhat less, in the next air; and the third another; and so on till the last image arrives at the crystalline, which they are of opinion is the chief organ of sight, or that which immediately moves the soul. These images they call intentional species.

The modern philosophers however, as the Cartesians and Newtonians, give a better account of vision. They all agree, that it is performed by rays of light reflected from the several points of objects received in at the pupil, refracted and collected in their passage, through the coats and humours to the retina; and this striking, or making an impression, on so many points of it; which impression is conveyed, by the correspondent capillaments of the optic nerve, to the brain, &c.

Baptista Porta's experiments with the camera obscura, about the middle of the 16th century, convinced him that vision is performed by the intermission of something into the eye, and not by visual rays proceeding from the eye, as had been the general opinion before his time; and he was the first who fully satisfied himself and others on this subject; though several philosophers still adhered to the old opinion.

As for the Peripatetic series or chain of images, it is a mere chimera; and Aristotle's meaning is better understood without than with them. In fact, setting these aside, the Aristotelian, Cartesian, and Newtonian doctrines of vision, are very consistent with one another; for

Newton imagines that vision is performed chiefly by the vibrations of a fine medium (which penetrates all bodies) excited in the bottom of the eye by the rays of light, and propagated through the capillaments of the optic nerve, to the sensorium. And Descartes maintains, that the sun pressing the materia subtilis, with which the whole universe is every where filled, the vibrations and pulses of that matter reflected from objects, are communicated to the eye, and thence to the sensory: so that the action or vibration of a medium is equally supposed in all.

It is generally concluded then, that the images of objects are represented on the retina; which is only an expansion of the fine capillaments of the optic nerve, and from whence the optic nerve is continued into the brain. Now any motion or vibration, impressed on one extremity of the nerve, will be propagated to the other: hence the impulse of the several rays, sent from the several points of the object, will be propagated as they are on the retina (that is, in their proper colours, &c, or in particular vibrations, or modes of pressure, corresponding to them) to the place where those capillaments are interwoven into the substance of the brain. And thus is vision brought to the common case of sensation.

Experience teaches us that the eye is capable of viewing objects at a certain distance, without any mental exertion. Beyond this distance, no mental exertion can be of any avail: but, within it, the eye possesses a power of adapting itself to the various occasions that occur, the exercise of which depends on the volition of the mind. How this is effected, is a problem that has very much engaged the attention of optical writers; but it is doubted whether it has yet been satisfactorily explained. The first theory for the solution of this problem is that of Kepler. He supposes that the ciliary processes contract the diameter of the eye, and lengthen its axis by a muscular power. But Dr. Thomas Young (in some ingenious Observations on Vision in the Philos. Trans. 1793) observes, that these processes neither appear to contain any muscular fibres, nor have any attachment by which they can be capable of performing this action.

Descartes ascribed this contraction and elongation to a muscularity of the crystalline, of which he supposed the ciliary processes to be the tendons: but he neither demonstrated this muscularity, nor sufficiently considered the connexion with the ciliary processes.

De Lahire allows of no change in the eye, except the contraction and dilatation of the pupil: this opinion he founds on an experiment which Dr. Smith has shown to be fallacious. Haller adopted his hypothesis, notwithstanding its inconsistency with the principles of optics and constant experience.

Dr. Pemberton supposes that the crystalline contains muscular fibres, by which one of its surfaces is flattened, while the other is made convex: but he has not demonstrated the existence of these fibres; and Dr. Jurin has proved that such a change as this is inadequate to the effect.

Dr. Porterfield conceives that the ciliary processes draw the crystalline forward, and make the cornea more convex. But the ciliary processes are incapable of this action; and it appears from Dr. Jurin's calculations, that a sufficient motion of this kind requires a very visible increase in the length of the axis of the eye; an increase which has never yet been observed.

Dr. Jurin maintains that the uvea, at its attachment to the cornea, is muscular; and that the contraction of this ring makes the cornea more convex. But this hypothesis is not sufficiently confirmed by observation.

Musschenbroek conjectures that the relaxation of this ciliary zone, which is nothing but the capsule of the vitreous humour where it receives the impression of the ciliary processes, permits the coats of the eye to push forward the crystalline and cornea. Such a voluntary relaxation however, Dr. Young observes, is wholly without example in the animal economy: besides, if it actually occurred, the coats of the eye could not act as he conceives; nor could they act in this manner without being observed. He adds, that the contraction of the ciliary zone is equally inadequate and unnecessary.

Dr. Young, having examined these theories, and some others of less moment, proceeds to investigate a more probable solution of this optical difficulty.—Adverting to the observation of Dr. Porterfield, that those who have been couched have not the power of accommodating the eye to different distances; and to the reflections of other writers on this subject; he was led to conclude that the rays of light, emitted by objects at a small distance, could only be brought to foci on the retina by a nearer approach of the crystalline to a spherical form; and he imagined that no other power was capable of producing this change, besides a muscularity of part or of the whole of its capsule:—but, on closely examining, first with the naked eye and then with a magnifier, the crystalline of an ox's eye turned out of its capsule, he discovered a structure which seemed to remove the difficulties that have long embarrassed this branch of optics.

"The crystalline of the ox," says he, "is composed of various similar coats, each of which consists of six muscles, intermixed with a gelatinous substance, and attached to six membranous tendons. Three of the tendons are anterior, and three posterior; their length is about two-thirds of the semidiameter of the coat; their arrangement is that of three equal and equidistant rays, meeting in the axis of the crystalline; one of the anterior is directed towards the outer angle of the eye, and one of the posterior towards the inner angle, so that the posterior are placed opposite to the middle of the interstices of the anterior, and planes passing through each of the six, and through the axis, would mark on either surface six regular equidistant rays. The muscular fibres arise from both sides of each tendon; they diverge till they reach the greatest circumference of the coat; and, having passed it, they again converge, till they are attached respectively to the sides of the nearest tendons of the opposite surface. The anterior or posterior portion of the six, viewed together, exhibits the appearance of three penniform-radiated muscles. The anterior tendons of all the coats are situated in the same planes, and the posterior ones in the continuations of these planes beyond the axis. Such an arrangement of fibres can be accounted for on no other supposition than that of muscularity. This mass is inclosed in a strong membranous capsule, to which it is loosely connected by minute vessels and nerves; and the connexion is more observable near its greatest circumference. Between the mass and its capsule is found a considerable quantity of an aqueous fluid, the liquid of the crystalline.

"When the will is exerted to view an object at a small distance, the influence of the mind is conveyed through the lenticular ganglion, formed from branches of the third and fifth pair of nerves by the filaments perforating the sclerotica, to the orbiculus ciliaris, which may be considered as an annular plexus of nerves and vessels; and thence by the ciliary processes to the muscle of the crystalline, which, by the contraction of its fibres, becomes more convex, and collects the diverging rays to a focus on the retina. The disposition of fibres in each coat is admirably adapted to produce this change; for, since the least surface that can contain a given bulk is that of a sphere (Simpson's Fluxions, pa. 486) the contraction of any surface must bring its contents nearer to a spherical form. The liquid of the crystalline seems to serve as a synovia in facilitating the motion, and to admit a sufficient change of the muscular part, with a smaller motion of the capsule."

Dr. Young proceeds to inquire whether these fibres can produce an alteration in the form of the lens sufficiently great to account for the known effects; and he finds, by calculation, that, supposing the crystalline to assume a spherical form, its diameter will be 642 thousandths of an inch, and its focal distance in the eye ·926. Then, disregarding the thickness of the cornea, we find (by Smith, art. 370) that such an eye will collect those rays on the retina, which diverge from a point at the distance of 12 inches and 8 tenths. This is a greater change than is necessary for an ox's eye; for if it be supposed capable of distinct vision at a distance somewhat less than 12 inches, yet it is probably far short of being able to collect parallel rays. The human crystalline is susceptible of a much greater change of form. The ciliary zone may admit of as much extension as this diminution of the diameter of the crystalline will require; and its elasticity will assist the cellular texture of the vitreous humour, and perhaps the gelatinous part of the crystalline, in restoring the indolent form.—Dr. Young apprehends that the sole office of the optic nerve is to convey sensation to the brain; and that the retina does not contribute to supply the lens with nerves.—As the human crystalline resembles that of the ox, it may reasonably be presumed that the action of both organs depends on the same general principles.

This theory of Dr. Young's however is strongly opposed by Dr. Hosack, (Philos. Trans. 1794, part 2, pa. 196). He contests the existence of the muscles, which Dr. Young has described, for several reasons. First, from the transparency they must possess; otherwise there would be some irregularity in the refraction of those rays which pass through the several parts, differing both in shape and density. Another circumstance is the number of these muscles. Dr. Young describes 6 in each lamina; and as Leuwenhoek makes 2000 laminæ in all, therefore the number of muscles must amount to 12 thousand, the action of which, Dr. Hosack apprehends, must exceed comprehension. But the existence of these muscles is still more doubtful, if the accuracy of Dr. Hosack's observations be admitted. With the assistance of the best glasses, and with the greatest attention, he could not discover the structure of the crystalline described by Dr. Young, but found it to be perfectly transparent. He first observed the lens in its viscid state, and then exposed different lenses to a moderate degree of heat, so that they became opaque and dry; and it was easy to separate the distinct layers described by Dr. Young. These were so numerous as not to admit of having, each of them six muscles. Another consideration, which seems to prove that these layers possess no distinct muscles, is that, in this opaque state, they are not visible, but consist of an almost infinite number of concentric fibres, not divided into particular bundles, but similar to as many of the finest hairs of equal thickness, arranged in similar order. This regular structure of layers, composed of concentric fibres, Dr. Hosack thinks is much better adapted to the transmission of the rays of light than the irregular structure of muscles. Besides, it ought to be considered that the crystalline lens is not the most essential organ in viewing objects at different distances; and if this be the case, the power of the eye cannot be owing to any changes in this lens. It is a fact, says Dr. Hosack, that we can, in a great degree, do without it; as is the case after couching or extraction, by which operation all its parts must be destroyed. Dr. Porterfield, however, and Dr. Young, on his authority, maintain that patients, after the operation of couching, have not the power of accommodating the eye to different distances of objects. On the whole, Dr. Hosack concludes that no such muscles, as Dr. Young has described, exist, and that he must have been deceived by some other appearances that resembled muscles: neither will he allow the effects ascribed to the ciliary processes in changing the shape or situation of the lens.

Dr. Hosack then proceeds to illustrate the structure and use of the external muscles of the eye; which are 6 in number, 4 called recti or straight, and 2 oblique, and by means of which he thinks the business is effected. The common purposes to which these muscles are subservient are well known: but besides these, Dr. Hosack suggests that it is not inconsistent with the general laws of nature, nor even with the animal economy to imagine that, from their combination, they should have a different action and an additional use. In describing the precise action of these muscles, he supposes an object to be seen distinctly, first at the distance of 6 feet; in which case the picture of it falls exactly on the retina. He then directs his attention to another object at the distance of 6 inches, as nearly as possible in the same line. While he is viewing this, he loses sight of the first object, though the rays proceeding from it still fall on the eye; and hence he infers that the eye must have undergone some change; so that the rays meet either before or behind the retina. But, as rays from a more distant object concur sooner than those from a nearer one, the picture of the more remote object must fall before the retina, while the others form a distinct image upon it. But yet the eye continued in the same place; and therefore the retina must, by some means, have been removed to a greater distance from the forepart of the eye, so as to receive the picture of the nearer object. This object, he contends, could not be seen distinctly, unless the retina were removed to a greater distance, or the refracting power of the media through which the rays passed were augmented:—but as the lens is the chief refracting medium, if we admit that this has no power of changing itself, we are under the necessity of adopting the first of these two suppositions.

The next object of inquiry is, how the external muscles are capable of producing these changes. The recti are strong, broad, and flat, and arise from the back part of the orbit of the eye; and, passing over the ball as over a pulley, they are inserted by broad flat tendons at the anterior part of the eye. The oblique are inserted towards the posterior part by similar tendons. When these different muscles act jointly, the eye being in the horizontal position, and every muscle in action contracting itself, the four recti by their combination must compress the various parts of the eye and lengthen its axis, while the oblique muscles serve to keep the eye in its proper direction and situation. The convexity of the cornea, by means of its great elasticity, is also increased in proportion to the degree of pressure, and thus the rays of light passing through it are necessarily more converged. The elongation of the eye serves also to lengthen the media, in the aqueous, crystalline, and vitreous humours through which the rays pass, so that their powers of refraction are proportionably increased. This is the general effect of the contraction of the external muscles, according to Dr Hosack's statement of it: to which it may be added, that we possess the same power of relaxing them in proportion to the greater distance of the object, till we arrive at the utmost extent of indolent vision. Dr. Hosack also illustrates this hypothesis by some experiments.

The misrepresentations of vision often depend on the distance of the object. Thus, if an opaque globe be placed at a moderate distance from the eye, the picture of it on the retina will be a circle properly diversified with light and shade, so that it will excite in the mind the sensation of a sphere or globe; but, if the globe be placed at a great distance from the eye, the distance between those lights and shades, which form the picture of a globe, will be imperceptible, and the globe will appear no otherwise than as a circular plane. In a luminous globe, distance is not necessary in order to take off the representation of prominent and flat; an iron bullet, heated very red hot, and held but a few yards distance from the eye, appears a plane, not a prominent body; it has not the look of a globe, but of a circular plane. It is owing to this misrepresentation of vision that we see the sun and moon flat by the naked eye, and the planets also, through telescopes, flat. It is in this light also that astronomers, when they speak of the sun, moon, and planets, as they appear to our view, call them the disks of the sun, moon, and planets, which we see.

The nearer a globe is to the eye, the smaller segment of it is visible, the farther off the greater, and at a due distance the half; and, on the same principle, the nearer the globe is to the eye, the greater is its apparent diameter, that is, under the greater angle it will appear; the farther off the globe is placed, the less is its apparent diameter. This is a proposition of importance, for, on this principle, we know that the same globe, when it appears larger, is nearer to our eye, and, when smaller, is farther off from it. Therefore, as the globes of the sun and moon continue always of the same size, yet appear sometimes larger and sometimes smaller to us, it is evident, that they are sometimes nearer and sometimes farther off from the place whence we view them. Two globes, of different magnitude, may be made to appear of exactly the same diameter, if they be placed at different distances, and those distances be exactly proportioned to their diameters. To this it is owing, that we see the sun and moon nearly of the same diameter; they are, indeed, vastly different in real bulk, but, as the moon is placed greatly nearer to our eyes, the apparent magnitude of that smaller globe is nearly the same with that of the greater.

In this instance of the sun and moon (for there cannot be a more striking one) we see the misrepresentation of vision in two or three several ways. The apparent diameters of these globes are so nearly equal, that, in their several changes of place, they do, at times, appear to us absolutely equal, or mutually greater than each other. This is often to be seen, but it is at no time so obvious, and so perfectly evinced, as in eclipses of the sun, which are total. In these we see the apparent magnitudes of the two globes vary so much according to their distances, that sometimes the moon is large enough exactly to cover the disk of the sun, sometimes it is larger, and a part of it every where extends beyond the disk of the sun; and, on the contrary, sometimes it is smaller, and, though the eclipse be absolutely central, yet it is annular, or a part of the sun's disk is seen in the middle of the eclipsed part, enlightened, and surrounding the opaque body of the moon in form of a lucid ring.

When an object, which is seen above, without other objects of comparison, is of a known magnitude, we judge of its distance by its apparent magnitude; and custom teaches us to do this with tolerable accuracy. This is a practical use of the misrepresentation of vision, and, in the same manner, knowing that we see things which are near us, distinctly, and those which are distant, confusedly, we judge of the distance of an object by the clearness, or confusion, in which we see it. We also judge yet more easily and truly of the distance of an object by comparing it to another seen at the same time, the distance of which is better known, and yet more by comparing it with several others, the distances of which are more or less known, or more or less easily judged of. These are the circumstances which assist us, even by the misrepresentation of vision, to judge of distance; but, without one or more of these, the eye does not, in reality, enable us to judge concerning the distance of objects.

This misrepresentation, though it serves us on some occasions, yet is very limited in its effects. Thus, though it helps us greatly in distinguishing the distance of objects that are about us, both with respect to ourselves and them, and with respect to themselves with one another, yet it can do nothing with the very remote. We see that immense concave circle, in which we suppose the fixed stars to be placed, at all this vast remove from us, and no change of place that we could make to get nearer to it, would be of any avail for determining the distance of the stars from one another. If we look at three or four churches from a distance of as many miles, we see them stand in a certain position with regard to one another. If we advance a great deal nearer to them, we see that position differ, but, if we move forward only 8 or 10 feet, the difference is not perceptible.

Thus, during the last two centuries, numerous doubts and disputations have been held among anatomists and philosophers, on the immediate mode and means of vision by the eye: some ascribing it to the instrumentality of the retina spread over the bottom or posterior part of the eye; and others to the opaque choroides, immediately behind the retina. By dissecting the eyes of animals, to discover the nature and uses of the several humours and coats of that organ, it appears that the eye is justly considered as a natural achromatic instrument, or camera obscura, in which pictures of the external objects are exhibited as painted on the retina, by rays introduced through the aperture of the pupil. This was beautifully demonstrated by the celebrated discovery of Scheiner. By taking the eye of an ox, recently killed, and stripping the sclerotic coat with the choroides from its posterior portion, carefully preserving the retina as it lies upon the vitreous humour; then placing the eye in a suitable aperture in the window-shutter of a darkened chamber, with the cornea outwards, a transparent miniature painting of the external landscape, in all its variety of figures and colours, is exhibited on the retina: this experiment established the general idea that it is these pictures that we see, the sensations of which are conveyed to the sensorium by the optic nerve, the expansion of its substance forming the retina.

This discovery however introduced a new difficulty: the objects exhibited on the retina were found to be completely inverted, the upper side being undermost, and the right side changed to the left, and vice versa. Though this inversion might be the natural optical effect of the structure of the eye, how comes it that we do not usually see objects by our eyes inverted, but always in their natural position. This circumstance led to numerous disquisitions, mechanical, optical, and metaphysical, to account for it—In the controversy relating to which are found the names of Kepler, Descartes, Newton, Hooke, Lahire, Berkeley, Porterfield, Smith, Reid, Michell, Priestley, Mariotte, Picard, Pacquet, and many others; most of these agreeing to the general idea of the retina being the chief cause of vision, but mostly endeavouring to account for the circumstance of the inversion of the images, while nevertheless the objects are seen in their due positions. At length it was accidentally discovered by Mariotte, that there is a particular part in the bottom of the eye on which no image is painted, or on which the rays have no effect, viz. the part where the optic nerve is inserted. Now if the retina is only the extension or continuation of this part, Mariotte inferred that if this were the cause of vision, the insertion of the nerve ought to be at least as sensible to the rays of light, as the rest of the retina, which is only a diffusion of the former. M. considering farther that the choroides lined the whole of the bottom of the eye, excepting the place of the insertion of the optic nerve, that is, the whole of the space exhibiting the painted images, he concluded that the choroides was the real seat and cause of vision, and not the retina.

This discovery and conclusion gave a new turn to the question, and the disquisitions of philosophers. Most of the before-mentioned persons entered into the dispute, some adopting the one opinion and some the other, but without coming to any settled and general decision. Dr. Porterfield agrees with the most part of optical writers, that the retina is the true seat of vision; and that though it is expanded over the whole concave surface of the eye as far as the ligamentum ciliare, yet it is not all equally sensible. While Mr. Walker, with several others, is of a contrary opinion: towards the close of his disquisition on vision this author adds, consistently with the theory just delivered, "I should conclude, that we have a decided proof that the posterior part of the retina is utterly insensible, since at the entrance of the nerve, where it exists in the greatest quantity, it can be demonstrated to be so; and that vision is wanting at this spot precisely, because where the nerve enters there is no choroides to reflect the rays to the sensible anterior portion." Dr. Reid, also decidedly concludes, "We have reason to believe that the rays of light make some impression on the retina; but we are not conscious of this impression; nor have anatomists or philosophers been able to discover the nature and effects of it; whether it produce a vibration in the nerve, or motion of some subtile fluid in the nerve, or something different from either, to which we cannot give a name." See an account of the several arguments of the different writers, at the end of Dr. Priestley's History of Optics.

After the contrary ideas and disquisitions of all the opticians and physiologists about the preference due to the one or the other of the two coats, the retina and the choroides, we have just seen a small pamphlet, part of a promised greater work, the production of a clergyman of the name of Horn, on "The Seat of Vision," in 8vo. 1813. In this little piece, after a neat and concise account of the different hypotheses and arguments of his predecessors in this line, the author relates some ingenious experiments accompanied with reflections on the subject, and finally deduces a theory which appears more rational and satisfactory than any of the former. He discharges the retina and the choroides each from the sole and exclusive office that had been assigned to it by the former contending parties, and assigns to each its necessary, but subordinate office, in the faculty of vision, the principle and ultimate part being performed by the optic nerve, which conveys the sensation immediately to the sensorium in the brain.

After some pertinent reflections this author adds, "Persuaded, therefore, that I had actually discovered the true origin of the retina, and that it had in consequence lost all claim to superior sensibility, and to the principle function in vision, I was induced, from a general survey of the organ, to conclude that the sole use of this transparent membrane, in the mechanism of vision, is to produce reflection, in a manner similar to the polished surface of a metallic reflector, or perhaps it might, with more propriety, be compared to glass, the choroides behind answering the purpose of the metallic coating upon the convex surface of a mirror.

"In prosecuting this inquiry, several circumstances contributed to direct my attention to the optic nerve, as the grand organ of vision. In surveying the general structure of the eye, I was particularly struck with the magnitude of this nerve, and the singular manner of its termination in the concave surface of the globe. The *optici* do not, like every other pair of nerves, terminate in branches; they are the largest in the system, yet the entire nervous substance *perforates* the globe *perpendicularly*, presenting in its concavity a well defined *circular base*, fringed with the choroides, and covered with the retina. The base was not only rendered remarkably distinct, by the following experiment; but at the same time I observed a beautiful effect produced by light upon the nerve. Having procured the eye of an ox recently killed, after dividing it transversely, and abstracting the vitreous humour from its posterior portion, leaving about 4 lines of the nerve attached, I placed the segment of the globe in a suitable aperture made in a window-shutter, with the concave surface inwards. Thus situated, having darkened the chamber, the base of the nerve exhibited, in its little hemisphere, an appearance beautifully distinct and luminous, having a striking resemblance to the sun, as seen through one of those brownish fogs with which the atmosphere is sometimes charged in the winter season. The light which produced this phenomenon, must have pervaded the whole extent of the nerve; for, being completely inclosed by the muscles and fat, it was impossible that any lateral light could have contributed to the appearance. The same phenomenon may be seen, though with less effect, by holding a similar portion of the globe between the eye and a lighted candle.

"The reader must have anticipated, and therefore will now readily comprehend the manner in which I conceive vision to be accomplished. Rays, from all points of such objects as are opposed to the organ, pass through the pupil, and, after refraction in the different humours, delineate perfect, but inverted pictures, on the retina at the bottom of the eye; these pictures are instantly reflected, in their various colours and shades, on the anterior portion of the concavity; another reflection from hence raises images of the external objects near the middle of the vitreous humour, in their natural order and position; these images make due impressions on the opposite base of the nerve, which are transmitted by it to the brain: thus the sensation is produced, and vision performed.

"Ever since Scheiner exhibited those beautiful pictures on the retina, philosophers have supposed the mind, *somehow*, affected by the impressions made on this membrane; but, mistaking the proper organ, they always found the optical phenomena, and the sensations of vision, at variance, and laboured in vain to reconcile them. However, having demonstrated, that neither the retina, nor the choroides, is the immediate seat of vision; and having restored the optic nerve to that dignified function in the theory which it naturally possesses in the organ, all the inferior instruments will be found harmoniously cooperating with it, in producing the various phenomena of vision.

"It is no longer a question, why the optic nerve has so very large a trunk bestowed on it; why the whole nervous substance enters the globe *perpendicularly*, and its *circular* base appears within, *destitute* of the choroides. If the medullary substance had not perforated the globe, or if the choroide membrane had covered the base of the nerve; in either case, it is evident, there could have been no impression made by the images in the eye on the nervous substance; consequently, in such a disposition of things, there would have been no vision.

"However, notwithstanding this surprising coincidence of things, in favour of the base of the nerve, as the immediate instrument of vision, those conversant with the subject may have foreseen what they deem an insuperable objection, which, as soon as it appears, they expect to find me drop, and the whole superstructure I have been raising come to the ground. In short, it is nothing less than the well-known fact, demonstrated by the experiment of Mariotte, that the organ is totally insensible to the impression of light, at the very spot that I have fixed on as the proper seat of vision.

"This phenomenon, I confess, appeared for some time a formidable obstacle; still, I felt a certain confidence powerfully inciting me to perseverance. More disposed to suspect some error in the conclusions drawn by philosophers from the experiment, than to doubt those principles, in the structure of the organ, by which the visual image is not only rectified, and other difficult phenomena solved, but upon which I conceived a satisfactory theory of vision might be established; I proceeded, the more anxiously, to seek another solution of this optical difficulty, than that commonly received.

"This insensible spot in the organ of vision is indeed the hidden rock, on which the most specious theories have been lost. Philosophers have been guilty of a fatal oversight—they have totally mistaken the real cause of this wonderful defect in vision; and consequently have left the most beautiful, if not the most important department of physical science, enveloped in mystery, and surrounded with difficulties, which they confess to be inexplicable. The following optical facts will at once dispel the darkness which has so long hung over this region of philosophy.

"If we take a convex lens, and place it in the window shutter of a dark room, and the eye be successively directed towards it, three effects will be produced. When the eye is situated farther from the lens than the focus of parallel rays, a very distinct, but diminished landscape, with all the objects inverted, is seen in the lens. On the contrary, if the eye be posited within the focal distance, the objects appear in their natural position, enlarged, but very indistinct. Now, undoubtedly, the medium distance between these two situations, in which the appearances of the objects are so very different, is the true focus of the lens, and the place where the images would be painted on a sheet of paper interposed. But when the eye is brought to occupy this point, no image whatever, in the lens, impresses the organ; a circular spot only is perceived, uniformly tinged with the prevailing colour of the landscape: for instance, if the ground be covered with snow the lens appears white; if the surrounding scenery consists of verdant fields, woods, &c, the colour exhibited by the lens is green; or if the prospect be upward to the sky, the lens in this case assumes an azure hue.

"Thus, the cause of that mysterious defect in the field of vision is detected; the above fact affording a clear demonstration of the effect produced on the base of the optic nerve, by the famous experiment with the patch upon the wall. Let the wall in this experiment be blue, or green, or any colour whatever, the paper is constantly lost in the general hue of the ground upon which it is fixed. But if the loss of the object proceeded from a real insensibility of the nerve, or retina at this place, whatever the colour of the wall might be, a very perceptible *dark* spot would, invariably, be substituted in its stead. So far is this, however, from being the effect produced by the experiment, that, when the wall happens to be white, and even a *black* paper is fixed upon it, no obscurity can be discerned: the black patch is entirely lost, and an uniform whiteness takes possession of its place.

"After this induction of facts, confirmed by the laws of optics, the conclusion can no longer be doubtful, that the surprising defect in vision, discovered by Mariotte, is neither to be attributed to any insensibility in the retina, nor to the nerve itself, which is the true seat of vision: the phenomenon proceeds solely from the pupil. When the base of the nerve is brought, by distorting the organ, into a straight direction with the pupil and the object, the pencils of rays, proceeding from the pupil, have their foci on the base of the nerve; and therefore, agreeably to the phenomenon of the lens above described, that portion of the cornea and humours in the axis of the eye, equal to the diameter of the pupil, is tinged with the colour of the ground upon which the paper is fixed; therefore, while the object, situated in a line with the pupil and base of the nerve, makes no impression upon this, still, the surrounding objects have their forms distinctly painted upon and reflected from the retina. The images, thus formed in the vitreous humour, make the same impressions upon the base of the nerve, as in ordinary vision: and hence a faithful representation is made to the mind of the whole scene, except that portion in the centre corresponding to the dimensions of the pupil, &c." See Mr. Hurn's tract above referred to.

Vision, in Optics. The laws of vision, brought under mathematical demonstrations, make the subject of optics, taken in the greatest latitude of that word: for, among mathematical writers, optics is generally taken, in a more restricted signification, for the doctrine of direct vision: catoptrics, for the doctrine of reflected vision; and dioptrics, for that of refracted vision.

Direct or *Simple* Vision, is that which is performed by means of direct rays; that is, of rays passing directly, or in right lines, from the radiant point to the eye. Such is that explained in the preceding article.

Reflected Vision, is that which is performed by rays reflected from speculums, or mirrors. The laws of which, see under Reflection, and Mirror.

Refracted Vision, is that which is performed by means of rays refracted, or turned out of their way, by passing through mediums of different density; chiefly through glasses and lenses. The laws of this, see under the article Refraction.

Arch of Vision. See Arch.

Distinct Vision, is that by which an object is seen distinctly. An object is said to be seen distinctly, when its outlines appear clear and well defined, and the several parts of it, if not too small, are plainly distinguishable, so that they can easily be compared one with another, in respect to their figure, size, and colour.

In order to such distinct vision, it had commonly been thought that all the rays of a pencil, flowing from a physical point of an object, must be exactly united in a physical, or at least in a sensible point of the retina. But Dr. Jurin has made it appear from experiments, that such an exact union of rays is not always necessary to distinct vision. He shows that objects may be seen with sufficient distinctness, though the pencils of rays issuing from the points of them do not unite precisely in the same point on the retina; but that since, in this case, pencils from either point either meet before they reach the retina, or tend to meet beyond it, the light that comes from them must cover a circular spot on it, and will therefore paint the image larger than perfect vision would represent it. Whence it follows, that every object, placed either too near or too remote for perfect vision, will appear larger than it is by a penumbra of light, caused by the circular spaces, which are illuminated by pencils of rays proceeding from the extremities of the object.

The smallest distance of perfect vision, or that in which the rays of a single pencil are collected into a physical point on the retina in the generality of eyes, Dr. Jurin, from a number of observations, states at 5, 6, or 7 inches. The greatest distance of distinct and perfect vision he found was more difficult to determine; but by considering the proportion of all the parts of the eye, and the refractive power of each, with the interval that may be discerned between two stars, the distance of which is known, he fixes it, in some cases, at 14 feet 5 inches; though Dr. Porterfield had restricted it to 27 inches only, with respect to his own eye.

For other observations on this subject, see Jurin's Essay on Distinct and Indistinct Vision, at the end of Smith's Optics; and Robins's Remarks on the same, in his Math. Tracts, vol. 2, pa. 278 &c. See also an ingenious paper on Vision in the Philos. Trans. 1793, pa. 169, by Dr. Thomas Young.

Field of Vision. See Field.

VISUAL, relating to sight, or seeing.

Visual *Angle*, is the angle under which an object is seen, or which it subtends. See Angle.

Visual *Line*. See Line.

Visual *Point*, in Perspective, is a point in the horizontal line, where all the ocular rays unite. Thus, a person standing in a long straight gallery, and looking forward; the sides, floor, and cieling seem to meet and touch one another in this point, or common centre.

Visual *Rays*, are lines of light, conceived to come from an object to the eye.

VITELLIO, or Vitello, a Polish mathematician, of the 13th century, as he flourished about 1254. We have of his a large Treatise on Optics, the best edition of which is that of 1572. Vitello was the first optical writer of any consequence among the modern Europeans. He collected all that was given by Euclid, Archimedes, Ptolemy, and Alhazen; though his work is of but little use in the present day.

VITREOUS *Humour*, or *Vitreus Humor*, denotes the third or glassy humour of the eye; thus called from its resemblance to melted glass. It lies under the crystalline; by the impression of which, its fore part is rendered concave. It greatly exceeds in quantity both the aqueous and crystalline humours taken together, and consequently occupies much the greatest part of the cavity of the globe of the eye. Scheiner says, that the refractive power of this humour is a medium between those of the aqueous, which does not differ much from water, and of the crystalline, which is nearly the same with glass. Hawksbee makes its refractive power the same with that of water; and, according to Robertson, its specific gravity agrees nearly with that of water.

VITRUVIUS (Marcus Vitruvius Pollio), a celebrated Roman architect, of whom however nothing particular is known, but what is to be collected from his ten books De Architectura, still extant. In the preface to the sixth book he states, that he was carefully educated by his parents, and instructed in the whole circle of arts and sciences; a circumstance which he speaks of with much gratitude, laying it down as certain, that no man can be a complete architect, without some knowledge and skill in every one of them. And in the preface to the first book he informs us, that he was known to Julius Cæsar; that he was afterwards recommended by Octavia to her brother Augustus Cæsar; and that he was so favoured and provided for by this emperor, as to be out of all fear of poverty as long as he might live.

It is supposed that Vitruvius was born either at Rome or Verona; but it is not known which. His books of architecture are addressed to Augustus Cæsar, and not only show consummate skill in that particular science, but also very uncommon genius and natural abilities. Cardan, in his 16th book De Subtilitate, ranks Vitruvius as one of the 12 persons, whom he supposes to have excelled all men in the force of genius and invention; and would not have scrupled to have given him the first place, if it could be imagined that he had delivered nothing but his own discoveries. Those 12 persons were, Euclid, Archimedes, Apollonius Pergæus, Aristotle, Archytas of Tarentum, Vitruvius, Achindus, Mahomet Ibn Moses the inventor or improver of Algebra, Duns Scotus, Richard Suisset surnamed the Calculator, Galen, and Heber of Spain.

The architecture of Vitruvius has been often printed; but the best edition is that of Amsterdam in 1649. Perrault also, the noted French architect, gave an excellent French translation of the same, with the addition of notes and figures; the first edition of which was published at Paris in 1673, and the second, much improved, in 1684. —Mr. William Newton too, an ingenious architect, and late surveyor to the works at Greenwich Hospital, published in 1780 &c, curious commentaries on Vitruvius, illustrated with figures; to which is added a description, with figures, of the Military Machines used by the Ancients.

VIVIANI (Vincentio), a celebrated Italian mathematician, was born at Florence in 1621 or 1622. He was the last disciple of the illustrious Galileo, and lived with him from the 17th to the 20th year of his age. After the death of his great master, he passed two or three years more in prosecuting geometrical studies without interruption; and in this time it was that he formed the design of his Restoration of Aristeus. This ancient geometrician, who was contemporary with Euclid, had composed five books of problems De Locis Solidis, the bare propositions of which were collected by Pappus, but the books are entirely lost; which Viviani undertook to restore by the force of his genius.

He discontinued this work, however, before it was finished, in order to apply himself to another of the same kind; and that was, to restore the 5th book of Apollonius's Conic Sections. While he was engaged in this, the famous Borelli found, in the library of the grand duke of Tuscany, an Arabic manuscript, with a Latin inscription, which imported, that it contained the 8 books of Apollonius's Conic Sections; of which the 8th however was not found to be there. He carried this manuscript to Rome, in order to translate it, with the assistance of a professor of the Oriental languages. Viviani, very unwilling to lose the fruits of his labours, procured a certificate that he did not understand the Arabic language, and knew nothing of that manuscript: he was so jealous on this head, that he would not even suffer Borelli to send him an account of any thing relating to it. At length he finished his book, and published it, 1659, in folio, with this title, De Maximis & Minimis Geometrica Divinatio in quintum Conicorum Apollonii Pergæi. It was found that he had more than divined; as he seemed superior to Apollonius himself.

After this, Viviani was obliged to interrupt his studies for the service of his prince, in an affair of great importance, which was, to prevent the inundations of the Tiber, in which Cassini and he were employed for some time, though nothing was entirely executed.

In 1664 he had the honour of a pension from Louis the 14th, a prince to whom he was not subject, nor could indeed be useful. In consequence he resolved to finish his Divination on Aristeus, with a view to dedicate it to that prince; but he was interrupted in this task again by public works, and some negociations which his royal master intrusted to him.—In 1666 he was honoured by the grand duke with the title of his first mathematician.—He resolved three problems, which had been proposed to all the mathematicians of Europe, and dedicated the work to the memory of Mr. Chapelain, under the title of Enodatio Problematum &c.—He proposed the problem of the quadrable spherical surface, of which Leibnitz and l'Hospital gave solutions by the Calculus Differentialis. —In 1669, he was chosen to fill, in the Royal Academy of Sciences, a place among the 8 foreign associates. This new favour reanimated his zeal; and he published three books of his Divination on Aristeus, at Florence in 1701, which he dedicated to the king of France. It is a thin folio, entitled, De Locis Solidis secunda Divinatio Geometrica, &c. This was a second edition enlarged; the first having been printed at Florence in 1673.—Viviani employed the fortune, which he had raised by the bounties of his prince, in building a magnificent house at Florence; in which he placed a bust of Galileo, with several inscriptions in honour of that great man; and died in 1703, at 81 years of age.

Viviani had, says Fontenelle, that innocence and simplicity of manners which persons commonly preserve, who have less commerce with men than with books; without that roughness, and a certain savage fierceness, which those often acquire who have only to deal with books, not with men. He was affable, modest, a steady and faithful friend, and, what includes many virtues in one, he was grateful in the highest degree for favours.

ULLAGE, *of a Cask*, in Gauging, is so much as it wants of being full.

ULLOA (Don Antonio de), a learned Spaniard, was born in 1716, and died in 1795. His progress in science was so rapid, that at the age of 18 he was associated with George Juan and la Condamine, at the instance of Louis the 15th of France, and under the patronage of the king of Spain, to proceed to South America, to make observations for ascertaining the figure of the earth. He continued in America till 1744, when returning, he was taken prisoner, and brought to England, where he was elected a F. R. S. He was afterwards made governor of Louisiana. An account of his voyage was published at Madrid in 1748, in 5 vols. 4to.

ULTERIOR, in Geography, is applied to some part of a country or province, which, with regard to the rest of that country, is situate on the farther side of a river, or mountain, or other boundary, which divides the country into two parts.

ULTIMATE Ratios. See Prime, &c.

ULTRAMUNDANE, beyond the world, is that part of the universe supposed to be without or beyond the limits of our world or system.

UMBILICUS, and Umbilical *Point*, in Geometry, the same with focus.

UMBRA, a Shadow. See Light, Shadow, Penumbra, &c.

UNCIA, a term generally used for the 12th part of a thing; in which sense it occurs in Latin writers, both for a weight, called by us an ounce, and a measure called an inch.

UNCIÆ, in Algebra, first used by Vieta, are the numbers prefixed to the letters in the terms of any power of a binomial; now more usually, and generally, called coefficients. Thus, in the 4th power of $a + b$, viz, $a^4 + 4a^3b + 6a^2b^2 + 4ab^3 + b^4$, the unciæ are 1, 4, 6, 4, 1.

Briggs first showed how to find these unciæ, one from another, in any power, independent of the foregoing powers. They are now usually found by what is called Newton's binomial theorem, which is the same rule as Briggs's, but in another form. See Binomial.

UNDECAGON, is a polygon of eleven sides.

If the side of a regular undecagon be 1, its area will be

9·3656399 = $\frac{11}{4}$ × tang. of $73\frac{7}{11}$ degrees; and therefore if this number be multiplied by the square of the side of any other regular undecagon, the product will be the area of that undecagon. See my Mensuration, pa. 85, &c, 4th edit.

UNDETERMINED, is sometimes used for INDETERMINATE.

UNDULATORY *Motion*, is applied to a motion in the air, by which its parts are agitated like the waves of the sea; as is supposed to be the case when the string of a musical instrument is struck. This undulatory motion of the air is supposed the matter or cause of sound.—Instead of the undulatory, some authors choose to call this a vibratory motion.

UNEVEN *Number*, the same as odd number, or such as cannot be divided by 2 without leaving 1 remaining. The series of uneven numbers are 1, 3, 5, 7, 9, &c. See NUMBER, and ODD *Number*.

UNFORMED *Stars*, are such as were not contained in the constellations. But on the modern celestial globes, the constellations are made to include those unformed stars.

UNGULA, in Geometry, is a part cut off a cylinder, cone, &c, by a plane passing obliquely through the base, and part of the curve surface; so called from its resemblance to the (ungula) hoof of a horse &c. For the contents &c of such ungulas, see my Mensuration, pa. 161, &c, 4th edition.

UNICORN, in Astronomy. See MONOCEROS.

UNIFORM or *Equable Motion*, is that by which a body passes always with the same celerity, or over equal spaces in equal times. See MOTION.—In uniform motions, the spaces described or passed over, are in the compound ratio of the times and velocities; but the spaces are simply as the times, when the velocity is given; and as the velocities, when the time is given.

UNIFORM *Matter*, in Natural Philosophy, is that which is all of the same kind and texture.

UNISON, in Music, is when two sounds are exactly alike, or the same note, or tone. What constitutes a unison, is the equality of the number of vibrations, made in the same time, by the two sonorous bodies.—It is a noted phenomenon in music, that an intense sound being raised, either with the voice or a sonorous body, another sonorous body near it, whose tone is either unison or octave to that tone, will sound its proper note, unison or octave, to the given note. The experiment is easily tried with the strings of two instruments; or with a voice and harpsichord; or a bell, or even a drinking-glass.

This phenomenon is thus accounted for: One string being struck, and the air put into a vibratory motion by it; every other string, within the reach of that motion, will receive some impression from it: but each string can only move with a determinate velocity of recourses or vibrations; and all unisons proceed from equal vibrations; and other concords from other proportions of vibration. The unison string then, keeping equal pace with the sounding string, as having the same measure of vibrations, must have its motion continued, and still improved, till at length its motion become sensible, and it give a distinct sound. Other concording strings have their motions propagated in different degrees, according to the frequency of the coincidence of their vibrations with those of the sounded string: the octave therefore most sensibly; then the 5th; after which, the crossing of the motions prevents any sensible effect.

This is illustrated, as Galileo first suggested, by the pendulum; which being set a-moving, the motion may be continued and augmented, by making frequent, light, coincident impulses; as blowing on it when the vibration is just finished: but if it be touched by any cross or opposite motion, and that frequently, the motion will be interrupted, and cease altogether. So, of two unison strings, if the one be forcibly struck, it communicates motion, by means of the air, to the other; and both performing their vibrations together, the motion of that other will be improved and heightened by the frequent impulses received from the vibrations of the first, because given precisely when the other has finished its vibration, and is ready to return: but if the vibrations of the chords be unequal in duration, there will be a crossing of motions, more or less, according to the proportion of the inequality; by which the motion of the untouched string will be so checked, as never to be sensible. And this we find to be the case in all consonances, except unison, octave, and the fifth.

UNIT, UNITE, or UNITY, in Arithmetic, the number one, or one single individual part of discrete quantity. See NUMBER.—The place of units, is the first place on the right hand in integer numbers.—According to Euclid, unity is not a number, for he defines number to be a multitude of units.

UNITY, the abstract or quality which constitutes or denominates a thing *one*.

UNIVERSE, a collective name, signifying the assemblage of heaven and earth, with all things in them. The Ancients, and after them the Cartesians, imagine the universe to be infinite; and the reason they give is, that it implies a contradiction to suppose it finite or bounded; since it is impossible not to conceive space beyond any limits that can be assigned; which space, according to the Cartesians, is body, and consequently part of the universe.

UNLIKE *Quantities*, in Algebra, are such as are expressed by different letters, or by different powers of the same letter. Thus, a, and b, and a^2, and ab are all unlike quantities.

UNLIKE *Signs*, are the different signs + and −.

UNLIMITED or *Indeterminate Problem*, is such a one as admits of many, or even of infinite answers. As, to divide a given triangle into two equal parts; or to describe a circle through two given points. See DIOPHANTINE and INDETERMINATE.

VOID *Space*, in Physics. See VACUUM.

VOLTAISM, or GALVANISM, is a curious and important branch of electricity, depending on metallic combinations first accidentally discovered by professor Galvani, of Bologna, about the year 1790. As we are indebted to that gentleman for the earliest insulated facts which paved the way to this science; so it appears we are indebted to professor Volta for their explanation, and application to purposes of real utility; and to sir Humphry Davy for the grand and simple law of nature by which they operate in the production of effects.

For a history of the dicovery and practice of this curious branch of electricity, see our article GALVANISM.

VOLUTE, in Architecture, a kind of spiral scroll, and used in the Ionic and Composite capitals; of which it makes the principal characteristic and ornament.

VORTEX, or WHIRLWIND, in Meteorology, a sudden, rapid, violent motion of the air, in circular whirling directions.

VORTEX is also used for an eddy or whirlpool, or a body of water, in certain seas and rivers, which runs rapidly round, forming a sort of cavity in the middle.

VORTEX, in the Cartesian Philosophy, is a system or collection of particles of matter moving the same way, and about the same axis.—Such vortices are the grand machines by which these philosophers attempt to solve most of the motions and other phenomena of the heavenly bodies. And accordingly, the doctrine of these vortices makes a great part of the Cartesian philosophy.

The matter of the world they hold to have been divided at the beginning into innumerable small equal particles, each endowed with an equal degree of motion, both about its own centre, and separately, so as to constitute a fluid. Several systems, or collections of this matter, they further state, have been endowed with a common motion about certain points, as common centres, placed at equal distances, and that the matters, moving round these, composed so many vortices.

Then, the primitive particles of the matter they suppose, by these intestine motions, to become, as it were, ground into spherical figures, and so to compose globules of divers magnitudes; which they call the matter of the second element: and the particles rubbed, or ground off them, to bring them to that form, they call the matter of the first element. And since there would be more of the first element than would suffice to fill all the vacuities between the globules of the second, they suppose the remaining part to be driven towards the centre of the vortex, by the circular motion of the globules; and that being there amassed into a sphere, it would produce a body like the sun.

This sun being thus formed, and moving about its own axis with the common matter of the vortex, would necessarily throw out some parts of its matter, through the vacuities of the globules of the second element constituting the vortex; and this especially at such places as are farthest from its poles; receiving, at the same time, in, by these poles, as much as it loses in its equatorial parts. And, by this means, it would be able to carry round with it those globules that are nearest, with the greater velocity; and the remoter, with less. And by this means, those globules which are nearest the centre of the sun, must be smallest; because, were they greater, or equal, they would, by reason of their velocity, have a greater centrifugal force, and recede from the centre. If it should happen, that any of these sun-like bodies, in the centres of the several vortices, should be so incrustated, and weakened, as to be carried about in the vortex of the true sun; if it were of less solidity, or had less motion, than the globules towards the extremity of the solar vortex, it would descend towards the sun, till it met with globules of the same solidity, and susceptible of the same degree of motion with itself; and thus, being fixed there, it would be for ever after carried about by the motion of the vortex, without either approaching any nearer to the sun, or receding from it; and so would become a planet.

Supposing then all this; we are next to imagine, that our system was at first divided into several vortices, in the centre of each of which was a lucid spherical body; and that some of these, being gradually incrustated, were swallowed up by others which were larger and more powerful, till at length they were all destroyed, and received by the largest solar vortex; except some few which were thrown off in right lines from one vortex to another, and so became comets.

But this doctrine of vortices is, at best, merely hypothetical. It does not pretend to show by what laws and means the celestial motions are effected, so much as by what means they possibly might, in case it should have so pleased the Creator. But we have another principle which accounts for the same phenomena as well, and far better than that of vortices; and which we plainly find has an actual existence in the nature of things: and this is gravity, or the weight of bodies.

There is, in the Philosophical Transactions, a Physico-mathematical demonstration of the impossibility and insufficiency of vortices to account for the Celestial Phenomena; by Mons. de Sigorne. See No. 457, sect. vi. pa. 409 et seq.—This author endeavours to show, that the mechanical generation of a vortex is impossible; and that it has only an axifugal force, and not a centrifugal and centripetal one; that it is not sufficient for explaining gravity and its properties; that it destroys Kepler's astronomical laws; and therefore he concludes, with Newton, that the hypothesis of vortices is fitter to disturb than explain the celestial motions. We must refer to the dissertation itself for the proof of these assertions. See CARTESIAN PHILOSOPHY.

But these vortices having long since been excluded by all philosophers, as utterly inconsistent with the laws and phenomena of the universe, it is useless to dwell longer upon them.

VOSSIUS (GERARD JOHN), one of the most learned and laborious writers of the 17th century, was of a considerable family in the Netherlands; and was born in 1577, in the Palatinate near Heidelberg, at a place where his father, John Vossius, was minister. He first learned Latin, Greek, and Philosophy at Dort, where his father had settled, and died. In 1595 he went to Leyden, where he farther pursued these studies, in conjunction with mathematics, in which science he made a considerable progress. He became master of arts and doctor in philosophy in 1598; and soon after, director of the college at Dort; then, in 1614, director of the theological college just founded at Leyden; and, in 1618, professor of eloquence and chronology in the academy there, the same year in which appeared his History of the Pelagian Controversy. This history procured him much odium and disgrace on the continent, but an ample reward in England, where archbishop Laud obtained leave of king Charles the 1st for Vossius to hold a prebendary in the church of Canterbury, while he resided at Leyden: this was in 1629, when he came over to be installed, took a doctor of laws degree at Oxford, and then returned.—In 1633 he was called to Amsterdam to fill the chair of a professor of history; where he died in 1649, at 72 years of age; after having written and published as many works as, when they came to be collected and printed at Amsterdam in 1695 &c, made 6 volumes folio, writings which will long continue to be read with pleasure and profit. The principal of these are,—1. Etymologicon Linguæ Latinæ.—2. De Origine & Progressu Idololatriæ.—3. De Historicis Græcis.—4. De Historicis Latinis.—5. De Arte Grammatica.—6. De Vitiis Sermonis & Glossematis Latino-Barbaris.—7 Institutiones Oratoriæ.—8. Institutiones Poeticæ.—9. Ars Historica.—10. De quatuor Artibus popularibus, Grammatice, Gymnastice, Musice, & Graphice.—11. De Philologia.—12. De Universa Matheseos Natura & Constitutione.—13. De Philosophia.—14. De Philosophorum Sectis.—15. De Veterum Poetarum Temporibus.

Vossius (Denis), son of the foregoing, died at 22 years of age, a prodigy of learning, whose incessant studies brought on him so immature a death. There are of his, among other smaller pieces, Notes on Cæsar's Commentaries, and on Maimonides on Idolatry.

Vossius (Francis), brother of Denis and son of Gerard John, died in 1645, after having published a Latin poem in 1640, on a naval victory gained by the celebrated Van Tromp.

Vossius (Gerard), brother of Denis and Francis, and son of Gerard John, wrote Notes upon Paterculus, which were printed in 1639. He was one of the most learned critics of the 17th century; but died in 1640, like his two brothers, at a very early age, and before their father.

Vossius (Isaac), was the youngest son of Gerard John, and the only one that survived him. He was born at Leyden in 1618, and was a man of great talents and learning. His father was his only preceptor, and his whole time was spent in study. His merit recommended him to a correspondence with queen Christina of Sweden, who employed him in some literary commissions. At her request, he made several journeys into Sweden, where he had the honour to teach her the Greek language; though she afterwards discarded him on hearing that he intended to write against Salmasius, for whom she had a particular regard. In 1663 he received a handsome present of money from Louis the 14th of France, accompanied with a complimentary letter from the minister Colbert.—In 1670 he came over to England, when he was created doctor of laws at Oxford, and king Charles the 2d made him canon of Windsor; though he knew his character well enough to say, there was nothing that Vossius refused to believe, excepting the Bible. He appears indeed, by his publications, which are neither so numerous nor so useful as his father's, to have been a most credulous man, while he afforded many circumstances to bring his religious faith in question. He died at his lodgings in Windsor Castle, in 1689; leaving behind him the best private library, as it was then supposed, in the world; which, to the shame and reproach of England, was suffered to be purchased and carried away by the university of Leyden. His publications chiefly were:—1. Periplus Scylacis Caryandensis, &c, 1639.—2. Justin, with Notes, 1640.—3. Ignatii Epistolæ, & Barnabæ Epistola, 1646.—4. Pomponius Mela de Situ Orbis, 1648.—5. Dissertatio de vera Ætate Mundi, &c, 1659.—6. De Septuaginta Interpretibus, &c, 1661.—7. De Luce, 1662.—8. De Motu Marium & Ventorum.—9. De Nili & aliorum Fluminum Origine.—10. De Poematum Cantu & Viribus Rythmi, 1673.—11. De Sibyllinis aliisque, quæ Christi natalem præcessere, 1679.—12. Catullus, & in eum Isaaci Vossii Observationes, 1684.—13. Variarum Observationum liber, 1685, in which are contained the following pieces: viz, De Antiquæ Romæ & aliarum quarundam Urbium Magnitudine; De Artibus & Scientiis Sinarum; De Origine & Progressu Pulveris Bellici apud Europæos; De Triremium & Liburnicarum Constructione; De Emendatione Longitudinum; De patefacienda per Septentrionem ad Japonenses & Indos Navigatione; De apparentibus in Luna circulis; Diurna Telluris conversione omnia gravia ad medium tendere.

VOUSSOIRS, vault-stones, are the stones which immediately form the arch of a bridge, &c, being cut somewhat in the manner of a truncated pyramid or wedge, their under sides constituting the intrados, to which their joints or ends should be every where in a perpendicular direction.

The length of the middle voussoir, or key-stone, and which is the least of all, should be about $\frac{1}{15}$ or $\frac{1}{16}$th of the span of the arch; from hence these stones should be made larger and larger, all the way down to the impost; that they may the better sustain the great weight which rests upon them, without being crushed or broken, and that they may also bind the firmer together.

To find the just length of the voussoirs, or the figure of the extrados, when that of the intrados is given; see the Principles of Bridges in my Tracts, or Emerson's Construction of Arches, in his volume of Miscellanies.

URANIBURGH, or celestial town, the name of a celebrated observatory, in a castle in the little island Weenen, in the Sound; built by the celebrated Danish astronomer, Tycho Brahé, who furnished it with instruments for observing the course and motions of the heavenly bodies.—This observatory, which was finished about the year 1580, had not subsisted above 17 years when Tycho, who little thought to have erected an edifice of so short a duration, and who had even published the figure and position of the heavens, which he had chosen for the moment to lay the first stone in, was obliged to abandon his country. Soon after this, the persons to whom the property of the island was given, demolished the building: part of the ruins was dispersed into divers places: the rest served to build Tycho a handsome seat upon his ancient estate, which to this day bears the name of Uraniburgh; and it was here that Tycho composed his catalogue of the stars. Its latitude is 55° 54′ north, and longitude 12° 47′ east of Greenwich.

M. Picart, making a voyage to Uraniburgh, found that Tycho's meridian line, there drawn, deviated from the meridian of the world; which seems to confirm the conjecture of some persons, that the position of the meridian line may vary.

URANOLITE; the same as Aerolite.

URANUS, a new primary planet, discovered by Dr. Herschel at Bath, in the night of March 13, 1781. It is sometimes also called the Georgian Planet, and the New Planet, from its having been newly or lately discovered, also Herschel's Planet, from the name of its discoverer, and the Planet Herschel, or simply Herschel. The planet is denoted by this character ♅.

This planet is the remotest of all those that are yet known, though not the largest, being in point of magnitude less than Saturn and Jupiter. Its light, says Dr. Herschel, is of a bluish-white colour, and its brilliancy between that of Venus and the moon. With a telescope that magnifies about 300 times, it appears to have a very well defined visible disk; but with instruments of a small power, it can hardly be distinguished from a fixed star of between the 6th and 7th magnitude. In a very fine clear night, when the moon is absent, a good eye will perceive it without a telescope.

From the observations and calculations of Dr. Herschel and other astronomers, the elements and dimensions &c of this planet, have been collected as below.

Place of the node - - - -	2ˢ 11° 49′ 30″
Place of the aphelion in 1795	11 23 33 55
Inclination of the orbit - - - - -	43 35
Time of the perihelion passage, Sept. 7, 1799	
Excentricity of the orbit - - -	·8203
Half the greater axis - - -	19·0818 of Earth's dist.
Revolution - - - - - - -	83¼ sidereal years
Diameter of the planet - - -	34217 miles
Propor. of diam. to the earth's	4·3177 to 1
Its bulk to the earth's - - -	80·4926 to 1
Its density as - - - - - -	·2204 to 1
Its quantity of matter - - -	17·7406 to 1

And heavy bodies fall on its surface 18 feet 8 inches in one second of time. See Planet, &c.

Dr. H. has also discovered 6 satellites belonging to this planet; the periodical revolutions of which are completed in the respective times following:—1st, 5d 21h 25m; 2d, 8d 17h 1m 9s; 3d, 10d 23h 4m; 4th, 13d 11h 5m 2s; 5th, 38d 1h 49m; 6th, 107d 16h 40m. The orbits of these satellites make very large angles with the ecliptic; and it has been asserted that their real motion is retrograde; but this is probably an optical illusion.

URSA, in astronomy, the Bear, a name common to two constellations of the northern hemisphere, near the pole, distinguished by Major and Minor.

Ursa *Major*, or the Great Bear, one of the 48 old constellations, and perhaps more ancient than many of the others; being familiarly known and alluded to by the oldest writers, and is mentioned by Homer as observed by navigators. It is supposed that this constellation is that mentioned in the book of Job, under the name of Chesil, which our translation has rendered Orion, where it is said, "Canst thou loose the bands of Chesil (Orion)?" It is further said that the ancients represented each of these two constellations under the form of a waggon drawn by a team of horses, and the Greeks originally called them waggons and two bears; they are to this day popularly called the wains, or waggons, and the greater of them Charles's Wain. Hence is remarked the propriety of the expression, "loose the bands &c," the binding and loosing being terms very applicable to a harness, &c.

Perhaps the Egyptians, or whoever else were the people that invented the constellations, placed those stars, which are near the pole, in the figure of a bear, as being an animal inhabiting towards the north pole, and making neither long journeys, nor swift motions. But the Greeks, in their usual way, have adapted some of their fables to it. They say this bear was Callisto, daughter of Lycaon, king of Arcadia; that being debauched by Jupiter, he afterwards placed her in the heavens, as well as her son Arcturus.

The Greeks called this constellation Arctos and Helice, from its turning round the pole. The Latins from the name of the nymph, as variously written, Callisto, Megisto, and Flemisto, and from the Arabians, sometimes Feretrum Majus, the Great Bier. And the Ursa Minor, they called Feretrum Minus, the Little Bier. The Italians have followed the same custom, and call them Cataletto. They spoke also of the Phenicians being guided by the Lesser Bear, but the Greeks by the Greater.

There are two remarkable stars in this constellation, viz, those in the middle of his body, considered as the two hindermost of the wain, and called the pointers, because they always point nearly in a direction towards the north pole star, and so are useful in finding out this star.

The stars in Ursa Major, are, according to Ptolemy's catalogue, 35; in Tycho's 56; in Hevelius's 73; but in the Britannic catalogue 87.

Ursa *Minor*, the Little Bear, called also Arctos Minor, Phœnice, and Cynosura, one of the 48 old constellations, and near the north pole, the large star in the tip of its tail being very near to it, and thence called the pole-star.

The Phenicians guided their navigations by this constellation, for which reason it was called Phenice, or the Phenician constellation. It was also called Cynosura by the Greeks, because, according to some, that was one of the dogs of the huntress Callisto, or the Great Bear; but according to others Cynosura was one of the Idæan nymphs that nursed the infant Jupiter; and some say that Callisto was another of them, and that, for their care, they were taken up together to the skies.—Ptolemy places in this constellation 8 stars, Tycho 7, Hevelius 12, and Flamsteed 24.

URSUS (Nicholas Raimarus), a very extraordinary character, and distinguished in the science of astronomy, was born at Henstedt in Dithmarsen, in the duchy of Holstein, about the year 1550. He was a swineherd in his youth, and did not begin to read till he was 18 years of age; but then he employed all the hours he could spare from his daily labour, in learning to read and write. He afterwards applied himself to study the languages; and, having a strong genius, made a rapid progress in Greek and Latin. He quickly learned also the French language, the mathematics, astronomy, and philosophy; and most of them without the assistance of a master.

Having left his native country, he gained a maintenance by teaching; which he did in Denmark in 1584, and on the frontiers of Pomerania and Poland in 1585 It was in this place that he invented a new system of astronomy, very little different from that of Tycho Brahé. This he communicated, in 1586, to the landgrave of Hesse, which gave rise to a terrible dispute between him and Tycho. This celebrated astronomer charged him with being a plagiary; who, as he related, happening to come with his master into his study, saw there, drawn on a piece of paper, the figure of his system; and afterwards insolently boasted that he himself was the inventor of it. Ursus, on this accusation, wrote furiously against Tycho, called the honour of his invention in question, ascribing the system to Apollonius Pergæus; and in short abused him in so brutal a manner, that he was like to be prosecuted for it. Ursus was afterwards invited by the emperor to teach the mathematics in Prague; from which city, to avoid the presence of Tycho, he withdrew silently in 1589, and died soon after.

He made some improvement in trigonometry, and wrote several books, which discover the marks of his hasty studies; his erudition being indigested, and his style incorrect, as is almost always to be observed of persons that are late-learned.

VULPECULA *et* Anser, the *Fox and Goose*, in Astronomy, one of the new constellations of the northern hemisphere, made out of the unformed stars by Hevelius, in which he reckons 27 stars; but Flamsteed counts 35.

W.

WAD, or Wadding, in Gunnery, a stopple of paper, hay, straw, old rope-yarn, or tow, rolled firmly up like a ball, or a short cylinder, and forced into a gun up to the powder, to keep it close in the chamber; or secure the shot from rolling out, as well as, according to some, to prevent the inflamed powder from dilating around the sides of the ball, by its windage, as it passes along the chace, which it was thought would much diminish the effort of the powder. But, from the accurate experiments lately made at Woolwich, it has not been found to have any such effect.

WADHOOK, or Worm, a long pole with a screw at the end, to draw out the wad, or the charge, or paper &c from a gun.

WAGGONER, in Astronomy, is the constellation Ursa Major, or the Great Bear, called also vulgarly Charles's Wain.

Waggoner is also used for a rootier, or book of charts, describing the seas, their coasts, &c.

Wales (William), F.R.S. by his natural talents and close application, rose from a low situation, little connected with learning, to some of the first ranks in literary pursuits. We observe his early labours in the correspondence of the Ladies' Diary, that very useful little work, which has formed most of our eminent mathematicians. Here, and in some other periodical publications, for many years is observed the gradual improvement of Mr. W. in the various mathematical sciences. Mr. W. was deemed a fit person to be sent to a distant country (Hudson's Bay), to observe the transit of Venus over the sun 1769; and the manner in which he discharged that trust did honour to his talents. On his return he communicated to the Royal Society an excellent paper of observations made at that station, which was inserted in their Transactions, vol. for 1769; and the year following came out his general observations made at Hodson's Bay, in a large 4to volume. Mr. W. next, in the character of astronomer, accompanied Capt. Cook, in his first voyage, 1772—1774; and again in his other voyage of 1776—1779. In 1777 came out his Observations on a voyage with Capt. Cook; and in 1778 Remarks on Dr. Forster's Account of the Voyage, in which he showed considerable talents as a controversial writer. Soon after his return from the last voyage, Mr. W. was elected a F.R.S. where he proved a very useful member; and, on the death of Mr. Daniel Harris, he was appointed mathematical master to Christ's Hospital, London; and, some years after, secretary to the board of longitude; both which offices he held till the time of his death, which happened in 1798, at about 64 years of age.

In 1781, Mr. W. published an Enquiry into the State of the Population in England and Wales: and in 1794 his treatise on the Longitude by Timekeepers. Mr. W. published an ingenious restoration of one of the lost pieces of Apollonius: and it has been said he was author of one of the dissertations on the achronical rising of the Pleiades, annexed to Dr. Vincent's Voyage of Nearchus, 1797. Besides all these, Mr. W. wrote some ingenious papers in the Philos. Trans. and in various periodical publications, particularly the Ladies' Diaries, sometimes signed with his own name, and sometimes under certain fictitious signatures, as G, Celti, Felix M'Carthy, &c.

WALLIS (Dr. John), an eminent English mathematician, was the son of a clergyman, and born at Ashford in Kent, Nov. 23, 1616. After being instructed, at different schools, in grammar learning, in Latin, Greek, and Hebrew, with the rudiments of logic, music, and the French language, he was placed in Emanuel college, Cambridge. About 1640 he entered into orders, and was chosen fellow of Queen's college. He kept his fellowship till it was vacated by his marriage, but quitted his college to be chaplain to sir Richard Darley; after a year spent in this situation, he passed two more as chaplain to lady Vere. While he lived in this family, he cultivated the art of deciphering, which proved very useful to him on several occasions: he met with rewards and preferment from the government at home for deciphering letters for them; and it is said, that the elector of Brandenburg sent him a gold chain and medal, for explaining for him some letters written in ciphers.

In 1643 he published Truth Tryed, or Animadversions on Lord Brooke's treatise, called The Nature of Truth &c; styling himself "a minister in London," probably of St. Gabriel Fenchurch, the sequestration of which had been granted to him.—In 1644 he was chosen one of the scribes or secretaries to the assembly of divines at Westminster.

Academical studies being much interrupted by the civil wars in both the universities, many learned men from them resorted to London, and formed assemblies there. Wallis belonged to one of these, the members of which met once a week, to discourse on philosophical matters; and this society was the rise and beginning of that which was afterwards incorporated by the name of the Royal Society, of which Wallis was one of the most early members.

The Savilian professor of geometry at Oxford being ejected by the parliamentary visitors, in 1649, Wallis was appointed to succeed him, and he opened his lectures there the same year. In 1650 he published some Animadversions on a book of Mr. Baxter's, entitled, "Aphorisms of Justification and the Covenant." And in 1653, in Latin, a Grammar of the English tongue, for the use of foreigners; to which was added, a tract De Loquela seu Sonorum Formatione, &c, in which he considers philosophically the formation of all sounds used in articulate speech, and shows how the organs being put into certain positions, and the breath forced out from the lungs, the person will thus be made to speak, whether he hear himself or not. Pursuing these reflections, he was led to think it possible, that a deaf person might be taught to speak, by being directed so to apply the organs of speech, as the sound of each letter required, which children learn by imitation and frequent attempts, rather than by art. He made a trial or two with success; and particularly on one Popham, which involved him in a dispute with Dr. Holder, of which some account has already been given in the life of that gentleman.

In 1654 he took the degree of doctor in divinity; and the year after became engaged in a long controversy with

Mr. Hobbes. This philosopher having, in 1655, printed his treatise De Corpore Philosophico, Dr. Wallis the same year wrote a confutation of it in Latin, under the title of Elenchus Geometriæ Hobbianæ; which so provoked Hobbes, that in 1656 he published it in English, with the addition of what he called, "Six Lessons to the Professors of Mathematics in Oxford." Upon this Dr. Wallis wrote an answer in English, entitled, "Due Correction for Mr. Hobbes; or School-discipline for not saying his Lessons right," 1656: to which Mr. Hobbes replied in a pamphlet called "ΣΤΙΓΜΑΙ, &c, or Marks of the absurd Geometry, Rural Language, Scottish Church-politics, and Barbarisms, of John Wallis, 1657." This was immediately rejoined to by Dr. Wallis, in Hobbiani Puncti Dispunctio, 1657. And here this controversy seems to have ended, at this time: but in 1661 Mr. Hobbes printed Examinatio & Emendatio Mathematicorum Hodiernorum in sex Dialogis; which occasioned Dr. Wallis to publish the next year, Hobbius Heautontimorumenos, addressed to Mr. Boyle.

In 1657 our author collected and published his mathematical works, in two parts, entitled, Mathesis Universalis, in 4to; and in 1658, Commercium Epistolicum de Quæstionibus quibusdam Mathematicis nuper habitum, in 4to; which was a collection of letters written by himself and many learned men, as Lord Brounker, Sir Kenelm Digby, Fermat, Schooten, and others.

Wallis was this year chosen Custos Archivorum of the university. On this occasion Mr. Stubbe, who, on account of his friend Mr. Hobbes, had before waged war also against Wallis, published a pamphlet, entitled, "The Savilian Professor's Case Stated," 1658. Dr. Wallis replied to this: and Mr. Stubbe republished his case, with enlargements, and a vindication against the exceptions of Dr. Wallis.

On the Restoration it appears he met with great respect; the king thinking favourably of him on account of some services he had done both to himself and his father Charles the first. He was therefore confirmed in his places, also admitted one of the king's chaplains in ordinary, and appointed one of the divines empowered to revise the Book of Common Prayer. He complied with the terms of the act of uniformity, and continued a steady conformist till his death. He was a very useful member of the Royal Society; and kept up a literary correspondence with many learned men. In 1670 he published his Mechanica; sive de Motu, 4to. In 1676 he gave an edition of Archimedis Syracusani Arenarius & Dimensio Circuli; and in 1682 he published from the manuscripts, Claudii Ptolomæi Opus Harmonicum, in Greek, with a Latin version and notes; to which he afterwards added, Appendix de veterum Harmonica ad hodiernam comparata, &c. In 1685 he published some theological pieces; and, about 1690, was engaged in a dispute with the Unitarians; also, in 1692, in another dispute about the sabbath. Indeed his books on subjects of divinity are very numerous, but nothing near so important as his mathematical works.

In 1685 he published his History and Practice of Algebra, in folio; a work replete with learned and useful matter. Besides the works above-mentioned, he published many others, particularly his Arithmetic of Infinites, a book of genius and good invention, and perhaps almost his only work that is so, for he was much more distinguished for his industry and judgment, than for his genius. Also a multitude of papers in the Philos. Trans. in almost every volume, from the 1st to the 25th volume. In 1697, the curators of the university press at Oxford thought it for the honour of the university to collect the doctor's mathematical works, which had been printed separately, some in Latin, some in English, and published them all together in Latin, in 3 vols. folio, 1699.

Dr. Wallis died at Oxford the 28th of October, 1703, in the 88th year of his age, leaving behind him one son and two daughters. We are informed that he was of a vigorous constitution, and of a mind which was strong, calm, serene, and not easily ruffled or discomposed. He speaks of himself, in his letter to Mr. Smith, in a strain which shows him to have been a very cautious and prudent man, whatever his secret opinions and attachments might be: he concludes, "It hath been my endeavour all along to act by moderate principles, being willing, whatever side was uppermost, to promote any good design, for the true interest of religion, of learning, and of the public good."

WALMESLEY (Charles), d.d. f.r.s. was an English Benedictine monk, and a Roman Catholic bishop; also senior bishop and vicar apostolic of the western district, as well as doctor of theology in the Sorbonne. He died at Bath in 1797, in the 76th year of his age, and the 41st of his episcopacy. Dr. W. was the last survivor of those eminent mathematicians, who were concerned in regulating the chronological style in England, which produced a change of the style in this country, in the year 1752. Besides some ingenious astronomical essays in the Philos. Trans. he published several separate works, both on mathematics and theology; as, 1. Analyse des Mesures des Rapports et des Angles, 4to, 1749; being an extension and explanation of Cotes's Harmonia Mensurarum. 2. Theorie du Monument des Apsides, 8vo, 1749. 3. De Inæqualitatibus Motuum Lunarium, 4to, 1758. An explanation of the Apocalypse, Ezekiel's Vision, &c: By the fire at Bath at the time of the riots, several valuable manuscripts, which he had been compiling during a well-spent life of labour, and travelling through many countries, were irretrievably lost.

WARD (Dr. Seth), an English prelate, chiefly famous for his knowledge in mathematics and astronomy, was the son of an attorney, and born at Buntingford, Hertfordshire, in 1617 or 1618. From hence he was removed and placed a student in Sidney-college, Cambridge, in 1632. Here he applied with great vigour to his studies, particularly to the mathematics, and was chosen fellow of his college. In 1640 he was pitched upon by the vice-chancellor to be prævaricator, which at Oxford is called terræ-filius; whose office it was to make a witty speech, and to laugh at any thing or any body: a privilege which he exercised so freely, that the vice-chancellor actually suspended him from his degree; though he reversed the censure the day following.

The civil war now breaking out, Ward was involved not a little in the consequences of it. He was ejected from his fellowship for refusing the Covenant; against which he soon after joined with several others, in drawing up that celebrated treatise, which was afterwards printed. Being now obliged to leave Cambridge, he resided for some time with certain friends about London, and at other times at Aldbury in Surrey, with the noted mathematician Oughtred, where he prosecuted his mathematical studies. He afterwards lived for the most part, till 1649, with Mr.

Ralph Freeman at Aspenden in Hertfordshire, whose sons he instructed as their preceptor; after which he resided some months with lord Wenman, of Thame Park, in Oxfordshire.

He had not been long in this family before the visitation of the university of Oxford began; the effect of which was, that many learned and eminent persons were turned out, and among them Mr. Greaves, the Savilian professor of Astronomy: this gentleman laboured to procure Ward for his successor, whose abilities as an astronomer were universally known and acknowledged; and effected it; Dr. Wallis succeeding to the Geometry professorship at the same time. Mr. Ward then entered himself of Wadham college, for the sake of Dr. Wilkins, who was the warden; and he lost no time in bringing the astronomy lectures, which had long been neglected and disused, into repute again; and for this purpose he read them very constantly, never missing one reading day, during the time he held the lecture.

In 1654, both the Savilian professors did their exercises, in order to proceed doctors in divinity; and when they were to be presented, Wallis claimed precedency. This occasioned a dispute; which being decided in favour of Ward, who was really the senior, Wallis went out grand compounder, and so obtained the priority. In 1659, Ward was chosen president of Trinity college; but was obliged at the Restoration to resign that place. He had recompense made him, however, by being presented in 1660 to the rectory of St. Laurence Jewry. The same year he was also installed precentor of the church of Exeter. In 1661 he became fellow of the Royal Society, and dean of Exeter; and the year following he was advanced to the bishopric of the same church. In 1667 he was translated to the see of Salisbury: and in 1671 was made chancellor of the order of the garter; an honour which he afterwards procured to be permanently annexed to the see of Salisbury, after it had been held by laymen for above 150 years.

Dr. Ward was one of those unhappy persons who have the misfortune to survive their senses, which happened in consequence of a fever badly cured: he lived till the Revolution, but without knowing any thing of the matter; and died in January 1689, about 71 years of age. He was the author of several Latin works in astronomy and different parts of the mathematics, which were thought excellent in their day; but their use has been superseded by later improvements and the Newtonian philosophy. Some of these were,

1. A Philosophical Essay towards an Eviction of the Being and Attributes of God, &c. 1652.—2. De Cometis, &c; 4to, 1653.—3. In Ismaelis Bullialdi Astronomia Inquisitio; 4to, 1653.—4. Idea Trigonometriæ demonstratæ; 4to, 1654.—5. Astronomia Geometrica; 8vo, 1656. In this work, a method is proposed, by which the astronomy of the planets is geometrically resolved, either on the Elliptical or Circular motion; it being in the third or last part of this work that he proposes and explains what is called Ward's Circular Hypothesis.—6. Exercitatio epistolica in Thomæ Hobbii Philosophiam, ad D. Joannem Wilkins; 1656, 8vo.

But that by which he has chiefly signalized himself, as to astronomical invention, is his celebrated approximation to the true place of a planet, from a given mean anomaly, founded on an hypothesis, that the motion of a planet, though it be really performed in an elliptic orbit, may yet be considered as equable as to angular velocity, or with an uniform circular motion round the upper focus of the ellipse, or that next the aphelion, as a centre. By this means he rendered the praxis of calculation much easier than any that could be used in resolving what has been commonly called Kepler's problem, in which the coequate anomaly was to be immediately investigated from that of the mean elliptic one. His hypothesis agrees pretty well with those orbits which are elliptical but in a very small degree, as that of the Earth and Venus: but in others, that are more elliptical or excentric, as those of Mercury, Mars, &c, this approximation stood in need of a correction, which was made by Bulliald. Both the method, and the correction, are very well explained and demonstrated, by Keill, in this Astronomy, lecture 24.

WARGENTIN (Peter), an ingenious Swedish mathematician and astronomer, was born Sept. 22, 1717, and died Dec. 13, 1783. He became secretary to the Academy at Stockholm in 1749, when he was only 32 years of age; and he became successively a member of most of the literary academies in Europe, as London, Paris, Petersburg, Gottingen, Upsal, Copenhagen, Drontheim, &c. In this country he is probably most known on account of his tables for computing the eclipses of Jupiter's satellites, which are annexed to the Nautical Almanac of 1779. I know not that he has published any separate work; but his communications were very numerous to several of those Academies of which he was a member; as the Academy of Stockholm, in which are 52 of his memoirs; in the Philosophical Transactions, the Upsal Acts, the Paris Memoirs, &c.

WARING (Edward), M. D. and F. R. S. was born about the year 1736, near Shrewsbury, were also he died, August 15, 1798, in the sixty-third year of his age. After his early education at that place, he was sent to Magdalen college, Cambridge, in 1753. Here his talents for abstruse calculations soon distinguished him; so that, on taking his first degree, in 1757, he was ranked as senior wrangler, or the first student of the year, Mr. John Jebb being the second on the list. The Lucasian professorship of mathematics in the university becoming vacant, by the death of Mr. John Colson, in 1759, Mr. W. was elected to that office in Jan. 1760. On this occasion some remarkable circumstances took place. Before his election, Mr. W. gave a small specimen of his abilities, as a proof of his fitness for that office, by the publication of the first chapter of his Miscellanea Analytica. This specimen was attacked, and his election opposed, by Dr. Powell, of St. John's college, with the view of serving his friend Mr. Maseres (the present cursitor baron of the exchequer), then a candidate also for the vacant professorship. This opposition produced several curious pamphlets between the two parties, by Dr. Powell and Mr. Maseres on the one side, and by Mr. Waring, assisted by his friend Mr. Wilson (afterwards one of the judges, sir John Wilson), on the other side; which however ended in the success and election of the latter.

In 1762 Mr. W. published complete his Miscellanea Analytica, one of the most abstruse books, written on the abstrusest parts of Algebra; which might at least have the effect of extending the author's title to ingenuity. Mathematics however did not engross the whole of his attention: he could allow some part of his time to the study of medicine; and in 1767 he was admitted to the degree of M. D. though he never after practised as a physician. Mathematics again engaged his chief attention, and he successively produced a number of pieces, of a like abstruse kind as the former; several of which were inserted in different volumes of the Philos. Trans., and some he published in separate works; as, the Meditationes Analyticæ, in 1770; the Proprietates Algebraicarum Curvarum, in 1772; and the Meditationes Analyticæ, in 1776. To these might be added a work, written in his retirement, on morals and metaphysics; of which a few copies only were printed, and presented to his friends. As also a pamphlet published at Cambridge, in which algebraic quantities are translated into probable relations, and some theorems on probabilities thence deduced. In the same pamphlet are farther added some new propositions on chances, on the values of lives, on survivorships, &c.

Most of these essays give proofs of the strong powers of the author's mind, both in abstract science, and its application to philosophy: though they labour, in common with his other works, under the disavantage of being conveyed in a very unattractive form.

In his disposition and character, Dr. W. is represented as of inflexible integrity, great modesty, plainness, and simplicity of manners; of a meekness and a diffidence of mind to such a degree, as to be always embarrassed before strangers. His extreme short-sightedness too, joined to the natural want of order and method in his mind, which appeared remarkably even in his hand-writing, rendered his mathematical compositions so confused and embarrassed, that in manuscript they were often utterly inexplicable: a circumstance which may account for the numerous typographical errors in his publications.

Besides the works before-mentioned, Dr. Waring gave a number of valuable papers to the Philosophical Transactions of the Royal Society.

WATCH, a small portable machine, or movement, for measuring time; having its motion commonly regulated by a spiral spring. Perhaps, strictly speaking, watches are all such movements as show the parts of time; as clocks are such as proclaim them, by striking on a bell, &c. But commonly, the term watch is appropriated to such as are carried in the pocket; and clock to the large movements, whether they strike the hour or not.

Spring or *Pendulum* WATCHES stand on much the same principle with pendulum clocks. For if a pendulum, describing small circular arcs, make vibrations of unequal lengths, in equal times, it is because it describes the greater arc with a greater velocity; so a spring put in motion, and making greater and less vibrations, as it is more or less strong, and as it has a greater or less degree of motion given it, performs them nearly in equal times. Hence, as the vibrations of the pendulum had been applied to large clocks, to rectify the inequality of their motions; so, to correct the unequal motions of the balance in watches, a spring is added, by the isochronism of whose vibrations the correction is to be effected. The spring is usually wound into a spiral; that, in the little compass allotted it, it may be as long as possible; and may have strength enough not to be mastered, and displaced by the inequalities of the balance it is to regulate. The vibrations of the two parts, viz, the spring and the balance, should be of the same length; but so adjusted, as that the spring, being more regular in the length of its vibrations than the balance, may occasionally communicate its precision to the latter.

The Invention of Spring or Pocket Watches, is due to the 16th century. It is true, as we are informed, in the history of Charles the 5th, that a watch was presented to that prince: but this was probably no more than a kind of clock to be set on a table: some resemblance of which we have still remaining in the ancient pieces made before the year 1670. Some accounts also state, the first watches were made at Nuremberg in 1500, by Peter Hell, and were called Nuremberg eggs, on account of their oval form. And farther, that the same year, George Purbach, a mathematician of Vienna, employed a watch that pointed to seconds, for astronomical observations, which was probably a kind of clock. In effect, it is between Hooke and Huygens that the glory of this excellent invention lies: but to which of them it properly belongs, has been greatly disputed; the English ascribing it to the former, and the French, Dutch, &c, to the latter. Derham, in his Artificial Clockmaker, says positively, that Dr. Hooke was the inventor; and adds, that he contrived various means of regulation: one was with a loadstone: another with a tender straight spring, one end of which played backward and forward with the balance; so that the balance was to the spring as the ball of a pendulum, and the spring as the rod of the same: a third method was with two balances, of which there were divers kinds; some having a spiral spring to the balance for a regulator, and others without. But the way that prevailed, and which still continues in mode, was with one balance, and one spring running round the upper part of the verge of it: though this has a disadvantage, which those with two springs, &c were free from; in that, a sudden jerk, or confused shake, will alter its vibrations, and disturb it very much.

The time of these inventions was about the year 1658; as appears, among other evidences, from an inscription on one of the double-balance watches presented to king Charles the second, viz, Rob. Hooke inven. 1658. T. Tompion fecit, 1675. The invention soon came into repute both at home and abroad; and two of the machines were sent for by the dauphin of France. Soon after this, M. Huygens's watch with a spiral spring got abroad, and excited uncommon interest in England, as if the longitude could be found by it. It is certain however, that this invention was later than the year 1673, when his book De Horol. Oscillat. was published; in which there is no mention of this, though he speaks of several other contrivances in the same way.

One of these the lord Brounker sent for from France, where M. Huygens obtained a patent for them. This watch agreed with Dr. Hooke's, in the application of the spring to the balance; only that of Huygens had a longer spiral spring, and its pulses and beats were much slower; also the balance, instead of turning quite round as Dr. Hooke's did, turned several times every vibration. Huygens also invented divers other kinds of watches, some of them without any string or chain at all, which he called pendulum watches.

Mr. Derham suggests that he suspects Huygens's fancy was first set to work by some intelligence he might have of Hooke's invention from Mr. Oldenburg, or some other of his correspondents in England: though Mr. Oldenburg vindicates himself against that charge, in the Philos. Trans. Nos. 118 and 129.

Watches, since their first invention, have gone on in a continued course of improvement, and they have lately been brought to great perfection, both in England and in

France, but more especially the former, particularly owing to the great encouragement that has been given to them by the board of longitude. Some of the chief writers and improvers of watches, are, Le Roy, Cummins, Harrison, Mudge, Emery, and Arnold. See Derham's Artificial Clockmaker; Cummins's Principles of Clock and Watch work; Mudge's Thoughts on the Means of improving Watches, &c.

Striking WATCHES, are such as, besides the proper watch part, for measuring time, have a clock part, for striking the hours, &c. These are real clocks; only moved by a spring instead of a weight; and are properly called pocket-clocks.

Repeating WATCHES, are such as, by pulling a string, &c, repeat the hour, quarter, or minute, at any time of the day or night.—This repetition was the invention of Mr. Barlow, being first put in practice by him in larger movements or clocks, about the year 1676. The contrivance immediately set the other artists to work, who soon devised many ways of effecting the same. But its application to pocket-watches was not known before king James the second's reign; when the ingenious inventor above mentioned was soliciting a patent for it. The talk of a patent engaged Mr. Quare to resume the thoughts of a like contrivance, which he had in view some years before: he now effected it; and being pressed to endeavour to prevent Mr. Barlow's patent, a watch of each kind was produced before the king and council; on trial of which, the preference was given to Mr. Quare's. The difference between them was, that Barlow's was made to repeat by pushing in two pieces on each side the watch-box; one of which repeated the hour, and the other the quarter: whereas Quare's was made to repeat by a pin that stuck out near the pendant, which being thrust in (as is now done by forcing in the pendant itself) repeated both the hour and quarter with the same thrust.

Of the Mechanism of a WATCH.

Watches, as well as clocks, are composed of wheels and pinions, with a regulator to direct the quickness or slowness of the wheels, and of a spring which communicates motion to the whole machine. But the regulator and spring of a watch are vastly inferior to the weight and pendulum of a clock, neither of which can be employed in watches. Instead of a pendulum, therefore, they are obliged to use a balance (pl. 40, fig. 4) to direct the motion of a watch; and of a spring (fig. 6), which serves, instead of a weight, to give motion to the wheels and balance.

The wheels of a watch, like those of a clock, are placed in a frame, formed of two plates and four pillars. Fig. 3. represents the inside of a watch, after the plate (fig. 5) is taken off. A is the barrel which contains the spring (fig. 6); the chain is rolled about the barrel, with one end of it fixed to the barrel A, and the other to the fusee B.

When a watch is wound up, the chain which was upon the barrel winds about the fusee, and by this means the spring is stretched; for the interior end of the spring is fixed by a spring to the immoveable axis, about which the barrel revolves; the exterior end of the spring is also fixed to the inside of the barrel, which turns upon an axis. It is there easy to perceive how the spring extends itself, and how its elasticity forces the barrel to turn round, and consequently causes the chain which is upon the fusee to unfold and turn the fusee; the motion of the fusee is communicated to the wheel CC; then by means of the teeth, to the pinion *c*, which carries the wheel D; then to the pinion *d*, which carries the wheel E; then to the pinion *e*, which carries the wheel F; then to the pinion *f*, upon which is the balance-wheel G, whose pivot runs in the piece A, called the potance, and B called a follower, which are fixed on the plate fig. 5. This plate, of which only a part is represented, is applied to that of fig. 3, in such a manner, that the pivots of the wheels enter into holes made in the plate fig. 3. Thus the impressed force of the spring is communicated to the wheels: and the pinion *f* being then connected to the wheel F, obliges it to turn (fig. 7). This wheel acts on the pallats of the verge 1, 2, (fig. 4) the axis of which carries the balance HH (fig. 4). The pivot 1, in the end of the verge, enters into the hole *e* in the potance A (fig. 5). In this figure the pallats are represented; but the balance is on the other side of the plate, as may be seen in fig. 11. The pivot 3 of the balance enters into a hole of the cock BC (fig. 10), as represented in fig. 12. Thus the balance turns between the cock and the potance *c* (fig. 5), as in a kind of cage. The action of the balance-wheel upon the pallats 1, 2, (fig. 4) is the same with that of the same wheel in the clock; i. e. in a watch the balance-wheel causes the balance to vibrate backwards and forwards like a pendulum.

At each vibration of the balance a pallat allows a tooth of the balance-wheel to escape; so that the quickness of the motion of the wheels is entirely determined by the celerity of the vibrations of the balance, and these vibrations of the balance and motion of the wheels are produced by the action of the spring.

But the quickness or slowness of the vibrations of the balance depends not solely on the action of the great spring, but chiefly on the action of the spring *abc*, called the spiral spring (fig. 13) situated under the balance H, and represented in (fig. 11); the exterior end of the spiral is fixed to the pin *a* (fig. 13). This pin is applied near the plate in *a* (fig. 11); the interior end of the spiral is fixed by a peg to the centre of the balance. Hence if the balance be turned upon itself, the plates remaining immoveable, the spring will extend itself, and make the balance perform one revolution. Now, after the spiral is thus extended, if the balance be left to itself, the elasticity of the spiral will bring back the balance, and in this manner the alternate vibrations of the balance are produced.

In fig. 7 all the wheels above described are represented in such a manner, that we may easily perceive at first sight how the motion is communicated from the barrel to the balance.

In fig. 8 are represented the wheels under the dial-plate, by which the hands are moved. The pinion *a* is made to fit tight on the prolonged pivot of the wheel D (fig. 7), and is called a cannon pinion. This wheel revolves in an hour. The end of the axis of the pinion *a*, upon which the minute hand is fixed, is square; the pinion (fig. 8) is indented into the wheel *b*, which is carried by the pinion *a*. Fig. 9 is a wheel fixed on a barrel, into the cavity of which the pinion *a* enters, and on which it turns freely. This wheel revolves in 12 hours, and carries along with it the hour-hand.

WATER, in Physiology, a clear, insipid, and colourless fluid, coagulable into a transparent solid substance, called ice, when placed in a temperature of 32° of Fahrenheit's thermometer, or lower, but volatile and fluid in every degree of heat above that; and when pure, or freed from heterogeneous particles, is reckoned one of the four elements.

By some late experiments of Messrs. Lavoisier, Watt, Cavendish, Priestley, Kirwan, &c, it appears, that water consists of dephlogisticated air, and inflammable air or phlogiston intimately united; or, as Mr. Watt conceives, of those two principles deprived of part of their latent heat. And in some instances it appears that air and water are mutually convertible into each other. Thus, Mr. Cavendish (Philos. Trans. vol. 74, pa. 128) recites several experiments, in which he changed common air into pure water, by decomposing it in conjunction with inflammable air. Dr. Priestley likewise, having decomposed dephlogisticated and inflammable air, by firing them together by the electric explosion, found a manifest decomposition of water, which, as nearly as he could judge, was equal in weight to that of the decomposed air. He also made a number of other curious experiments, which seemed to favour the idea of a conversion of water into air, without absolutely proving it. The difficulty which M. Deluc and others have found in expelling all air from water, is best accounted for on the supposition of the generation of air from water; and, admitting that the conversion of water into air is effected by the intimate union of what is called the principle of heat with the water, it appears sufficiently analogous to other changes, or rather combinations, of substances. Is not, says Dr. Priestley, the acid of nitre, and also that of vitriol, a thing as unlike to air as water is, their properties being as remarkably different? And yet it is demonstrable that the acid of nitre is convertible into the purest respirable air, and probably by the union of the same principle of heat. Philos. Trans. vol. 73, pa. 414 &c.

Indeed there seems to be water in all bodies, and particles of almost all kinds of matter in water; so that it is hardly ever sufficiently pure to be considered as an element. Water, if it could be had alone and pure, Boerhaave argues, would have all the requisites of an element, and be as simple as fire; but there is no expedient hitherto discovered for procuring it so pure. Rain water, which seems the purest of all those we know of, is replete with infinite exhalations of all kinds, which it imbibes from the air: so that, if filtered and distilled a thousand times, there still remain fæces. Besides this, and the numberless impurities it acquires after it is raised, by mixing with all sorts of effluvia in the atmosphere, and by falling upon and running over the earth, houses, and other places. There is also fire contained in all water; as appears from its fluidity, which is owing to fire alone. Nor can any kinds of filtering through sand, stone, &c, free it entirely from salts &c. Nor have all the experiments that have been invented by the philosophers, ever been able to derive water perfectly pure. Hence Boerhaave says, that he is convinced no person ever saw a drop of pure water; that the utmost of its purity known, only amounts to its being free from this or that kind of matter; and that it can never, for instance, be quite deprived of salt; since air will always accompany water, and air always contains salt.

Water seems to be diffused everywhere, and to be present in all space wherever there is matter. There are hardly any bodies in nature but what will yield water: it is even asserted that fire itself is not without it. A single grain of the fiery salt, which in a moment's time will penetrate through a man's hand, readily imbibes half its weight of water, and melts even in the driest air possible. Among innumerable instances, hartshorn, kept 40 years, and turned as hard and dry as any metal, so that it will yield sparks of fire when struck against a flint, yet being put into a glass vessel, and distilled, will afford ⅛th part of its quantity of water. Bones dead and dried 25 years, and thus become almost as hard as iron, yet by distillation have yielded half their weight of water. And the hardest stones, ground and distilled, always discover a portion of it. But hitherto no experiment shows, that water enters as a principle into the combination of metallic matters, or even into that of vitrescible stones.

From such considerations, philosophers have been led to hold the opinion, that all things were made of water. Basil Valentine, Paracelsus, Van Helmont, and others have maintained, that water is the elemental matter or stamen of all things, and suffices alone for the production of all the visible creation. Thus too Newton: "All birds, beasts, and fishes, insects, trees, and vegetables, with their several parts, do grow out of water, and watery tinctures, and salts; and by putrefaction they all return again to watery substances." And the same doctrine is held, and confirmed by experiments, by Van Helmont, Boyle, and others.

But Dr. Woodward endeavours to show that the whole is a mistake.—Water containing extraneous corpuscles, some of which, according to him, are the proper matter of nutrition; the water being still found to afford so much the less noorishment, the more it is purified by distillation. So that water, as such, does not seem to be the proper nutriment of vegetables; but only the vehicle which contains the nutritious particles, and carries them along with it, through all the parts of the plant.

Helmont however carries his system still farther, and imagines that all bodies may be reconverted into water. His alkahest, he affirms, adequately resolves plants, animals, and minerals, into one liquor, or more, according to their several internal differences of parts; and the alkahest, being abstracted again from these liquors, in the same weight, and with the same virtues, as when it dissolved them, the liquors may, by frequent cohobations from chalk, or some other proper matter, be totally deprived of their seminal endowments, and at last return to their first matter; which is insipid water.

Spirit of wine, of all other spirits, seems freest from water: yet Helmont affirms, it may be so united with water, as to become water itself. He adds, that it is material water, only under a sulphureous disguise. And the same thing he observes of all salts, and of oils, which may be almost wholly changed into water.

No standard for the Weight and Purity of Water.—Water hardly ever continues two moments exactly of the same weight; by reason of the air and fire contained in it. The expansion of water in boiling shows what effect the different degrees of fire have on the gravity of water. This makes it difficult to fix the specific gravity of water, in order to settle its degree of purity. However, the purest water we can obtain, according to the experiments of Hawskbee, is 850 times heavier than atmospheric air: or according to the experiments of Mr. Cavendish, the thermometer being at 50° and the barometer at 29¾, about 800 times as heavy as air: and according to the experiments of sir Geo. Shuckburgh, when the barometer is at 29·27 and the thermometer at 53°, water is 836 times heavier than air; whence also may be deduced this general proportion, which may be accounted a standard, viz, that, when the barometer is at 30° and the thermometer at 55°, then water is 820 times heavier than air; also that in such a state the cubic foot of water weighs 1000 ounces avoirdupois, and that of air 1·222, or $1\frac{2}{9}$ nearly, also that of mercury 13600 ounces; and for other states of the thermometer and barometer, the allowance is after this rate, viz, that the column of mercury in the barometer varies its length by the 10 thousandth part of itself for a change of each single degree of temperature, and water changes by $\frac{3}{10000}$ part of its height or magnitude by each degree of the same. However, we have not any very exact standard in air; for water being so much heavier than air, the more water there is contained in the air, the heavier of course must the air be; as indeed a considerable part of the weight of the atmosphere seems to arise from the water that is contained in it.

Properties and Effects of WATER.—Water is a very volatile body. It is entirely reduced into vapours and dissipated, when exposed to the action of fire and unconfined.

Water heated in an open vessel, acquires no more than a certain determinate degree of heat, whatever be the intensity of the fire to which it is exposed; which greatest degree of heat is when it boils violently.

It has been found that the degree of heat necessary to make water boil, is variable, according to the purity of the water and the weight of the atmosphere. The annexed table shows the degree of heat at which water boils, at various heights of the barometer, being a medium between those resulting from the experiments of sir Geo. Shuckburgh and M. Deluc.

Water is found the most penetrative of all bodies, after fire, and the most difficult to confine; passing through leather, bladders, &c, which will confine air; making its way gradually through woods; and is only retainable in glass and metals; nay it was determined by experiment at Florence, that when shut up in a spherical vessel of gold, which was pressed with a great force, it made its way through the pores even of the gold itself.

Water, by this penetrative quality alone, may be inferred to enter the composition of all bodies, both vegetable, animal, fossil, and even mineral; with this particular circumstance, that it is easily, and with a gentle heat, separable again from bodies it had united with.

And yet the same water, as little cohesive as it is, and as easily separated from most bodies, will cohere firmly with some others, and bind them together in the most solid masses; as in the tempering of earth, or ashes, clay, or powdered bones, &c, with water, and then dried and burnt, when the masses become hard as stones, though without the water they would be mere dust or powder. Indeed it appears wonderful that water, which is otherwise an almost universal dissolvent, should nevertheless be a great coagulator.

Some have imagined that water is incompressible, and therefore non-elastic; founding their opinion on the celebrated Florentine experiment above mentioned, with the globe of gold; when the water being, as they say, incapable of condensation, rather than yield, transuded through the pores of the metal, so that the ball was found wet all over the outside; till at length making a cleft in the gold, it squirted out with great vehemence. But the truth of the conclusions drawn from this Florentine experiment has been very justly questioned; Mr. Canton having proved by accurate experiments, that water is actually compressed even by the weight of the atmosphere. See COMPRESSION.

Besides, the diminution of size which water suffers when it passes to a less degree of heat, sufficiently shows that the particles of this fluid are, like those of all other known substances, capable of approaching nearer together.

Ditch WATER, is often used as an object for the microscope, and seldom fails to afford a great variety of animalcules; often appearing of a greenish, reddish, or yellowish colour, from the great multitudes of them. And to the same cause is to be ascribed the green skim on the surface of such water. Dunghill water is also full of an immense crowd of animalcules.

Fresh WATER, is said of that which is insipid, or without salt, and inodorous; being the natural and pure state of the element.

Hard WATER, or *Crude* WATER, is that in which soap does not dissolve completely or uniformly, but is curdled. The dissolving power of hard water is less than that of soft; and hence its unfitness for washing, bleaching, dyeing, boiling kitchen vegetables, &c. The hardness of water may arise either from salts, or from gas. That which arises from salts, may be discovered and remedied by adding some drops of a solution of fixed alkali; but the latter by boiling, or exposure to the open air.—Spring waters are often hard; but river water soft. Hard waters are remarkably indisposed to corrupt; they even preserve putrescible substances for a considerable length of time: hence they seem to be best fitted for keeping at sea, especially as they are so easily softened by a little alkaline salt.

Putrid WATER, is that which has acquired an offensive smell and taste by the putrescence of animal or vegetable substances contained in it. This kind of water is in the highest degree pernicious to the human constitution, and capable of bringing on mortal diseases even by its smell. Quicklime put into water is useful to preserve it longer sweet; or even exposure to the air in broad shallow vessels. And putrid water may be in a great measure sweetened, by passing a current of fresh air through it, from bottom to top.

Rain WATER may be considered as the purest distilled water, but impregnated during its passage through the air with a considerable quantity of putrescent matter; whence it is superior to any other in fertilizing the earth. Hence also it is inferior for domestic purposes to spring or river water, even if it could be readily procured: but such as is obtained from spouts placed below the roofs of houses, the common way of procuring it in this country, is evidently very impure, and becomes putrid in a short time.

River or *Running* WATER, is next in purity to snow or distilled water; and for domestic purposes superior to both, in having less putrescent matter, and more fixed air. That however is much the purest that runs over a clean rocky or stony bottom. River waters generally putrefy sooner than those of springs. During the putrefaction, they throw off a part of their heterogeneous matter, and at length become sweet again, and purer than at first; after which they commonly preserve a long time: this is remarkably the case with the Thames water, taken up about London; which is commonly used by seamen, in their voyages.

Salt WATER, such as has much salt in it, so as to be sensible to the taste.

Sea WATER, or Water of the sea, is an assemblage of bodies, in which water can scarcely be said to have the principal part: it is an universal colluvies of all the bodies in nature, sustained and kept floating in water as a vehicle: being a solution of common salt, sal catharticus amarus, a selenitic substance, and a compound of muriatic acid with magnesia, mixed together in various proportions. It may be freshened by simple distillation without any addition, and thus it has sometimes been useful in long voyages at sea. Sea water by itself has a purgative quality, owing to the salt it contains; and has been greatly recommended in scrophulous disorders. Sea water is about 3 parts in 100 heavier than common water; and its temperature at great depths is from 34 to 40 degrees; but near the surface it follows more nearly the temperature of the air.

Snow WATER, is the purest of all the common waters, when the snow has been collected pure. Kept in a warm place, in clean glass vessels, not closely stopped, but covered from dust, &c, snow water becomes in time putrid; though in well-stopped bottles it remains unaltered for several years. But distilled water suffers no alteration in either circumstance.

Spring WATER is commonly impregnated with a small portion of imperfect neutral salt, extracted from the different strata through which it percolates. Some contain a vast quantity of stony matter, which they deposit as they run along, and thus form masses of stone; sometimes incrustating various animal and vegetable matters, which they are therefore said to petrify. Spring water is much used for domestic purposes, and on account of its coolness is an agreeable drink; but on account of its being usually somewhat hard, is inferior to that which has run for a considerable way in a channel. Spring water arises from the rain, and from the mists and moisture in the atmosphere. These falling upon hills and other parts of the earth, soak into the ground, and pass along till they find a vent out again, in the form of a spring.

WATER-*Bellows*, in Mechanics, are bellows, for blowing air into furnaces, that are worked by the force of water; or air blown in by the fall of water.

WATER-*Clock*. See CLEPSYDRA.

WATER-*Engine*, an engine for extinguishing fires; or any engine to raise water; or any engine moved by the force of water. See ENGINE, and STEAM-*Engine*.

WATER-*Gage*, an instrument for measuring the depth or quantity of any water. See GAGE.

WATER-*Level*, is the true level which the surface of still water takes, and is the most correct of any.

WATER-*Logged*, in Sea-Language, denotes the state of a ship when, by receiving a great quantity of water into her hold, by leaking, &c, she has become heavy and inactive upon the sea, so as to yield without resistance to the effort of every wave rushing over her deck.

WATER-*Machine*. See MACHINE.

WATER-*Measure*. Salt, sea-coal, &c, while on board vessels in the pool, or river, are measured with the corn-bushel heaped up; or else 5 striked pecks are allowed to the bushel. This is called water-measure; and it exceeds Winchester measure by about 3 gallons in the bushel.

WATER-*Microscope*. See MICROSCOPE.

WATER-*Mill*. See MILL.

Motion of WATER, in Hydraulics. The theory of the motion of running water is one of the principal objects of hydraulics, and to which many eminent mathematicians have paid their attention. But it were to be wished that their theories were more consistent with each other, and with experience. The inquisitive reader may consult Newton's Principia, lib. 2, pr. 36, with the comment. Dan. Bernoulli's Hydrodynamica. J. Bernoulli, Hydraulica, Oper. tom. 4, pa. 389. Dr. Jurin, in the Philos. Trans. No. 452. Gravesande, Physic. Elem. Mathem. lib. 3, par. 2. Maclaurin's Flux. art. 537. Poleni de Castellis, Ximenes, D'Alembert, Bossu, Buat, and many others.

But notwithstanding the labours of all these eminent authors, this intricate subject still remains in a great measure obscure and uncertain. Even the simple case of the motion of running water, when it issues from a hole in the bottom of a vessel, has never yet been determined, so as to give universal satisfaction to the learned. On this head, it is now pretty generally allowed, that the velocity of the issuing stream, is equal to that which a heavy body acquires by falling through the height of the fluid above the hole, as may be demonstrated by theory: but in practice, the quantity of the effluent water is much less than what is given by this theory, owing to the obstruction to the motion in the hole, partly from the sides of it, and partly from the different directions of the parts of the water in entering it, which thence obstruct each other's motion. And this obstruction, and the diminution in the quantity of water run out, is still the more in proportion as the hole is the smaller; in such sort, that when the hole is very small, the quantity is diminished in the ratio of $\sqrt{2}$ to 1 very nearly, which is the ratio of the greatest diminution; and for larger apertures, the diminution is always less and less. This fact is ascertained, or admitted by Newton, and all the other philosophers above mentioned, with some small variations.

That the velocity of the water in the hole, or at least some part of it, as that for example in the middle of the stream, is equal to that above-mentioned, is even evinced by experiment, by directing the stream either sideways, or upwards: for in the former case, it is found to range upon an horizontal plane, a distance that just answers to that velocity, by the nature of projectiles; and in the latter case, the jet rises nearly to the height of the water in the vessel; which it could not do, if its velocity were not equal to that acquired by the free descent of a body through that height. Hence it is evident then, that the particles of the water, which are in the hole at the same moment of time, do not all issue out with the same velocity; and, in fact, the velocity is found to decrease all the way from the middle of the hole, where it is greatest, towards the side or edge, where it is the least.

At a small distance from the hole, the diameter of the vein of water is much less than that of the aperture itself. Thus, if the diameter of the hole be 1, the diameter of the vein of water just without it, will be $\frac{21}{25}$, or 0·84, according to Newton's measure, who first observed this phenomenon; and according to Poleni's measure 0·78 nearly.

By the experiments of Buat (Principes d'Hydraulique), the quantity by theory is to that by experiment, for a small aperture made in the thin side of a reservoir, as 8 to 5. When a short pipe is added to the hole outwards, of the length of two or three times its diameter, that ratio is as 16 to 13. And when the short pipe is all within side the vessel, as in the margin, the same ratio becomes that of 3 to 2. Poleni also found that the quantity of water flowing through a pipe or tube, was much greater than that through a hole of the same diameter in the thin side or bottom of the vessel, the height of the head of water above each being the same. See also many other curious circumstances in Buat's Principes above-mentioned.

Some authors give this rule for finding the height due to the velocity in a flat orifice, or a medium among all the parts of it, such that this medium velocity being drawn into the area of the hole, shall give the quantity per second that runs through: viz, let A denote the area of the surface of the water in the vessel, a the area of the orifice by which the water issues, and H the height of the water above the orifice; then, as $2A - a : A :: H : h$, the height due to the medium velocity, or the height from which a body must freely descend, by the force of gravity, to acquire that mean velocity.

Authors are not yet agreed as to the force with which a vein of water, spouting from a round hole in the side of a vessel, presses on a plane directly opposed to the motion of the vein. Most authors agree, that the pressure of this vein, flowing uniformly, ought to be equal to the weight of a cylinder of water, whose base is equal to the orifice through which the water flows, and its height equal to the height of the water in the vessel above the hole. The experiments made by Mariotte, and others, seem to countenance this opinion. But Dan. Bernoulli rejects it, and estimates this pressure by the weight of a column of the fluid, whose diameter is equal to the contracted vein (according to Newton's observation above-mentioned), and the height of which is equal to double the altitude due to the real velocity of the spouting water; and this pressure is also equal to the force of repulsion, arising from the reaction of the spouting water on the vessel. The ingenious author remarks that he speaks only of single veins of water, the whole of which are received by the planes on which they press; for as to the pressures exerted by fluids surrounding the bodies they press upon, as the wind, or a river, the case is different, though confounded with the former by writers on this subject. Hydrodynamica, pa. 289.

Another rule however had been adopted by the Academicians of Paris, who made a number of experiments to confirm or establish it. Hist. Acad. Paris, ann. 1679, sect. 3, cap. 5.

D. Bernoulli, on the other hand, thinks his own theory is sufficiently established by the experiments he relates; for the particulars of which see the Acta Petropolitana, vol. 8, pa. 122. This ingenious author is also of opinion that his theory of the quantity of the force of repulsion, exerted by a vein of spouting water, might be usefully applied to move ships by pumping; and he thinks the motion produced by this repulsive force would fall little, if at all, short of that produced by rowing. He has given his reasons and computations at length in his Hydrodynamica, pa. 293 &c.

This science of the pressures exerted by water or other fluids in motion, is what Bernoulli calls *Hydraulico-statica*. This science differs from hydrostatics, which considers only the pressure of water and other fluids at rest; whereas hydraulico-statics considers the pressure of water in motion. Thus the pressure exerted by water moving through pipes, upon the sides of those pipes, is an hydraulico-statical consideration, and has been erroneously determined by many, who have given no other rules in these cases, but such as are applicable only to the pressure of fluids at rest. See Hydrodynam. pa. 256 &c.

WATER-*Poise*. See HYDROMETER, and AREOMETER.

Dr. Hooke contrived a water-poise, which may be of good service in examining the purity &c of water. It consists of a round glass ball, like a bolt head, about 3 inches diameter, with a narrow stem or neck, the 24th of an inch in diameter; which being poised with red lead, so as to make it but little heavier than pure sweet water, and thus fitted to one end of a fine balance, with a counterpoise at the other end; on the least addition of even the 2000th part of salt to a quantity of water, half an inch of the neck will emerge above the water. Philos. Trans. No. 197.

Raising of WATER, in Hydraulics. The great advantage of raising water by engines for the various purposes of life, is well known. Machines have in all ages been contrived with this view; a detail of the best of which, with the theory of their construction, would be very curious and instructive. M. Belidor has executed this in part in his Architecture Hydraulique. Dr. Desaguliers has also given a description of several engines to raise water, in his Course of Experimental Philosophy, vol. 2; and there are several other smaller works of the same kind.

Engines for raising water are either such as throw it up with a great velocity, as in jets; or such as raise it from one place to another by a gentle motion. For the general theory of these engines, see Bernoulli's Hydrodynamica. —Desaguliers has settled the maximum of engines for raising water, thus: A man with the best water engine cannot raise above one hogshead of water in a minute, 10 feet high, to hold it all day; but he can do almost twice as much for a minute or two.

WATER-*Spout*. See SPOUT.

WATER-*Wheel*, an engine for raising water in great quantity out of a deep well, &c. See PERSIAN-*Wheel*.

WATER-*Works*. See *Raising of* WATER.

WAVE, in Physics, a volume of water elevated by the action of the wind &c, upon its surface, into a state of fluctuation, and accompanied by a cavity. The extent from the bottom or lowest point of one cavity, and across the elevation, to the bottom of the next cavity, is the breadth of the wave.

Waves are considered as of two kinds, which may be distinguished from each other by the names of natural and accidental waves. The natural waves are those which are regularly proportioned in size to the strength of the wind which produces them. The accidental waves are those occasioned by the wind's reacting on itself by repercussion from hills or high shores, and by the dashing of the waves themselves, otherwise of the natural kind, against rocks and shoals; by which means these waves acquire an elevation much above what they can have in their natural state.

Boyle proved, by numerous experiments, that the most violent wind never penetrates deeper than 6 feet into the water; and it seems a natural consequence of this, that the water moved by it can only be elevated to the same height of 6 feet from the level of the surface in a calm; and these 6 feet of elevation being added to the 6 of excavation, in the part from whence that water so elevated was raised, should give 12 feet for the utmost elevation of a wave. This is a calculation that does great honour to its author; as many experiments and observations have proved that it is very nearly true in deep seas, where the waves are purely natural, and have no accidental causes to render them larger than their just proportion.

It is not to be understood however, that no wave of the sea can rise more than 6 feet above its natural level in open and deep water; for some vastly higher than these are formed in violent tempests in the great seas. These however are not to be accounted waves in their natural state, but as compound waves formed by the union of many others; for in these wide plains of water, when one wave is raised by the wind, and would elevate itself up to the exact height of 6 feet, and no more, the motion of the water is so great, and the succession of waves so quick, that while this is rising, it receives into it several other waves, each of which would have been at the same height with itself; these run into the first wave one after another, as it is rising; by which means its rise is continued much longer than it naturally would have been, and it becomes accumulated to an enormous size. A number of these complicated waves rising together, and being continued in a long succession by the continuation of the storm, make the waves so dangerous to ships, which the sailors in their phrase call mountains high.

Different waves do not disturb one another when they move in different directions. The reason is, that whatever figure the surface of the water has acquired by the motion of the waves, there may in that be an elevation and depression; as also such a motion as is required in the motion of a wave.

Waves are often produced by the motion of a tremulous body, which also expand themselves circularly, though the body goes and returns in a right line; for the water which is raised by the agitation, descending, forms a cavity, which is every where surrounded with a rising.

The Motion of the WAVES, is a subject which makes an article in the Newtonian philosophy; that author having explained their motions, and calculated their velocity from mathematical principles, similar to the motion of a pendulum, and to the reciprocation of water in the two legs of a bent and inverted syphon or tube.

His proposition concerning such canal or tube is the 44th of the 2d book of his Principia, and is this: "If water ascend and descend alternately in the erected legs of a canal or pipe; and a pendulum be constructed, whose length between the point of suspension and the centre of oscillation, is equal to half the length of the water in the canal; then the water will ascend and descend in the same times in which the pendulum oscillates." The author hence infers, in prop. 45, that the velocity of waves is in the subduplicate ratio of their breadths; and in prop. 46, he proceeds "To find the velocity of waves," as follows: "Let a pendulum be constructed, whose length between the point of suspension and the centre of oscillation is equal to the breadth of the waves; and in the time that the pendulum will perform one single oscillation, the waves will advance forward nearly a space equal to their breadth. That which I call the breadth of the waves, is the transverse measure lying between the deepest part of the hollows, or between the tops of the ridges. Let ABCDEF represent the surface of stagnant water ascending and descending in successive waves; also let A, C, E, &c, be the

tops of the waves; and B, D, F, &c, the intermediate hollows. Because the motion of the waves is carried on by the successive ascent and descent of the water, so that the parts of it, as A, C, E, &c, which are highest at one time, become lowest immediately after; and because the motive force, by which the highest parts descend and the lowest ascend, is the weight of the elevated water, that alternate ascent and descent will be analogous to the reciprocal motion of the water in the canal, and observe the same laws as to the times of its ascent and descent; and therefore (by prop. 44, above-mentioned) if the distances between the highest places of the waves A, C, E, and the lowest B, D, F, be equal to twice the length of any pendulum, the highest parts A, C, E, will become the lowest in the time of one oscillation, and in the time of another oscillation will ascend again. Therefore between the passage of each wave, the time of two oscillations will intervene; that is, the wave will describe its breadth in the time that the pendulum will oscillate twice; but a pendulum of 4 times that length, and which therefore is equal to the breadth of the waves, will just oscillate once in that time. *Q. E. I.*

"*Corol.* 1. Therefore waves, whose breadth is equal to $39\frac{1}{8}$ inches, or $3\frac{1}{12}$ feet, will advance through a space equal to their breadth in one second of time; and therefore in one minute they will go over a space of $195\frac{1}{2}$ feet; and in an hour a space of 11737 feet, nearly, or 2 miles and almost a quarter.

"*Corol.* 2. And the velocity of greater or less waves, will be augmented or diminished in the subduplicate ratio of their breadth.

"These things (Newton adds) are true on the supposition, that the parts of water ascend or descend in a right line; but in fact, that ascent and descent is rather performed in a circle; and therefore I propose the time defined by this proposition as only near the truth."

Stilling WAVES *by means of Oil.* This curious property, though well known to the ancients, as appears from the writings of Pliny, was for many ages either quite unnoticed, or treated as fabulous by succeeding philosophers. Of late it has, by means of Dr. Franklin, again attracted the attention of the learned; though it appears, from some anecdotes, that seafaring people have always been acquainted with it. In Martin's description of the Western Islands of Scotland, we have the following passage: "The steward of Kilda, who lives in Pabbay, is accustomed, in time of a storm, to tie a bundle of puddings, made of the fat of sea-fowl, to the end of his cable, and let it fall into the sea behind his rudder. This, he says, hinders the waves from breaking, and calms the sea." Mr. Pennant, in his British Zoology, vol. iv, under the article Seal, takes notice, that when these animals are devouring a very oily fish, which they always do under water, the waves above are remarkably smooth; and by this mark the fishermen know where to find them. Sir Gilbert Lawson, who served long in the army at Gibraltar, assured Dr. Franklin, that the fishermen in that place are accustomed to pour a little oil on the sea, in order to still its motion, that they may be enabled to see the oysters lying at its bottom, which are there very large, and which they take up with a proper instrument. A similar practice obtains among fishermen in various other parts, and Dr. Franklin was informed by an old sea-captain, that the fishermen of Lisbon, when about to return into the river, if they saw too great a surf on the bar, would empty a bottle or two of oil into the sea, which would suppress the breakers, and allow them to pass freely.

The doctor having resolved in his mind all these pieces of information, became impatient to try the experiment himself. At last having an opportunity of observing a large pond very rough with the wind, he dropped a small quantity of oil into it. But having at first applied it on the lee-side, the oil was driven back again upon the shore. He then went to the windward side, and poured on about a tea-spoon-full of oil; this produced an instant calm over a space several yards square, which spread amazingly, and extended itself gradually till it came to the lee-side; making all that quarter of the pond, perhaps half an acre, as smooth as glass. This experiment was often repeated in different places, and always with success. Our author accounts for it in the following manner:

"There seems to be no natural repulsion between water and air, to keep them from coming into contact with each other. Hence we find a quantity of air in water; and if we extract it by means of the air pump, the same water again exposed to the air will soon imbibe an equal quantity.—Therefore air in motion, which is wind, in passing over the smooth surface of water, may rub as it were upon that surface, and raise it into wrinkles; which, if the wind continues, are the elements of future waves. The smallest wave once raised does not immediately subside and leave the neighbouring water quiet; but in subsiding raises nearly as much of the water next to it, the friction of the parts making little difference. Thus a stone dropped into a pool raises first a single wave round itself, and leaves it, by sinking to the bottom; but that first wave subsiding raises a second, the second a third, and so on in circles to a great extent.

"A small power continually operating, will produce a great action. A finger applied to a weighty suspended bell, can at first move it but little; if repeatedly applied, though with no greater strength, the motion increases till the bell swings to its utmost height, and with a force that cannot be resisted by the whole strength of the arm and body. Thus the small first raised waves being continually acted on by the wind, are, though the wind does not increase in strength, continually increased in magnitude, rising higher and extending their bases, so as to include a vast mass of water in each wave, which in its motion acts with great violence. But if there be a mutual repulsion between the particles of oil, and no attraction between oil and water, oil dropped on water will not be held together by adhesion to the spot whereon it falls; it will not be imbibed by the water; it will be at liberty to expand itself; and it will spread on a surface that, besides being smooth to the most perfect degree of polish, prevents, perhaps by repelling the oil, all immediate contact, keeping it at a minute distance from itself; and the expansion will continue, till the mutual repulsion between the particles of the oil is weakened and reduced to nothing by their distance.

"Now I imagine that the wind blowing over water thus covered with a film of oil cannot easily catch upon it, so as to raise the first wrinkles, but slides over it, and leaves it smooth as it finds it. It moves the oil a little indeed, which being between it and the water, serves to slide with, and prevents friction, as oil does between those parts of a machine that would otherwise rub hard together. Hence the oil dropped on the windward side of a pond proceeds gradually to leeward, as may be seen by the smoothness it carries with it quite to the opposite side. For the wind being thus prevented from raising the first wrinkles that I call the elements of waves, cannot produce waves, which are to be made by continually acting on and enlarging those elements; and thus the whole pond is calmed.

"Totally therefore we might suppress the waves in any required place, if we could come at the windward place where they take their rise. This in the ocean can seldom if ever be done. But perhaps something may be done on particular occasions to moderate the violence of the waves when we are in the midst of them, and prevent their breaking when that would be inconvenient. For when the wind blows fresh, there are continually rising on the back of every great wave a number of small ones, which roughen its surface, and give the wind hold, as it were, to push it with greater force. This hold is diminished by preventing the generation of those small ones. And possibly too, when a wave's surface is oiled, the wind, in passing over it, may rather in some degree press it down, and contribute to prevent its rising again, instead of promoting it.

"This, as mere conjecture, would have little weight, if the apparent effects of pouring oil into the midst of waves were not considerable, and as yet not otherwise accounted for.

"When the wind blows so fresh, as that the waves are not sufficiently quick in obeying its impulse, their tops, being thinner and lighter, are pushed forward, broken, and turned over in a white foam. Common waves lift a vessel without entering it; but these, when large, sometimes break above and pour over it, doing great damage.

"That this effect might in any degree be prevented, or the height and violence of waves in the sea moderated, we had no certain account; Pliny's authority for the practice of seamen in his time being slighted. But discoursing lately on this subject with his excellency Count Bentinck of Holland, his son the honourable captain Bentinck, and the learned professor Allemand (to all whom I showed the experiment of smoothing in a windy day the large piece of water at the head of the green park), a letter was mentioned which had been received by the count from Batavia, relative to the saving of a Dutch ship in a storm by pouring oil into the sea."

WAY *of a Ship*, is sometimes used for her wake or track. But more commonly the term is understood of the course or progress which she makes on the water under sail: thus, when she begins her motion, she is said to be under way; when that motion increases, she is said to have fresh way through the water; when she goes apace, they say she has a good way; and the account of her rate of sailing by the log, they call, keeping an account of her way. And because most ships are apt to fall a little to the leeward of their true course, it is customary, in casting up the log-board, to allow something for her leeward way, or leeway. Hence also a ship is said to have head-way, and stern-way.

WAY-WISER, an instrument for measuring the road, or distance travelled; called also PERAMBULATOR, and PEDOMETER. See these two articles.

Mr. Lovell Edgworth communicated to the Society of

Arts, &c, an account of a way-wiser of his invention; for which he obtained a silver medal. This machine consists of a nave, formed of two round flat pieces of wood, 1 inch thick and 8 inches in diameter. In each of the pieces there are cut eleven grooves, $\frac{1}{4}$ of an inch wide, and $\frac{3}{8}$ deep; and when the two pieces are screwed together, they enclose eleven spokes, forming a wheel of spokes, without a rim; the circumference of the wheel is exactly one pole; and the instrument may be easily taken to pieces, and put up in a small compass. On each of the spokes there is driven a ferril, to prevent them from wearing out; and in the centre of the nave, there is a square hole to receive an axle. Into this hole is inserted an iron or brass rod, which has the thread of a very fine screw worked upon it from one end to the other; upon this screw hangs a nut which, as the rod turns round with the wheel, advances towards the nave of the wheel or recedes from it. The nut does this, because it is prevented from turning round with the axle, by having its centre of gravity placed at some distance below the rod, so as always to hang perpendicularly like a plummet. Two sides of this screw are filed away flat, and have figures engraved on them, to show by the progressive motion of the nut, how many circumvolutions of the wheel and its axle have been made: on one side the divisions of miles, furlongs, and poles are in a direct order, and on the other side the same divisions are placed in a retrograde order.

If the person who uses this machine places it at his right hand side, holding the axle loosely in his hands, and walks forward, the wheel will revolve, and the nut advance from the extremity of the rod towards the nave of the wheel. When two miles have been measured, it will have come close to the wheel. But to continue this measurement, nothing more is necessary than to place the wheel at the left hand of the operator; and the nut will, as he continues the course, recede from the axle-tree, till another space of two miles is measured.

It appears, from the construction of this machine, that it operates like circular compasses; and does not, like the common wheel way-wiser, measure the surface of every stone and molehill, &c, but passes over most of the obstacles it meets with, and measures the chords only, instead of the arcs of any curved surfaces upon which it rolls.

WEATHER, denotes the state or disposition of the atmosphere, with regard to heat and cold, drought and moisture, fair or foul, wind, rain, hail, frost, snow, fog, &c. See ATMOSPHERE, HAIL, HEAT, FROST, RAIN, &c.

There does not appear in all philosophy any circumstance of more immediate concern to us, than the state of the weather; as it is in, and by means of the atmosphere, that all plants are nourished, and all animals live and breathe; and as any alterations in the density, heat, purity, &c, of that, must necessarily be attended with proportionable ones in the state of these.

The great, but regular alterations, a little change of weather produces in many parts of inanimate matter, every person knows, from the common instance of barometers, thermometers, hygrometers, &c; and it is owing partly to our inattention, and partly to our unequal and intemperate course of life, that we also, like many other animals, do not feel as great and as regular ones in the tubes, chords, and fibres of our own bodies.

To establish a proper theory of the weather, it would be necessary to have registers carefully kept in divers parts of the globe, for a long series of years; from which we might be enabled to determine the directions, breadth, and bounds of the winds, and of the weather they bring with them; with the correspondence between the weather of divers places, and the difference between one kind and another at the same place. We might thus probably in time learn to foretell many great emergencies; as, extraordinary heats, rains, frosts, droughts, dearths, and even plagues, and other epidemical diseases, &c.

It is however but very few, and partial registers or accounts of the weather, that have been kept. The Royal Society, the French Academy, and a few particular philosophers, have at times kept such registers as their fancies have dictated, but never a regular and correspondent series in many different places, at the same time, followed with particular comparisons and deductions from the whole, &c. The most of what has been done in this way, is as follows: The volumes of the Philosophical Transactions from year to year; the same, for instructions and examples pertaining to the subject, vol. 65, part 2, art. 16; Eras. Bartholin has observations of the weather for every day in the year 1671; Mr. W. Merle made the like at Oxford, for 7 years; Dr. Plot did the same at the same place, for the year 1684; Mr. Hillier, at Cape Corse, for the years 1686 and 1687; Mr. Hunt and others at Gresham College, for the years 1695 and 1696; Dr. Derham at Upminster in Essex, for the years 1691, 1692, 1697, 1698, 1699, 1703, 1704, 1705; Mr. Townley, in Lancashire, in 1697, 1698; Mr. Cunningham, at Emin in China, for the years 1698, 1699, 1700, 1701; Mr. Locke, at Oats in Essex, 1692; Dr. Scheuchzer, at Zurich, 1708; and Dr. Tilly, at Pisa, the same year; professor Toaldo, at Padua, for many years; Mr. T. Barker, at Lyndon, in Rutland, for many years in the Philos. Trans.: Mr. Dalton for Kendal, and Mr. Crosthwaite for Keswick, in the years 1788, 1789, 1790, 1791, 1792, &c; and several others. The register now kept, for many years, in the Philos. Trans. contains an account, two times every day, of the thermometer, barometer, hygrometer, quantity of rain, direction and strength of the wind, and appearance of the atmosphere, as to fair, cloudy, foggy, rainy, &c. And if similar registers were kept in many other parts of the globe, and printed in such-like public transactions, they might readily be consulted, and a proper use made of them, for establishing this science on the true basis of experiment.

From many experiments, some general observations have been made, as follow: That barometers generally rise and fall together, even at very distant places, and a consequent conformity and similarity of weather; but this is the more uniformly so, as the places are nearer together, as might be expected. That the variations of the barometer are greater, as the places are nearer the pole; thus, for instance, the mercury at London has a greater range by 2 or 3 lines than at Paris; and at Paris, a greater than at Zurich; and at some places near the equator, there is scarcely any variation at all. That the rain in Switzerland and Italy is much greater in quantity, for the whole year, than in Essex; and yet the rains are more frequent, or there are more rainy days, in Essex, than at either of those places. That cold contributes greatly to rain; and this apparently by condensing the suspended vapours, and so causing them to descend: thus, very cold months, or seasons, are commonly followed immediately by very rainy ones; and cold summers are always wet ones. That high ridges of mountains, as the Alps, and the snows with which they are covered, not only affect the neighbouring places by the colds, rains, vapours, &c, which they produce; but even distant countries, as England, often partake of their effects. See a collection of ingenious and meteorological observations and conjectures, by Dr. Franklin, in his Experiments, &c, pa. 182, &c. Also a Meteorological Register kept at Mansfield Woodhouse, from 1784 to 1794, Nottingham 1795, 8vo; and Kirwin's ingenious papers on this subject in the Transactions of the Irish Academy, vol. 5. See also the articles EVAPORATION, RAIN, and WIND.

Other Prognostics and Observations, are as follow:

That a thick dark sky, lasting for some time, without either sun or rain, always becomes first fair, and then foul, i. e. it changes to a fair clear sky, before it turns to rain. And the reason is obvious: the atmosphere is replete with vapours which, though sufficient to reflect and intercept the sun's rays from us, yet want density to descend; and while the vapours continue in the same state, the weather will do so too: accordingly, such weather is commonly attended with moderate warmth, and with little or no wind to disturb the vapours, and a heavy atmosphere to sustain them; the barometer being commonly high; but when the cold approaches, and by condensing the vapours drives them into clouds or drops, then way is made for the sun beams; till the same vapours, by farther condensation, be formed into rain, and fall down in drops.

That a change in the warmth of the weather is followed by a change in the wind. Thus, the northerly and southerly winds, though commonly accounted the causes of cold and warm weather, are really the effects of the cold or warmth of the atmosphere; of which Dr. Derham assures us he had so many confirmations, that he makes no doubt of the fact. Thus, it is common to observe a warm southerly wind suddenly changed to the north, by the fall of snow or hail; or to have the wind, in a cold frosty morning, north, when the sun has well warmed the air, shift towards the south; and again turn northerly or easterly in the cold evening.

That most vegetables expand their flowers and down in sunshiny weather: and towards the evening, and against rain, close them again; especially at the beginning of their flowering, when their seeds are tender and sensible. This is visible enough in the down of dandelion, and other downs; and eminently so in the flowers of pimpernel; the opening and shutting of which make what is called the countryman's weather-wiser, by which he foretels the weather of the following day. The rule is, when the flowers are close shut up, it betokens rain, and foul weather; but when they are spread abroad, fair weather.

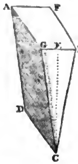
The stalk of trefoil, lord Bacon observes, swells against rain, and grows more upright; and the like may be observed, though less sensibly, in the stalks of most other plants. He adds, that in the stubble fields there is found a small red flower, called by the country people pimpernel, which, opening in a morning, is a sure indication of a fine day.

It is very conceivable that vegetables should be affected by the same causes as the weather, as they may be considered as so many hygrometers and thermometers, consisting of an infinite number of tracheæ, or air-vessels; by which they have an immediate communication with the air, and partake of its moisture, heat, &c.

Hence it is, that every kind of wood, even the hardest and most solid, swells in moist weather; the vapours easily insinuating themselves into the pores, especially of the lighter and drier kinds. And hence is derived a very extraordinary use of wood, viz, for breaking rocks or milstones. The method at the quarries is this: Having cut a rock into the form of a cylinder, the workmen divide it into several thinner cylinders, of horizontal courses, by making holes at proper distances round the great one; into these holes they drive pieces of sallow wood, dried in an oven; these in moist weather, imbibing the humidity from the air, swell, and, acting like wedges, they break or cleave the rock into several flat stones. And, in like manner, to separate large blocks of stone in the quarry, they wedge such pieces of wood into holes, forming the block into the intended shape, and then pour water upon the wedges, to produce the effect more immediately.

WEATHER-*Glasses*, are instruments contrived to show the state of the atmosphere, as to heat, cold, moisture, weight, &c; and so to measure the changes that take place in those respects; by which means we are enabled to predict the alteration of weather, as to rain, wind, frost, &c.—Under the class of weather-glasses, are comprehended barometers, thermometers, hygrometers, manometers, and anemometers.

WEDGE, in Geometry, is a solid, having a rectangular base, and two of its opposite sides ending in an acies or edge. Thus, AB is the rectangular base; and DC the edge; a perpendicular CE, from the edge to the base, is the height of the wedge. When the length of the edge DC is equal to the length of the base BF, which is the most common form of it, the wedge is equal to half a rectangular prism of the same base AB and height EC; or it is then a whole triangular prism, having the triangle BCG for its base, and AG or DC for its height.



If the edge be more or less than AG, its solid content will also be more or less. But, in all cases of the wedge, the following is a general rule for finding the content of it, viz,

To twice the length of the base add the length of the edge, multiply the sum by the breadth of the base, and the product by the height of the wedge; then $\frac{1}{6}$ of the last product will be the solid content.

That is, $(2AG + DC) \times AF \times \frac{1}{6} EC =$ the content. See this rule demonstrated, and illustrated with examples, in my Mensuration, pa. 141, 4th edition.

WEDGE, in Mechanics, one of the five mechanical powers, or simple engines; being a geometrical wedge, or very acute triangular prism, applied to the splitting of wood, or rocks, or raising great weights.

This machine is made of iron, or some other hard matter, and applied to the raising of vast weights, or separating very firm blocks of wood or stone, by introducing the thin edge of the wedge, and driving it in by blows struck upon the back by hammers or mallets.

The wedge is the most powerful of all the simple machines, having an almost unlimited and double advantage over all the other simple mechanical powers; both as it may be made vastly thin, in proportion to its height; in which consists its own natural power; and as it is urged by the force of percussion, or of smart blows, which is a force incomparably greater than any mere dead weight or pressure, such as is employed on other machines. And accordingly we find it produces effects vastly superior to those of any other power whatever; such as the splitting and raising the largest and hardest rocks; or even the raising and lifting the largest ship, by driving a wedge under it; which a man can do by the blow of a mallet: and thus, the small blow of a hammer, on the back of a wedge, appears to be incomparably greater than any mere pressure, and will overcome it.

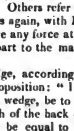
To the wedge may be referred all edge-tools, and instruments that have a sharp point, in order to cut, cleave, slit, split, chop, pierce, bore, or the like; as knives, hatchets, swords, bodkins, &c.

In the wedge, the friction against the sides is very great, at least equal to the force to be overcome; because the wedge retains any position to which it is driven; and therefore the resistance is at least doubled by the friction.

Authors have been of various opinions concerning the principle from which the wedge derives its power. Aristotle considers it as two levers of the first kind, inclined towards each other, and acting in opposite directions. Guido Ubaldi, Mersenne, &c, will have them to be levers of the second kind. But Delanis shows, that the wedge cannot be reduced to any lever at all. Others refer the wedge to the inclined plane. And others again, with Destair, will hardly allow the wedge to have any force at all in itself; ascribing much the greatest part to the mallet which drives it.

The doctrine of the force of the wedge, according to some writers, is contained in this proposition: "If a power directly applied to the head of a wedge, be to the resistance to be overcome, as the breadth of the back GB, is to the height EC; then the power will be equal to the resistance; and if increased, it will overcome it."

But Desaguliers has proved that, when the resistance acts perpendicularly against the sides of the wedge, the power is to the whole resistance, as the thickness of the back is to the length of both the sides taken together. And the same proportion is adopted by Wallis (Op. Math. vol. 1, pa. 1016), Keill (Intr. ad Ver. Phys.), Gravesande (Elem. Math. Lib. 1, cap. 14), and by almost all the modern mathematicians. Gravesande indeed distinguishes the mode in which the wedge acts, into two cases, one in which the parts of a block of wood, &c, are separated farther than the edge has penetrated to, and the other in which they have not separated farther: In his Scholium de Ligno findendo (ubi supra), he observes, that when the parts of the wood are separated before the wedge, the equilibrium will be when the force by which it is pushed in, is to the resistance of the wood, as the line DE drawn from the middle of the base to the side of the wedge but perpendicular to the separated side of the wood FG continued, is to the height of the wedge DC; but when the parts of the wood are separated no farther than the wedge is driven in, the equilibrium will be, when the power is to the resistance, as the half base AD, is to its side AC.



Mr. Ferguson, in estimating the proportion of equilibrium in the two cases last mentioned by Gravesande, agrees with this author, and other modern philosophers, in the latter case; but in the former he contends, that when the wood cleaves to any distance before the wedge, as it generally does, then the power impelling the wedge, will be to the resistance of the wood, as half its thickness, is to the length of either side of the cleft, estimated from the top or acting part of the wedge: for, supposing the wedge to be lengthened down to the bottom of the cleft, the power will be to the resistance, as half the thickness of the wedge is to the length of either of its sides. See Ferguson's Lect. pa. 40, &c, 4to. See also Desagu. Exp. Phil. vol. 1, pa. 107; and Ludlam's Essay on the Power of the Wedge, printed in 1770; &c.

The generally acknowledged property of the wedge, and the simplest way of demonstrating it, may be the following: When a wedge is kept in equilibrio, the power acting against the back, is to the force acting perpendicularly against either side, as the breadth of the back AB, is to the length of the side AC or BC.—*Demonstra.* For any three forces which sustain one another in equilibrio, are as the corresponding sides of a triangle that are drawn perpendicular to the directions in which the forces act. But AB is perpendicular to the force acting on the back, to drive the wedge forward; and the sides AC and BC are perpendicular to the forces acting on them; therefore the three forces are as the said lines AB, AC, BC.

Hence, the thinner a wedge is, the greater is its effect, in splitting any body, or in overcoming any resistance against the side of the wedge.

WEDNESDAY, the 4th day of the week, formerly consecrated by the inhabitants of the northern nations to Woden or Oden; who, being reputed the author of magic, and inventor of all the arts, was thought to answer to the Mercury of the Greeks and Romans, in honour of whom the same day was by them called dies Mercurii; and hence it is denoted by astronomers by the character of Mercury ☿.

WEEK, a division of time that comprises seven days.

The origin of this division of weeks, or of computing time by sevenths, is much controverted. It has often been thought to have taken its rise from the four quarters or intervals of the moon, between her changes of phases, which, being about 7 days distant, gave occasion to the division: but others more probably from the seven planets.

Be this however as it may, the division is certainly very ancient. The Syrians, Egyptians, and most of the oriental nations, appear to have used it from the earliest ages: though it did not get footing in the west till introduced by Christianity. The Romans reckoned their days not by sevenths, but by ninths; and the ancient Greeks by decads, or tenths; in imitation of which the new French calendar seems to have been framed.

The Jews divided their time by weeks, of 7 days each, as prescribed by the law of Moses; in which they were appointed to work 6 days, and to rest the 7th, in commemoration of the creation, which being effected in 6 days, God rested on the 7th.

Some authors will even have the use of weeks, among the other eastern nations, to have proceeded from the Jews; but with little appearance of probability. It is with better reason that others suppose the use of weeks, among the eastern nations, to be a remnant of the tradition of the creation, which they had still retained with divers others; or else from the number of the planets.

The Jews denominated the days of the week, the first, second, third, fourth, and fifth; and the sixth day they named the preparation of the sabbath, or 7th day, which answered to our Saturday. And the like method is still kept up by the christian Arabs, Persians, Ethiopians, &c.

The ancient heathens denominated the days of the week from the seven planets; which names are still mostly retained among the christians of the west: thus, the first day was called dies solis, sun-day; the 2d dies lunæ, moon-day; &c; a practice the more natural on Dion's principle, that the Egyptians took the division of the week itself from the seven planets.

In fact, the true reason for these denominations seems to be founded in astrology. For the astrologers distributing the government and direction of all the hours in the week among the seven planets, ♄ ♃ ♂ ☉ ♀ ☿ ☽, so as that the government of the first hour of the first day fell to Saturn, that of the second day to Jupiter, &c, they gave each day the name of the planet which, according to their doctrine, presided over the first hour of it, and that according to the order above stated. So that the order of the planets in the week bears little relation to that in which they follow in the heavens; the former being grounded on an imaginary power each planet has, in its turn, on the first hour of each day.

Dion Cassius gives another reason for the denomination, drawn from the celestial harmony. For it being observed, that the harmony of the diatessaron, which consists in the ratio of 4 to 3, is of great force and effect in music; it was thought proper to proceed directly from Saturn to the Sun; because, according to the old system, there are three planets between Saturn and the Sun, and 4 from the Sun to the Moon.

Our Saxon ancestors, before their conversion to Christianity, named the seven days of the week from the sun and moon and some of their deified heroes, to whom they were peculiarly consecrated, and representing the ancient gods or planets; which names we have received and still retain: Thus, Sunday was devoted to the Sun; Monday to the Moon; Tuesday to Tuisco; Wednesday to Woden; Thursday to Thor, the thunderer; Friday to Friga or Friya of Fræa, the wife of Thor; and Saturday to Seater. And nearly according to this order, the modern astronomers express the days of the week by the seven planets as annexed.

☉	Sunday
☾	Monday
♂	Tuesday
☿	Wednesday
♃	Thursday
♀	Friday
♄	Saturday

In the same order and number also do these obtain in the Hindu days of the week. See Kindersley's Specimens of Hindu Literature, just published, 8vo.

WEIDLER (JOHN FREDERICK) was professor of mathematics at Wittemberg. Besides a number of communications to the Royal Society, contained in vols. 36, 38, 39, 40, 41, of the Philos. Trans. he was author of several separate works: as, 1. Institutiones Mathematicæ, in 8vo, 1725. This is a very thick volume, and contains a general, though concise course, of all the mathematical sciences. 2. Observationes Meteorologicæ et Astronomicæ, 1729. 3. Historia Astronomica, in 4to, 1741.

WEIGH, WAY, or WEY, a weight of cheese, wool, &c, containing 256 pounds avoirdupois. Of corn, the weigh contains 40 bushels; of barley or malt, 6 quarters.

WEIGHT, or *Gravity*, in Physics, a quality in natural bodies, by which they tend towards the centre of the earth: and it is equal to the effort necessary to prevent a body from falling. See GRAVITY.

Weight, like gravity, may be distinguished into absolute specific, and relative. Newton demonstrates, 1. That the weights of all bodies, at equal distances from the centre of the earth, are directly proportional to the quantities of matter that each contains: Whence it follows, that the weights of bodies have no dependence on their shapes or textures; and that all spaces are not equally full of matter.

2. On different parts of the earth's surface, the weight of the same body is different; owing to the spheroidal figure of the earth, which causes the body on the surface to be nearer the centre in going from the equator towards the poles: and the increase in the weight is nearly in proportion to the versed sine of double the latitude; or, which is the same thing, to the square of the right sine of the latitude: the weight at the equator to that at the pole, being as 229 to 230; or the whole increase of weight from the equator to the pole, is the 229th part of the former.

3. That the weights of the same body, at different distances above the earth, are inversely as the squares of the distances from the centre. So that, a body at the distance of the moon, which is 60 semidiameters from the earth's centre, would weigh only the 3600th part of what it weighs at the earth's surface.

4. That at different distances within the earth, or below the surface, the weights of the same body are directly as the distances from the earth's centre: so that, at half way toward the centre, a body would weigh but half as much, and at the very centre it would have no weight at all.

5. A body immersed in a fluid, which is specifically lighter than itself, loses so much of its weight, as is equal to the weight of a quantity of the fluid of the same bulk with itself. Hence, a body loses more of its weight in a heavier fluid than in a lighter one: and therefore it weighs more in a lighter fluid than in a heavier one.

The weight of a cubic foot of pure water, is 1000 ounces, or 62½ pounds, avoirdupois. And the weights of the cubic foot of other bodies, are as set down under the article *Specific* GRAVITY.

In the Philos. Trans. (No. 458, pa. 457 &c) is contained some account of the analogy between English weights and measures, by Mr. Barlow. He states, that anciently the cubic foot of water was assumed as a general standard for liquids. This cubic foot, of 62½ lb, multiplied by 32, gives 2000, the weight of a ton: and hence 8 cubic feet of water made a hogshead, and 4 hogsheads a tun, or ton, in capacity and denomination, as well as weight.

Dry measures were raised on the same model. A bushel of wheat, assumed as a general standard for all sorts of grain, also weighed 62½lb. Eight of these bushels make a quarter, and 4 quarters, or 32 bushels, a ton weight. Coals were sold by the chaldron, supposed to weigh a ton, or 2000 pounds; though in reality it weighs perhaps upwards of 3000 pounds.

Hence a ton in weight is the common standard for liquids, wheat, and coals. Had this analogy been adhered to, the confusion now complained of would have been avoided.—It may reasonably be supposed that corn and other commodities, both dry and liquid, were first sold by weight; and that measures, for convenience, were afterwards introduced, as bearing some analogy to the weights before used.

WEIGHT, *Pondus*, in Mechanics, denotes any thing to be raised, sustained, or moved by a machine; or any thing that in any manner resists the motion to be produced. In all machines, there is a natural and fixed ratio between the weight and the moving power; and if they be such as to balance each other in equilibrio, and then the machine be put in motion by any other force; the weight and power will always be reciprocally as the velocities of them, or of their centres of gravity; or their momentums will be equal, that is, the product of the weight multiplied by its velocity, will be equal to the product of the power multiplied by its velocity.

WEIGHT, in Commerce, denotes a body of a known weight, appointed to be put into a balance against other bodies, whose weight is required to be known. These weights are usually of lead, iron, or brass; though in several parts of the East Indies common flints are used; and in some places a sort of little beans. The diversity of weights, in all nations, and at all times, makes one of the most perplexing circumstances in commerce, &c. And it would be a very great convenience if all nations could agree on a universal standard, and system, both of weights and measures.

Weights may be distinguished into ancient and modern, foreign and domestic.

Modern WEIGHTS, *used in the several parts of Europe, and the Levant.*

English WEIGHTS. By the 27th chapter of Magna Charta, the weights are to be the same all over England; but for different commodities there are two different kinds, viz, troy weight, and avoirdupois weight.

The origin from which both of these are raised, is the grain of wheat, gathered in the middle of the ear:

32 of these, well dried, made one pennyweight,
20 pennyweights - - - one ounce, and
12 ounces - - - - - one pound troy;

by Stat. 51 Hen. III; 31 Edw. I; 12 Hen. VII.

A learned writer has shown that, by the laws of assize, from William the Conqueror to the reign of Henry VII, the legal pound weight contained a pound of 12 ounces, raised from 32 grains of wheat; and the legal gallon measure contained 8 of those pounds of wheat, 8 gallons making the bushel, and 8 bushels the quarter.

Henry VII. altered the old English weight, and introduced the troy pound in its stead, being 3 quarters of an ounce only heavier than the old Saxon pound, or 1-16th heavier. The first statute that directs the use of the avoirdupois weight, is that of 24 Henry VIII; and the particular use to which this weight is thus directed, is simply for weighing butcher's meat in the market; though it is now used for weighing all kinds of coarse and large articles. This pound contains 7000 troy grains; while the troy pound itself contains only 5760 grains, and the old Saxon pound weight but 5400 grains. Philos. Trans. vol. 65, art. 3.

Hence there are now in common use in England, two different weights, viz, troy weight, and avoirdupois weight, the former being employed in weighing such fine articles as jewels, gold, silver, silk, liquors, &c: and the latter for coarse and heavy articles, as bread, corn, flesh, butter, cheese, tallow, pitch, tar, iron, copper, tin, &c, and all grocery wares. And Mr. Ward supposes that it was brought into use from this circumstance, viz, as it was customary to allow larger weight, of such coarse articles, than the law had expressly enjoined, and this he observes happened to be a 6th part more. Apothecaries buy their drugs by avoirdupois weight, but they compound them by troy weight, though under some little variation of name and divisions.

The troy or trone pound weight in Scotland, which by statute is to be the same as the French pound, is commonly supposed equal to 15¾ English troy ounces, or 7560 grains; but by a mean of the standards kept by the dean of gild of Edinburgh, it weighs 7599$\frac{1}{18}$ or 7600 grains nearly.

The following tables show the divisions of the troy and avoirdupois weights.

Table of Troy Weight, as used,

1. By the Goldsmiths, &c.

Grains		Pennywt.				
24	=	1 dwt.				
480	=	20	=	1 oz.		
5760	=	240	=	12	=	1 lb.

2. By the Apothecaries.

Grains		Scruples						
20	=	1 ℈						
60	=	3	=	1 Dram ʒ				
480	=	24	=	8	=	1 Ounce ℥		
5760	=	288	=	96	=	12	=	1 lb.

Table of Avoirdupois Weight.

Drams		Ounces								
16	=	1								
256	=	16	=	1 lb.						
7168	=	448	=	28	=	1 quar.				
28672	=	1792	=	112	=	4	=	1 cwt.		
573440	=	35840	=	2240	=	80	=	20	=	1 ton.

Mr. Ferguson (Lect. on Mech. pa. 100, 4to) gives the following comparison between troy and avoirdupois weight.

175 troy pounds are equal to 144 avoirdup. pounds.
175 troy ounces are equal to 192 avoirdup. ounces.
1 troy pound contains 5760 grains.
1 avoirdupois pound contains 7000 grains.
1 avoirdupois ounce contains 437½ grains.
1 avoirdupois dram contains 27·34375 grains.
1 troy pound contains 13 oz. 2·651428576 drams avoirdupois
1 avoirdup. lb. contains 1 lb. 2 oz. 11 dwts 16 gr. troy

The moneyers, jewellers, &c, have a particular class of weights, for gold and precious stones, viz, carat and grain, the carat being 24 grains; and for silver, the pennyweight and grain. The first have also a peculiar subdivision of the troy grain: thus, dividing

the grain into 20 mites
the mite into 24 droits
the droit into 20 periots
the periot into 24 blanks.

The dealers in wool have likewise a particular set of weights; viz, the sack, weigh, tod, stone, and clove, the proportions of which are as below: viz,

the sack containing 2 weighs
the weigh - - 6½ tods
the tod - - - 2 stones
the stone - - 2 cloves
the clove - - 7 pounds.

Also 12 sacks make a last or 4368 pounds.

Farther,

56 lb of old hay, or 60 lb new hay, make a truss.

40 lb of straw make a truss.

36 trusses make a load, of hay or straw.

14 lb make a stone.

5 lb of glass a stone.

French WEIGHTS. The common or Paris old pound weight, is to the English troy pound, as 21 to 16, and to the avoirdupois pound as 27 to 25; it therefore contains 7560 troy grains; and it is divided into 16 ounces like the pound avoirdupois, but more particularly thus: the pound into 2 marcs; the marc into 8 ounces; the ounce into 8 gros, or drams; the gross or dram into 3 deniers, Paris scruples or pennyweights; and the pennyweight into 24 grains; the grain being an equivalent to a grain of wheat. So that the Paris ounce contains 472$\frac{1}{2}$ troy grains, and therefore it is to the English troy ounce as 63 to 64. But in several of the French provinces, the pound is of other different weights. A quintal is equal to 100 pounds.

Table of old French Weights with the Equivalent in Troy and Avoirdupois Weight.

French.	Troy. oz.	dwt.	grs.	Avoirdupois. oz.	drs.	hds.
1 Pound	15	14	20	17	4	34
1 Marc	7	17	10	8	10	17
1 Ounce		19	16$\frac{1}{2}$	1	1	27
1 Gros		2	11		2	16
1 Scruple			19$\frac{2}{3}$			72
1 Grain			$\frac{4}{5}$			03

The new French weights are those which have for their measure a unit, called a gramme. This gramme is the absolute weight of the cube of the centimetre, or 100th part of the metre, or 3$\frac{2}{7}$ English feet, of distilled water, taken at its maximum of density; and answers to 19 Paris grains, or to 15$\frac{4}{9}$ English grains. The kilogramme, or the weight of a 1000 grammes, is equal to about 32$\frac{1}{8}$ troy ounces. See the article MEASURES.

The weights above enumerated under the two articles of English and French weights, are the same as are used throughout the greatest part of Europe; only under somewhat different names, divisions, and proportions. And besides, particular nations have also certain weights peculiar to themselves, of too little consequence here to be enumerated. But to show the proportion of these several weights to one another, there may be here added a reduction of the divers pounds in use throughout Europe, by which the other weights are estimated, to one standard pound, viz, the old pound of Amsterdam, Paris, and Bourdeaux; as they were accurately calculated by M. Ricard, and published in the new edition of his Traité de Commerce in 1722.

Proportion of the WEIGHTS *of the chief Cities in Europe, to that of Amsterdam, or the old French Pound.*

100 pounds of Amsterdam are equal to

108 lbs of	Alicant	95$\frac{1}{2}$ lbs of	Bergen, Norw.
105	Antwerp	111	Bern
120	Archangel, or 3 poedes	100	Besançon
		100	Bilboa
105	Arschot	105	Bois le Duc
120	Avignon	151	Bologna
98	Basil	100	Bourdeaux
100	Bayonne	104	Bourg en Bresse
166	Bergamo	103	Bremen
97	Berg. op Zoom	125	Breslaw

WEIGHTS *continued.*

100 pounds of Amsterdam are equal to

105 lbs of	Bruges	114 lbs of	Madrid
105	Brussels	105	Malines
105	Cadiz	123$\frac{1}{2}$	Marseilles
105	Cologne	154	Messina
107$\frac{1}{2}$	Copenhagen	168	Milan
87	Constantinople	120	Montpelier
113$\frac{1}{2}$	Dantzic	125	Muscovy
100	Dort	100	Nantes
97	Dublin	100	Nancy
97	Edinburgh	169	Naples
143	Florence	98	Nuremberg
98	Franckfort, sur Maine	100	Paris
		112$\frac{1}{2}$	Revel
105	Gaunt	109	Riga
89	Geneva	100	Rochel
163	Genoa	146	Rome
102	Hamburg	100	Rotterdam
125	Koningsberg	96	Rouen
105	Leipsic	100	S. Malo
106	Leyden	100	S. Sebastian
143	Leghorn	158$\frac{1}{7}$	Saragosa
105$\frac{1}{2}$	Liege	100	Seville
106	Lisbon	114	Smyrna
114	Lisle	110	Stetin
109	London, avoirdupois	81	Stockholm
		118	Tholouse
105	Louvain	151	Turin
105	Lubeck	158$\frac{1}{2}$	Valencia
141$\frac{1}{2}$	Lucca	182	Venice
116	Lyons		

Ancient WEIGHTS.

1. The weights of the ancient Jews, reduced to the English troy weights, will stand as below:

	lb	oz	dwt	gr
Shekel - -	0	0	9	2$\frac{4}{7}$
Manch - -	2	3	6	10$\frac{2}{7}$
Talent - -	113	10	1	10$\frac{2}{7}$

2. Grecian and Roman weights, reduced to English troy weight, are as in the following table:

	lb	oz	dwt	gr
Lentes - -	0	0	0	0$\frac{85}{112}$
Siliquæ - -	0	0	0	3$\frac{1}{28}$
Obolus - -	0	0	0	9$\frac{3}{28}$
Scriptulum -	0	0	0	18$\frac{3}{14}$
Drachma - -	0	0	2	6$\frac{5}{14}$
Sextula - -	0	0	3	0$\frac{6}{7}$
Sicilicus - -	0	0	4	13$\frac{5}{7}$
Duella - -	0	0	6	1$\frac{5}{7}$
Uncia - -	0	0	18	5$\frac{1}{7}$
Libra - -	0	10	18	13$\frac{5}{7}$

The Roman ounce is the English avoirdupois ounce, which they divide into 7 denarii, as well as 8 drachms; and as they reckoned their denarius equal to the Attic drachm, this will make the Attic weights one-eighth heavier than the correspondent Roman weights. Arbuth.

Regulation of WEIGHTS *and Measures.*—This is a branch of the king's prerogative. For the public convenience, these ought to be universally the same throughout the nation, the better to reduce the prices of articles to equivalent values. But as weight and measure are things in their nature arbitrary and uncertain, it is necessary that they be reduced to some fixed rule or standard. It is however impossible to fix such a standard by any written law or oral proclamation; as no person can, by words only, give to another an adequate idea of a pound weight, or foot-rule. It is therefore expedient to have recourse to some visible, palpable, material standard; by forming a comparison with which all weights and measures may be reduced to one uniform size. Such a standard was anciently kept at Winchester: and we find in the laws of king Edgar, near a century before the conquest, an injunction that that measure should be observed throughout the realm.

Most nations have regulated the standard of measures of length from some parts of the human body; as the palm, the hand, the span, the foot, the cubit, the ell (*ulna* or arm), the pace, and the fathom. But as these are of different dimensions in men of different proportions, ancient historians inform us, that a new standard of length was fixed by our king Henry the first; who commanded that the ulna or ancient ell, which answers to the modern yard, should be made of the exact length of his own arm.

A standard of long measure being once obtained, all others are easily derived from it; those of greater length by multiplying that original standard, those of less by dividing it. Thus, by the statute called compositio ulnarum et perticarum, 5½ yards make a perch; and the yard is subdivided into 3 feet, and each foot into 12 inches; which inches will be each of the length of 3 barley-corns. But some, on the contrary, derive all measures, by composition, from the barley-corn.

Superficial measures are derived by squaring those of length; and measures of capacity by cubing them.

The standard of weights was originally taken from grains or corns of wheat, whence our lowest denomination of weights is still called a grain; 32 of which are directed, by the statute called compositio mensurarum, to compose a pennyweight, 20 of which make an ounce, and 12 ounces a pound, &c.

Under king Richard the first it was ordained, that there should be only one weight and one measure throughout the nation, and that the custody of the assize or standard of weights and measures, should be committed to certain persons in every city and borough; whence the ancient office of the king's ulnager seems to have been derived. These original standards were called pondus regis, and mensura domini regis, and are directed by a variety of subsequent statutes to be kept in the exchequer chamber, by an officer called the clerk of the market, except the wine gallon, which is committed to the city of London, and kept in Guildhall.

The Scottish standards are distributed among the oldest boroughs. The elwand is kept at Edinburgh, the pint at Stirling, the pound at Lanark, and the firlot at Linlithgow.

The two principal weights established in Great Britain, are troy weight and avoirdupois weight, as before mentioned. Under the head of the former it may farther be added, that

A carat is a weight of 4 grains; but when the term is applied to gold, it denotes the degree of fineness. Any quantity of gold is supposed divided into 24 parts. If the whole mass be pure gold, it is said to be 24 carats fine; if there be 23 parts of pure gold, and one part of alloy or base metal, it is said to be 23 carats fine, and so on.

Pure gold is too soft to be used for coin. The standard coin of this kingdom is 22 carats fine. A pound of standard gold is coined into 44½ guineas, and therefore every guinea should weigh 5 dwts $9\frac{39}{89}$ grains.

A pound of silver for coin contains 11 oz 2 dwts pure silver, and 18 dwts alloy: and standard silver-plate, 11 ounces pure silver, with 1 ounce alloy. A pound of standard silver is coined into 62 shillings; and therefore the weight of a shilling should be 3 dwts $20\frac{28}{31}$ grains.

Universal Standard for WEIGHTS *and Measures.*

Philosophers, from their habits of generalizing, have often made speculations for forming a general standard for weights and measures through the whole world. These have been devised chiefly of a philosophical nature, as best adapted to universality. After the invention of pendulum clocks, it first occurred that the length of a pendulum which should vibrate seconds, would be proper to be made a universal standard for lengths; whether it should be called a yard, or any thing else. But it was found, that it would be difficult in practice, to measure and determine the true length of such a pendulum, that is the distance between the point of suspension and the point of oscillation. Another cause of inaccuracy was afterwards discovered, when it was found that the seconds pendulum was of different lengths in all the different latitudes, owing to the spheroidal figure of the earth, which causes that all places in different latitudes are at different distances from the centre, and consequently the pendulums are acted on by different forces of gravity, and therefore require to be of different lengths. In the latitude of London this is found to be 39⅕ inches.

The Society of Arts in London, among their many laudable and patriotic endeavours, offered a handsome premium for the discovery of a proper standard for weights and measures. This brought them many expedients, but none that merited any attention, except one, an improvement in the method of the pendulum, by Mr. Hatton, in the year 1779. This consisted in the application of a moveable point of suspension to one and the same pendulum, in order to produce the full and absolute effect of two pendulums, the difference of whose lengths was the intended measure. Here also the ratio of their lengths was easily determined, from observing the number of vibrations performed in a given time at each point of suspension. Whence there being two equations and two unknown quantities, the actual lengths of the pendulums themselves might be readily deduced by simple algebraic rules.

The late ingenious Mr. Whitehurst much improved on Mr. Hatton's original notion, in his essay published in 1787 under the title of "An attempt towards obtaining invariable Measures of Length, Capacity, and Weight, from the Mensuration of Time, &c." Mr. Whitehurst's proposal is to obtain a measure of the greatest length that conveniency will permit, from two pendulums whose vibrations are in the ratio of 2 to 1, and whose length coincide with the English standard in whole numbers. His numbers were chosen with considerable judgment and skill. On a supposition that the length of the seconds pendulum, in the latitude of London, is 39⅕ inches, the length of one vibrating 42 times in a minute must be 80 inches; and that of another vibrating 84 times in a minute must be 20 inches; their difference 60 inches, or 5 feet is his standard measure. The difference of the lengths of two pendulums, however, resulting from his experiment, was 59 892 inches, instead of 60, the difference being occasioned by an error in the original assumption of 39·2 inches instead of 39·128 or 39⅛ inches, as it is very nearly. Still, Mr. Whitehurst has accomplished a principal part of his grand design, by showing how an invariable standard may always be found for the same latitude. But this is by no means all that is wanted.

The French philosophers have gone much farther, and have very judiciously deduced the measures of capacity, and those of weight from the standard linear measure; confining themselves throughout to the decimal division.

But their system is liable to this heavy objection, that it depends on an accurate measure of a quarter meridian of the earth, at the same time that no such accurate measure has as yet been obtained; and at the same time probably that the meridians differ so widely among themselves as to leave no reasonable expectation that a correct medium length of a meridian will ever be found.

Some other method then must be resorted to, if we wish to obtain a universal measure, which at the same time that it shall be invariable, shall be easily recovered on the supposition that the actual standard is lost. Perhaps the least objectionable way would be to take for the length of the metre the length of a simple pendulum vibrating seconds at the equator, at a certain height above the surface of the sea, when the thermometer is at a fixed medium temperature: the length of the metre would then be about 39·027 English inches, instead of 39·37023, the metre of the new French system. The magnitude of the are, the stere, the gramme, &c, (or any other terms thought proper to introduce for similar purposes), might have the same relations to the metre as in the French system. Thus should we possess a standard taken from the gravitating force of the globe we inhabit, and which might be safely considered as invariable, so long as the constitution of the earth and its time of rotation remain the same.

The material standard itself also might be chosen of some shape that should possess the double advantage of being little affected by changes of temperature, and being a pendulum whose distance between the point of suspension and centre of oscillation, should be exactly equal to a fixed dimension of the pendulum that might readily be measured with exactness. Such a body we have in a right-angled cone, or one the diameter of whose base is equal to its altitude; for when this cone is suspended by its vertex as a centre of motion, the centre of oscillation is in the centre of the base; and when it is suspended by its base, the centre of oscillation coincides with the vertex of the solid; the length of the isochronous simple pendulum being in both cases equal to the altitude of the cone, or to the diameter of its base.

The universal standard for lengths being once established, those of weights, &c. evidently follow. For instance, a vessel of certain dimensions, being filled with distilled water, or some other homogeneous matter, the weight of that may be considered as a standard for weights. See also our article MEASURE.

WEIGHT of the Air, Water, &c. See those articles severally. See also SPECIFIC GRAVITY.

WERNER (JOHN), of Nuremberg, was born in 1468 and died 1528, and appears to have been the best mathematician of his time, being highly distinguished as an astronomer, a geometrician, &c, and well deserving of being better known than he is, having contributed by his writings on trigonometry, and other parts of the mathematics, to diffuse a taste for these sciences. It appears that he wrote 5 books on triangles. In his time the use of the cross-staff began to be introduced among seamen; this ancient instrument being described by him, in his Annotations on the first book of Ptolemy's Geography, printed in 1514; where he recommends it for observing the distance between the moon and some star, in order thence to determine the longitude. In 1522, he published Opera Mathematica at Nuremberg, in 4to, containing a specimen of the Conics, with some solid problems, and in which also he determined the precession of the equinox more exactly than it had before been done.

WERST, a Russian measure of length, equal to 3500 English feet, or ⅔ of an English mile.

WEST, one of the cardinal points of the horizon, or of the compass, diametrically opposite to the east, or lying on the left hand when we face the north. Or west is strictly the intersection of the prime vertical with the horizon, on that side where the sun sets.

WEST *Wind*, is also called Zephyrus, and Favonius.

WEST *Dial*. See DIAL.

WESTERN *Amplitude, Horizon, Ocean*. See the several articles.

WESTING, in Navigation, is the quantity of departure made good to the westward from the meridian.

WEY. See WEIGH.

WHALE, in Astronomy, one of the constellations. See CETUS.

WHEEL, in Mechanics, a simple machine, consisting of a circular piece of wood, metal, or other matter, that revolves on an axis. This is otherwise called Wheel and Axle, or Axis in Peritrochio, as a mechanical power, being one of the most frequent and useful of any. In this capacity of it, the wheel is a kind of perpetual lever, and the axis another lesser one; or the radius of the wheel and that of its axis may be considered as the longer and shorter arms of a lever, the centre of the wheel being the fulcrum or point of suspension. Whence it is, that the power of this machine is estimated by this rule: As the radius of the axis is to the radius of the wheel or of the circumference; so is any given power, to the weight it will sustain.

Wheels, as well as their axes, are frequently dented, or cut into teeth, and are then of use on many occasions; as in jacks, clocks, mill-work, &c; by which means they are capable of moving and acting on one another, and of being combined together to any extent; the teeth either of the axis or circumference working in those of other wheels or axles; and thus, by multiplying the power to any extent, a very great effect is produced.

To compute the power of a combination of Wheels; the teeth of the axis of every wheel acting on those in the circumference of the next following. Multiply continually together the radii of all the axes, as also the radii of all the wheels; then it will be, as the former product is to the latter, so is a given power applied to the circumference, to the weight it can sustain. Thus, for example, in a combination of five wheels and axles, to find the weight a man can sustain, or raise, whose force is equal to 150 pounds, the radii of the wheels being 30 inches, and those of the axes 3 inches.

Here $3 \times 3 \times 3 \times 3 \times 3 = 243$,
and $30 \times 30 \times 30 \times 30 \times 30 = 24300000$,
therefore as 243 : 24300000 : : 150 : 15000000 lb, the weight he can sustain, which is more than 6696 tons weight. So prodigious is the increase of power in a combination of wheels!

But it is to be observed, that in this, as well as every other mechanical engine, whatever is gained in power, is lost in time; that is, the weight will move as much slower than the power, as the force is increased or multiplied, which in the example above is 100000 times slower.

Hence, having given any power, and the weight to be raised, with the proportion between the wheels and axles necessary to that effect; to find the number of the wheels and axles. Or, having the number of the wheels and axles given, to find the ratio of the radii of the wheels and axles. Here, putting

p = the power acting on the last wheel,
w = the weight to be raised,
r = the radius of the axles,
R = the radius of the wheels,
n = the number of the wheels and axles;

then, by the general proportion, as $r^n : R^n :: p : w$; therefore $pR^n = wr^n$ is a general theorem, from whence may be found any one of these five letters or quantities, when the other four are given. Thus, to find n the number of wheels: we have first

$\frac{R^n}{r^n} = \frac{w}{p}$, then $n = \frac{\log. w - \log. p}{\log. R - \log. r}$. And to find the ratio of the wheel to the axle, it is $\frac{R}{r} = \sqrt[n]{\frac{w}{p}}$.

WHEELS *of a Clock, &c*, are, the crown wheel, contrat wheel, great wheel, second wheel, third wheel, striking wheel, detent wheel, &c.

WHEELS *of Coaches, Carts, Waggons, &c.* With respect to wheels of carriages, the following particulars are collected from the experiments and observations of Desaguliers, Beighton, Camus, Ferguson, Jacob, &c.

1. The use of wheels, in carriages, is twofold; viz, that of diminishing or more easily overcoming the resistance or friction from the carriage; and that of more easily overcoming obstacles in the road. In the first case, the friction on the ground is transferred in some degree from the outer surface of the wheel to its nave and axle; and in the latter, they serve easily to raise the carriage over obstacles and asperities met with on the roads. In both these cases, the height of the wheel is of material consideration, as the spokes act as levers, the top of an obstacle being the fulcrum, their length enables the carriage more easily to surmount them; and the greater proportion of the wheel to the axle serves more easily to diminish or to overcome the friction of the axle. See Jacob's Observations on Wheel Carriages, pa. 23 &c.

2. The wheels should be exactly round; and the fellies at right angles to the naves, according to the inclination of the spokes.

3. It is the most general opinion, that the spokes be somewhat inclined to the naves, so that the wheels may be dishing or concave. Indeed if the wheels were always to roll on smooth and level ground, it would be best to make the spokes perpendicular to the naves, or to the axles; because they would then bear the weight of the load perpendicularly. But because the ground is commonly uneven, one wheel often falls into a cavity or rut, when the other does not, and then it sustains much more of the weight than the other does; in which case it is best for the wheels to be dished, because the spokes become perpendicular in the rut, and therefore have the greatest strength when the obliquity of the road throws most of the weight on them; while those on the high ground have less weight to bear, and therefore need not be at their full strength.

4. The axles of the wheels should be quite straight, and perpendicular to the shafts, or to the pole. When the axles are straight, the rims of the wheels will be parallel to each other, in which case they will move the easiest, because they will be at liberty to proceed straight forwards. But in the usual way of practice, the ends of the axles are bent downwards; which always keeps the sides of the wheels that are next the ground nearer to each other than their upper sides are; and this not only makes the wheels drag sideways as they go along, and gives the load a much greater power of crushing them than when they are parallel to each other, but also endangers the overturning the carriage when a wheel falls into a hole or rut, or when the carriage goes on a road that has one side lower than the other, as along the side of a hill. Mr. Beighton however has offered several reasons to prove that the axles of wheels ought not to be straight; for which see Desaguliers's Exp. Phil. vol. 2, Appendix.

5. Large wheels are found more advantageous for rolling than small ones, both with regard to their power as a longer lever, and to the degree of friction, and to the advantage in getting over holes, rubs, and stones, &c. If we consider wheels with regard to the friction on their axles, it is evident that small wheels, by turning oftener round, and swifter about the axles, than large ones, must have much more friction. Again, if we consider wheels as they sink into holes or soft earth, the large wheels, by sinking less, must be much easier drawn out of them, as well as more easily over stones and obstacles, from their greater length of lever or spokes. Desaguliers has brought this matter to a mathematical calculation, in his Experim. Philos. vol. 1, pa. 171, &c. See also Jacob's Observ. pa. 63.

Hence it appears then, that wheels are the more advantageous as they are larger, provided they are not more than 5 or 6 feet diameter; for when they exceed these dimensions, they become too heavy; or if they are made light, their strength is proportionably diminished, and the length of the spokes renders them more liable to break; besides, horses applied to such wheels would not be capable of exerting their utmost strength, by having the axles higher than their breasts, so that they would draw downwards; which is even a greater disadvantage than small wheels have in occasioning the horses to draw upwards.

6. Carriages with 4 wheels, as waggons or coaches, are much more advantageous than carriages with 2 wheels, as carts and chaises; for, with 2 wheels it is plain the tiller horse carries part of the weight, in one way or other: in going down hill, the weight bears on the horse; and in going up hill, the weight falls the other way, and lifts the horse, which is still worse. Besides, as the wheels sink into the holes in the roads on different sides, the shafts strike against the tiller's sides, which occasions the death of many horses: moreover, when one of the wheels sinks into a hole or rut, half the weight falls that way, which endangers the overturning of the carriage.

7. It would be much more advantageous to make the 4 wheels of a coach or waggon large, and nearly of a

height, than to make the fore wheels of only half the diameter of the hind wheels, as is usual in many places. The fore wheels have commonly been made of a less size than the hind ones, both on account of turning short, and to avoid cutting the braces. Crane-necks have also been invented for turning yet shorter, and the fore wheels have been lowered, so as to go quite under the bend of the crane-neck.

It is accounted a great disadvantage in small wheels, that as their axle is below the bow of the horses' breasts, the horses not only have the loaded carriage to draw along, but also part of its weight to bear, which tires them soon, and makes them grow much stiffer in their hams, than they would if they drew on a level with the fore axle.

But Mr. Beighton disputes the propriety of fixing the line of traction on a level with the breast of a horse, and says it is contrary to reason and experience. Horses, he says, have little or no power to draw but what they derive from their weight; without which they could not take hold of the ground, and then they must slip, and draw nothing. Common experience also teaches, that a horse must have a certain weight on his back or shoulders, that he may draw the better. And when a horse draws hard, it is observed that he bends forward, and brings his breast near the ground; and then if the wheels are high, he is pulling the carriage against the ground. A horse tackled in a waggon will draw two or three ton, because the point or line of traction is below his breast, by the lowness of the wheels. It is also common to see, when one horse is drawing a heavy load, especially up hill, his fore feet will rise from the ground; in which case it is usual to add a weight on his back, to keep his fore part down, by a person mounting on his back or shoulders, which will enable him to draw that load, which he could not move before. The greatest stress, or main business of drawing, says this ingenious writer, is to overcome obstacles; for on level plains the drawing is but little, and then the horse's back need be pressed but with a small weight.

8. The utility of broad wheels, in amending and preserving the roads, has been so long and generally acknowledged, as to have occasioned the legislature to enforce their use. At the same time, the proprietors and drivers of carriages seem to be convinced by experience, that a narrow-wheeled carriage is more easily and speedily drawn by the same number of horses, than a broad-wheeled one of the same burthen: probably because they are much lighter, and have less friction on the axle.

On the subject of this article, see Jacob's Observ. &c. on Wheel-Carriages, 1773, pa. 81; Desagul. Exper. Phil. vol. 1, pa. 201; Martin's Phil. Brit. vol. 1, pa. 229; and Brewster's valuable edition of Ferguson's Lectures, both the work itself and the Appendix to the same, where several new observations &c are given on this subject. See also the Report of the Committee of the House of Commons, on Acts regarding the use of Broad Wheels, and other matters relating to the Preservation of the Public Roads.—Abridged in the Repertory of Arts, No. 64, New Series.

Blowing Wheel, is a machine contrived by Desaguliers, for drawing the foul air out of any place, or for forcing in fresh, or doing both successively, without opening doors or windows. See Philos. Trans. No. 437. The intention of this machine is the same as that of Hales's ventilator, but not so effectual, nor so convenient. See Desag. Exper. Philos. vol. 2, pa. 563, 568.—This wheel is also called a centrifugal wheel, because it drives the air with a centrifugal force.

Water Wheel, of a Mill, that which receives the impulse of the stream by means of ladle-boards or float-boards. M. Parent, of the Academy of Sciences, has determined that the greatest effect of an undershot wheel, is when its velocity is equal to the 3d part of the velocity of the water that drives or keeps it in motion: but it ought to be the half of that velocity, as is fully shown in the article Mill, in this Dictionary. In fixing an undershot wheel, it ought to be considered whether the water can run clear off, so as to cause no back-water to stop its motion. Concerning this article, see Desagul. Exp. Philos. vol. 2, pa. 422. Also a variety of experiments and observations relating to undershot and overshot wheels, by Mr. Smeaton, in the Philos. Trans. vol. 51, pa. 100.

WHIRL-POOL, an eddy, vortex, or gulf, where the water is continually turning round.

Those in rivers are very common, from various accidents, and are usually very trivial, and of little consequence. In the sea they are more rare, but more dangerous. Sibbald has related the effects of a very remarkable marine whirlpool among the Orcades, which would prove very dangerous to strangers, though it is of no consequence to the people who are used to it. This is not fixed to any particular place, but appears in various parts of the limits of the sea among these islands. Wherever it appears it is very furious; and boats &c would inevitably be drawn in and perish with it; but the people who navigate them are prepared for the event, and always carry an empty vessel, a log of wood, or large bundle of straw, or some such thing, in the boat with them; as soon as they perceive the whirlpool, they toss this within its vortex, keeping themselves out; this substance, whatever it be, is immediately received into the centre, and carried under water; and as soon as this is done, the surface of the place where the whirlpool was becomes smooth, and they row over it with safety: and in about an hour they see the vortex begin again in some other place, usually at about a mile's distance from the first.

WHIRLING-TABLE, a machine contrived for representing several phenomena in philosophy and nature; as, the principal laws of gravitation, and of the planetary motions in curvilinear orbits.

The figure of this instrument is exhibited fig. 1, pl. 41: where AA is a strong frame of wood; B a winch fixed on the axis C of the wheel D, about which is the catgut string F, which also goes round the small wheels G and K, crossing between them and the great wheel D. On the upper end of the axis of the wheel G, above the frame, is fixed the round board *d*, to which may be occasionally fixed the bearer MSX. On the axis of the wheel H is fixed the bearer NTZ, and when the winch B is turned, the wheels and bearers are put into a whirling motion. Each bearer has two wires W, X, and Y, Z, fixed and screwed tight into them at the ends by nuts on the outside; and when the nuts are unscrewed, the wires may be drawn out in order to change the balls U, V, which slide upon the wires by means of brass loops fixed into the balls, and preventing their touching the wood below them. Through each ball there passes a silk line, which is fixed to it at any length from the centre of the bearer to its end, by a nut-screw at the top of the ball; the shank of the screw going into the centre of the ball, and pressing the line against the under side of the hole which it runs through. The line goes from the ball, and under a small pulley fixed in the middle of the bearer; then up through a socket in the round plate (S and T) in the middle of each bearer; then through a slit in the middle of the square top (O and P) of each tower, and going over a small pulley on the top comes down again the same way, and is at last fastened to the upper end of the socket fixed in the middle of the round plate above-mentioned. Each of these plates S and T has four round holes near their edges, by which they slide up and down on the wires, which make the corner of each tower. The balls and plates being thus connected, each by its particular line, it is plain that if the balls be drawn outward, or towards the end M and N of their respective bearers, the round plates S and T will be drawn up to the top of their respective towers O and P.

There are several brass weights, some of 2, some of 3, and others of 4 ounces, to be occasionally put within the towers O and P, on the round plates S and T: each weight having a round hole in the middle of it, for going on the sockets or axes of the plates, and being slit from the edge to the hole, that it may slip over the line which comes from each ball to its respective plate.

For a specimen of the experiments to be made with this machine, may be subjoined the following.

1. Removing the bearer MX, put the loop of the line *b* to which the ivory ball *a* is fastened over a pin in the centre of the board *d*, and turn the winch B; and the ball will not immediately begin to move with the board, but, on account of its inactivity, endeavour to remain in its state of rest. But when the ball has acquired the same velocity with the board, it will remain on the same part of the board, having no relative motion upon it. However, if the board be suddenly stopped, the ball will continue to revolve on it, until the friction stops its motion: so that matter resists every change of state, from that of rest to that of motion, and vice versa.

2. Put a longer cord to this ball; let it down through the hollow axis of the bearer MX and wheel G, and fix a weight to the end of the cord below the machine; and this weight, if left at liberty, will draw the ball from the edge of the whirling board to its centre. Draw off the ball a little from the centre, and turn the winch; then the ball will continue to revolve with the board, and gradually fly farther from the centre, raising up the weight below the machine. And thus it appears that all bodies, revolving in circles, have a tendency to fly off from those circles, and must be retained in them by some power proceeding from or tending to the centre of motion. Stop the machine, and the ball will continue to revolve for some time on the board; but as the friction gradually stops its motion, the weight acting upon it will bring it nearer and nearer to the centre in every revolution, till it brings it quite thither. Hence it appears, that if the planets met with any resistance in going round the sun, its attractive power would bring them nearer and nearer to it in every revolution, till they would fall into it.

3. Take hold of the cord below the machine with one hand, and with the other throw the ball upon the round board as it were at right angles to the cord, and it will revolve on the board. Then, observing the velocity of its motion, pull the cord below the machine, and thus bring the ball nearer the centre of the board, and the ball will be seen to revolve with an increasing velocity, as it approaches the centre: and thus the planets which are nearest the sun perform quicker revolutions than those which are more remote, and move with greater velocity in every part of their respective circles.

4. Remove the ball *a*, and apply the bearer MX, whose centre of motion is in its middle at *w*, directly over the centre of the whirling board *d*. Then put two balls (V and U) of equal weight on their bearing wires, and having fixed them at equal distances from their respective centres of motion *w* and *x* upon their silk cords, by the screw nuts, put equal weights in the towers O and P. Lastly, put the catgut strings E and F on the grooves G and H of the small wheels, which, being of equal diameters, will give equal velocities to the bearers above, when the winch B is turned; and the balls U and V will fly off toward M and N, and raise the weights in the towers at the same instant. This shows, that when bodies of equal quantities of matter revolve in equal circles with equal velocities, their centrifugal forces are equal.

5. Take away these equal balls, and put a ball of 6 ounces into the bearer MX, at a 6th part of the distance *wz* from the centre, and put a ball of one ounce into the opposite bearer, at the whole distance $xy = wz$; and fix the balls at these distances on their cords, by the screw nuts at the top: then the ball U, which is 6 times as heavy as the ball V, will be at only a 6th part of the distance from its centre of motion; and consequently will revolve in a circle of only a 6th part of the circumference of that in which V revolves. Let equal weights be put into the towers, and the winch be turned: as the catgut string is on equal wheels below, it will cause the balls to revolve in equal times; but V will move 6 times as fast as U, because it revolves in a circle of 6 times its radius, and both the weights in the towers will rise at once. Hence it appears, that the centrifugal forces of revolving bodies are in direct proportion to their quantities of matter multiplied into their respective velocities, or into their distance from the centres of their respective circular orbits.

If these two balls be fixed at equal distances from their respective centres of motion, they will move with equal velocities; and if the tower O has 6 times as much weight put into it as the tower P, the balls will raise their weights exactly at the same moment: i. e. the ball U, being 6 times as heavy as the ball V, has 6 times as much centrifugal force in describing an equal circle with an equal velocity.

6. Let two balls, U and V, of equal weights, be fixed on their cords at equal distances from their respective centres of motion *w* and *x*; and let the catgut string E be put round the wheel K (whose circumference is only half that of the wheel H or G) and over the pulley *s* to keep it tight, and let 4 times as much weight be put into the tower P as in the tower O. Then turn the winch B, and the ball V will revolve twice as fast as the ball U in a circle of the same diameter, because they are equidistant from the centres of the circles in which they revolve; and the weights in the towers will both rise at the same instant; which shows that a double velocity in the same circle will exactly balance a quadruple power of attraction in the centre of the circle: for the weights in the towers may be considered as the attractive forces in the

centres, acting on the revolving balls; which moving in equal circles, are as if they both moved in the same circle. Whence it appears that, it bodies of equal weights revolve in equal circles with unequal velocities, their centrifugal forces are as the squares of the velocities.

7. The catgut string remaining as before, let the distance of the ball V from the centre *x* be equal to 2 of the divisions on its bearer; and the distance of the ball U from the centre *w* be 3 and a 6th part; the balls themselves being equally heavy, and V making two revolutions by turning the winch, whilst U makes one; so that if we suppose the ball V to revolve in one second, the ball U will revolve in 2, the squares of which are 1 and 4: therefore, the square of the period of V is contained 4 times in the square of the period of U. But the distance of V is 2, the cube of which is 8, and the distance of U is $3\frac{1}{6}$, the cube of which is 32 very nearly, in which 8 is contained 4 times: and therefore, the squares of the periods V and U are to each other as the cubes of their distances from *x* and *w*, the centres of their respective circles. And if the weight in the tower O be 4 ounces, or equal to the square of 2, which is the distance of V from the centre *x*; and the weight in the tower P be 10 ounces, nearly equal to the square of $3\frac{1}{6}$, the distance of U from *w*; it will be found on turning the machine by the winch, that the balls U and V will raise their respective weights at very nearly the same instant of time. This experiment confirms the famous proposition of Kepler, viz, that the squares of the periodical times of the planets round the sun are in proportion as the cubes of their distances from him; and that the sun's attraction is inversely as the square of the distance from his centre.

8. Take off the string E from the wheels D and H, and let the string F remain on the wheels D and O; take away also the bearer MX from the whirling-board *d*, and instead of it put on the machine AB (fig. 2), fixing it to the centre of the board by the pins *c* and *d*, so that the end *ef* may rise above the board to an angle of 30 or 40 degrees. On the upper part of this machine, there are two glass tubes *a* and *b*, closely stopped at both ends, each tube being about three quarters full of water. In the tube *a* is a little quicksilver, which naturally falls down to the end *a* in the water; and in the tube *b* is a small cork, floating on the top of the water, and small enough to rise or fall in the tube. While the board *b* with this machine on it continues at rest, the quicksilver lies at the bottom of the tube *a*, and the cork floats on the water near the top of the tube *b*. But, on turning the winch and moving the machine, the contents of each tube fly off towards the uppermost ends, which are farthest from the centre of motion; the heaviest with the greatest force. Consequently, the quicksilver in the tube *a* will fly off quite to the end *f*, occupying its bulk of space, and excluding the water, which is lighter than itself: but the water in the tube *b*, flying off to its higher end *e*, will exclude the cork from that place, and cause it to descend toward the lowest end of the tube; for the heavier body, having the greater centrifugal force, will possess the upper part of the tube, and the lighter body will keep between the heavier and the lower part.

This experiment demonstrates the absurdity of the Cartesian doctrine of vortices; for, if a planet be more dense or heavy than its bulk of the vortex, it will fly off in it farther and farther from the sun; if less dense, it will descend to the lowest part of the vortex, at the sun: and the whole vortex itself, unless prevented by some obstacle, would fly quite off, together with the planets.

9. If a body be so placed on the whirling-board of the machine (fig. 1) that the centre of gravity of the body be directly over the centre of the board, and the board be moved ever so rapidly by the winch B, the body will turn round with the board, without removing from its middle; for, as all parts of the body are in equilibrio round its centre of gravity, and the centre of gravity is at rest in the centre of motion, the centrifugal force of all parts of the body will be equal at equal distances from its centre of motion, and therefore the body will remain in its place. But if the centre of gravity be placed ever so little out of the centre of motion, and the machine be turned swiftly round, the body will fly off towards that side of the board on which its centre of gravity lies. Then if the wire C (fig. 3) with its little ball B be taken away from the semi-globe A, and the flat side *f* of the semi-globe be laid on the whirling-board, so that their centres may coincide; if then the board be turned ever so quickly by the winch, the semi-globe will remain where it was placed: but if the wire C be screwed into the semi-globe at *d*, the whole becomes one body, whose centre of gravity is at or near *d*. Fix the pin C in the centre of the whirling-board, and let the deep groove *b* cut in the flat side of the semi-globe be put on the pin, so that the pin may be in the centre of A (see fig. 4), where the groove is to be represented at *b*, and let the board be turned by the winch, which will carry the little ball B (fig. 3) with its wire C, and the semi-globe A, round the centre pin *c i*; and then, the centrifugal force of the little ball B, weighing one ounce, will be so great as to draw off the semi-globe A, weighing two pounds, until the end of the groove at C strikes against the pin *c*, and so prevents A from going any farther: otherwise, the centrifugal force of B would have been sufficient to have carried A quite off the whirling-board. Hence we see that, if the sun were placed in the centre of the orbits of the planets, it could not possibly remain there; for the centrifugal forces of the planets would carry them quite off, and the sun with them; especially when several of them happened to be in one quarter of the heavens. For the sun and planets are as much connected by the mutual attraction subsisting between them, as the bodies A and B are by the wire C fixed into them both. And even if there were but one planet in the whole heavens to revolve about ever so large a sun in the centre of its orbit, its centrifugal force would soon carry off both itself and the sun: for the greatest body placed in any part of free space could be easily moved; because, if there were no other body to attract it, it would have no weight or gravity of itself, and consequently, though it could have no tendency of itself to remove from that part of space, yet it might be very easily moved by the force of any other substance.

10. As the centrifugal force of the light body B will not allow the heavy body A to remain in the centre of motion, even though it be 24 times as heavy as B; let the ball A (fig. 5) weighing 6 ounces be connected by the wire C with the ball B, weighing one ounce, and let the fork E be fixed into the centre of the whirling-board; then, hang the balls on the fork by the wire C in such a manner that they may exactly balance each other, which will be when the centre of gravity between them, in the wire at *d*, is supported by the fork. And this centre of gravity is as much nearer to the centre of the ball A than

to the centre B, as A is heavier than B; allowing for the weight of the wire on each side of the fork. Then, let the machine be moved, and the balls A and B will revolve about their common centre of gravity *d*, keeping their balance, because either will not allow the other to fly off with it. For, supposing the ball B to be only one ounce in weight, and the ball A to be six ounces; then, if the wire C were equally heavy on each side of the fork, the centre of gravity *d* would be 6 times as far from the centre of B as from the centre of A, and consequently B will revolve with 6 times the velocity of A, which will give B 6 times as much centrifugal force as any single ounce of A has; but then as B is only one ounce, and A six ounces, the whole centrifugal force of A will exactly balance that of B; and therefore, each body will detain the other, so as to retain it in its circle.

Hence it appears, that the sun and planets must all move round the common centre of gravity of the whole system, in order to preserve that just balance which takes place among them.

11. Remove the forks and balls from the whirling-board, and place the trough AB (fig. 6) thereon, fixing its centre to that of the board by the pin H. In this trough are two balls D and E of unequal weights, connected by a wire *f*, and made to slide easily on the wire stretched from end to end of the trough, and made fast by nut screws on the outside of the ends. Place these balls on the wire *c*, so that their common centre of gravity *g*, may be directly over the centre of the whirling-board. Then turn the machine by the winch ever so swiftly, and the trough and balls will move round their centre of gravity, so as neither of them will fly off; because, on account of the equilibrium, each ball detains the other with an equal force acting against it. But if the ball E be drawn a little more towards the end of the trough at A, it will remove the centre of gravity towards that end from the centre of motion; and then, upon turning the machine, the little ball E will fly off, and strike with a considerable force against the end A, and draw the great ball B into the middle of the trough. Or, if the great ball D be drawn towards the end B of the trough, so that the centre of gravity may be a little towards that end from the centre of motion; and the machine be turned by the winch, the great ball D will fly off, and strike violently against the end B of the trough, and will bring the little ball E into the middle of it. If the trough be not made very strong, the ball D will break through it.

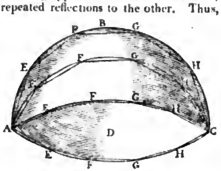
12. Mr. Ferguson has explained the reason why the tides rise at the same time on opposite sides of the earth, and consequently in opposite directions, by the following new experiment on the whirling-table. For this purpose, let *a b c d* (fig. 7) represent the earth, with its side *c* turned toward the moon, which will then attract the water so as to raise them from *c* to *g*: and in order to show that they will rise as high at the same time on the opposite side from *a* to *e*; let a plate AB (fig. 8) be fixed on one end of the flat bar DC, with such a circle drawn on it as *a b c d* (fig. 7) to represent the round figure of the earth and sea; and an ellipse as *e f g h* to represent the swelling of the tide at *e* and *g*, occasioned by the influence of the moon. Over this plate AB suspend the three ivory balls *e*, *f*, *g*, by the silk lines *h*, *i*, *k*, fastened to the tops of the wires H, I, K, so that the ball at *e* may hang freely over the side of the circle *e*, which is farthest from the moon M at the other end of the bar; the ball at *f* over the centre, and the ball at *g* over the side of the circle *g*, which is nearest the moon. The ball *f* may represent the centre of the earth, the ball *g* water on the side next the moon, and the ball *e* water on the opposite side. On the back of the moon M is fixed a short bar N parallel to the horizon, and there are three holes in it above the little weights *p*, *q*, *r*. A silken thread *o* is tied to the line *k* close above the ball *g*, and passing by one side of the moon M goes through a hole in the bar N, and has the weight *p* hung to it. Such another thread *m* is tied to the line *i*, close above the ball *f*, and, passing through the centre of the moon M and middle of the bar N, has the weight *q* hung to it, which is lighter than the weight *p*. A third thread *m* is tied to the line *h*, close above the ball *e*, and, passing by the other side, of the moon M through the bar N, has the weight *r* hung to it, which is lighter than the weight *q*. The use of these three unequal weights is to represent the moon's unequal attraction at different distances from her; so that if they are left at liberty, they will draw all the three balls towards the moon with different degrees of force, and cause them to appear as in fig. 9, in which case they are evidently farther from each other than if they hung freely by the perpendicular lines *h*, *i*, *k*. Hence it appears, that as the moon attracts the side of the earth which is nearest her with a greater degree of force than she does the centre of the earth, she will draw the water on that side more than the centre, and cause it to rise on that side: and as she draws the centre more than the opposite side, the centre will recede farther from the surface of the water on that opposite side, and leave it as high there as she raised it on the side next her. For, as the centre will be in the middle between the tops of the opposite elevations, they must of course be equally high on both sides at the same time.

However, upon this supposition, the earth and moon would soon come together; and this would be the case if they had not a motion round their common centre of gravity, to produce a degree of centrifugal force, sufficient to balance their mutual attraction. Such motion they have; for as the moon revolves in her orbit every month, at the distance of 240000 miles from the earth's centre, and of 234000 miles from the centre of gravity of the earth and moon, the earth also goes round the same centre of gravity every month at the distance of 6000 miles from it, i. e. from it to the centre of the earth. But the diameter of the earth being, in round numbers, 8000 miles, its side next the moon is only 2000 miles from the common centre of gravity of the earth and moon, its centre 6000 miles from it, and its farthest side from the moon 10000 miles. Consequently the centrifugal forces of these parts are as 2000, 6000, and 10000; i. e. the centrifugal force of any side of the earth, when it is turned from the moon, is 5 times as great as when it is turned towards the moon. And as the moon's attraction, expressed by the number 6000 at the earth's centre, keeps the earth from flying out of this monthly circle, it must be greater than the centrifugal force of the waters on the side next her; and consequently, her greater degree of attraction on that side is sufficient to raise them; but as her attraction on the opposite side is less than the centrifugal force of the water there, the excess of this force is sufficient to raise the water just as high on the opposite side.

To prove this experimentally, let the bar DC with its furniture be fixed on the whirling-board of the machine (fig. 1.) by pushing the pin P into the centre of the board; which pin is in the centre of gravity of the whole bar with its three balls, e, f, g, and moon M. Now if the whirling-board and bar be turned slowly round by the winch, till the ball f hangs over the centre of the circle, as in fig. 10, the ball g will be kept towards the moon by the heaviest weight p (fig. 8), and the ball e, on account of its greater centrifugal force, and the less weight r, will fly off as far to the other side, as in fig. 10. And thus, while the machine is kept turning, the balls e and g will hang over the ends of the ellipse lfk. So that the centrifugal force of the ball e will exceed the moon's attraction just as much as her attraction exceeds the centrifugal force of the ball g, while her attraction just balances the centrifugal force of the ball f, and makes it keep in its circle. Hence it is evident, that the tides must rise to equal heights at the same time on opposite sides of the earth. See Ferguson's Lectures on Mechanics, lect. 2, and Desag. Ex. Phil. vol. 1, lect. 5.

WHIRLWIND, a wind exceedingly rapid and impetuous, which moves in a spiral manner, as well as horizontally, which is but only of short duration. Dr. Franklin, in his Physical and Meteorological Observations, read to the Royal Society in 1756, supposes a whirlwind and a waterspout to proceed from the same cause, namely a stream of elastic matter rushing violently into the atmosphere out of the earth: their only difference being, that the latter passes over the water, and the former over the land. This opinion is corroborated by the observations of M. de la Pryme, and many others, who have remarked the appearances and effects of both to be the same. They have both a progressive as well as a circular motion; they usually rise after calms and great heats, and mostly happen in the warmer latitudes: the wind blows every way from a large surrounding space, both to the waterspout and whirlwind; and a waterspout has, by its progressive motion, passed from the sea to the land, and produced all the phenomena and effects of a whirlwind: so that there is no reason to doubt that they are meteors arising from the same general cause, and explicable on the same principles, furnished by electrical experiments and discoveries. See HURRICANE, and WATERSPOUT. For Dr. Franklin's ingenious method of accounting for both these phenomena, see his Letters and Papers, &c, vol. 1, pa. 191, 216, &c.

WHISPERING-*Places*, are places where a whisper, or other small noise, may be heard from one part to another, to a great distance. They depend on a principle, that the voice, &c, being applied to one end of an arch, easily passes by repeated reflections to the other. Thus, let ABC represent the segment of a sphere; and suppose a low voice uttered at A, the vibrations extending themselves every way, some of them will impinge on the



points E, E, &c; and thence be reflected to the points F, F, &c; thence to G, G, &c; till at last they meet in C; where by their union they cause a much stronger sound than in any part of the segment whatever, even louder than at the point from which they set out. Accordingly, all the contrivance in a whispering-place is, that near the person who whispers, there be a smooth wall, arched either cylindrically, or elliptically, &c. A circular arch will do, but not so well.

Some of the most remarkable places for whispering, are the following: viz, The prison of Dionysius at Syracuse, which increased a soft whisper to a loud noise; or a clap of the hand to the report of a cannon, &c. The aqueducts of Claudius, which conducted a voice 16 miles: beside divers others mentioned by Kircher in his Phonurgia. In England, the most considerable whispering places are, the dome of St. Paul's church, London, where the ticking of a watch may be heard from side to side, and a very soft whisper may be sent quite round the dome: this Dr. Derham found to hold not only in the gallery below, but above on the scaffold, where a whisper would be carried over a person's head round the top of the arch, though there be a large opening in the middle of it into the upper part of the dome. And the celebrated whispering-place in Gloucester cathedral, which is only a gallery above the east end of the choir, leading from one side of it to the other. See Birch's Hist. of the Royal Soc. vol. 1. pa. 120.

WHISTON (WILLIAM), an English divine, philosopher, and mathematician, of uncommon abilities, learning, and extraordinary character, was born the 9th of December 1667, at Norton in the county of Leicester, where his father was rector. He was educated under his father till he was 17 years of age, when he was sent to Tamworth school, and two years after admitted of Clare-hall, Cambridge, where he pursued his studies, and particularly the mathematics, with great diligence. During this time he became afflicted with a great weakness of sight, owing to close study in a whitened room; which was in a good measure relieved by a little relaxation from study, and taking off the strong glare of light by hanging the place opposite his seat with green.

In 1693 he became master of arts and fellow of the college, and soon after commenced one of the tutors; but his ill state of health soon after obliged him to relinquish this profession. Having entered into orders, in 1694 he became chaplain to Dr. More, bishop of Norwich; and while in this station he published his first work, A New Theory of the Earth &c; in which he undertook to prove that the Mosaic doctrine of the earth was perfectly agreeable to reason and philosophy: which work, having much ingenuity, though it was written against by Mr. John Keill, brought considerable reputation to the author.

In the year 1698, bishop More gave him the living of Lowestoff in Suffolk, where he immediately went to reside, and devoted himself with great diligence to the discharge of that trust.—In the beginning of the last century he was made sir Isaac Newton's deputy, and afterwards his successor, in the Lucasian professorship of mathematics; when he resigned his living at Lowestoff, and went to reside at Cambridge. From this time his publications became very frequent, both in theology and mathematics. Thus, in 1702 he published, A Short View of the Chronology of the Old Testament, and of the Harmony of the four Evangelists.—In 1707, Prælectiones Astronomicæ; besides 8 Sermons on the Accomplishment of the Scripture Prophecies, preached at Boyle's lecture; and Newton's Arithmetica Universalis.—In 1708, Tacquet's Euclid, with select Theorems of Archimedes; the former of which had accidentally been his first introduction to the study of the mathematics.—In the same year he drew up an Essay on the Apostolical Constitutions, which the vice chancellor refused his licence for printing. The author informs us, he had read over the two first centuries of the church, and found that the Eusebian or Arian doctrine was chiefly the doctrine of those ages, which, though deemed heterodox, he thought it his duty to discover.—In 1709, he published a volume of Sermons and Essays on various subjects.—In 1710, Prælectiones Physico-Mathematicæ, which, with the Prælectiones Astronomicæ, were translated and published in English. And it may be said, with no small honour to the memory of Mr. Whiston, that he was one of the first who explained the Newtonian philosophy in a popular way, so as to be intelligible to the generality of readers.—Among other things also, he translated the Apostolical Constitutions into English, which favoured the doctrine of the supremacy of the Father and subordination of the Son, vulgarly called the Arian heresy: on which his friends began to be alarmed for him; and the consequence showed it was not groundless; for, Oct. 30, 1710, he was deprived of his professorship, and expelled the university of Cambridge, after he had been formally convened and interrogated for several successive days.—At the conclusion of this year, he wrote his Historical Preface, afterwards prefixed to his Primitive Christianity Revived, containing the reasons for his dissent from the commonly received notions of the Trinity, which work he published the next year, in 4 volumes 8vo, for which the Convocation fell upon him most vehemently.

In 1713, he and Mr. Ditton composed their scheme for finding the longitude, which they published the year following, a method which consisted in measuring distances by means of the velocity of sound; some more particulars of which are related in the life of Mr. Ditton.—In 1719, he published an ironical Letter of Thanks to doctor Robinson, bishop of London, for his late Letter to his clergy against the use of New Forms of Doxology. And, the same year, a Letter to the earl of Nottingham, concerning the Eternity of the Son of God, and his Holy Spirit.—In 1720, he was proposed by sir Hans Sloane and Dr. Halley to the Royal Society as a member; but was refused admittance by sir Isaac Newton the president.

On Mr. Whiston's expulsion from Cambridge, he went to London, where he conferred with Doctors Clarke, Hoadley, and other learned men, who endeavoured to moderate his zeal, which however he would not suffer to be tainted or corrupted, and many were not much satisfied with the authority of these constitutions, but approved his integrity. Mr. Whiston now settled in London with his family; where, without suffering his ardour to be intimidated, he continued to write, and to propagate his Primitive Christianity with as much fervency as if he had been in the most flourishing circumstances; which however were so bad, that, in 1721, a subscription was made for the support of his family, which amounted to 470l. For though he drew some profits from reading astronomical and philosophical lectures, and also from his publications, which were very numerous, yet these of themselves were very insufficient; nor, when joined with the benevolence and charity of those who loved and esteemed him for his learning, integrity, and piety, did they prevent his being frequently in great distress.—In 1722 he published an Essay towards restoring the true text of the Old Testament.—In 1724, The Literal Accomplishment of Scripture Prophecies.—Also, The Calculation of Solar Eclipses without Parallaxes.—In 1726, Of the Thundering Legion &c.—In 1727, A Collection of Authentic Records belonging to the Old and New Testament.—In 1730, Memoirs of the Life of Dr. Samuel Clarke.—In 1732, A Vindication of the Testimony of Phlegon, or an Account of the Great Darkness and Earthquake at our Saviour's Passion, described by Phlegon.—In 1736, Athanasian Forgeries, &c. And the Primitive Eucharist revived.—In 1737, The Astronomical Year, particularly of the Comet foretold by sir Isaac Newton.—Also the Genuine Works of Flavius Josephus.—In 1739, Mr. Whiston put in his claim to the mathematical professorship at Cambridge, then vacant by the death of Dr. Saunderson, in a letter to Dr. Ashton, the master of Jesus-college; but no regard was paid to it.—In 1745, he published his Primitive New Testament in English.—In 1748, his Sacred History of the Old and New Testament. Also, Memoirs of his own Life and Writings, which are very curious.

Whiston continued many years a member of the established church; but at length forsook it, on account of the reading of the Athanasian Creed, and went over to the Baptists; which happened while he was at the house of Samuel Barker, Esq. at Lindon in Rutlandshire, who had married his daughter; where he died, after a week's illness, the 22d of August 1752, at upwards of 84 years of age.—We have mentioned the principal of his writings in the foregoing memoir; to which may be added, Chronological Tables, published in 1750; and one paper only in the Philos. Trans. vol. 31, on two mock suns, and a halo seen in Oct. 1721.

The character of this conscientious and worthy man has been attempted by two very able personages, who were well acquainted with him, namely, bishop Hare and Mr. Collins, who unite in giving him the highest applauses, for his integrity, piety, &c.—Mr Whiston left some children behind him; among them, Mr. John Whiston, who was for many years a very considerable bookseller in London.

WHITE, one of the colours of bodies. Though white cannot properly be said to be one colour, but rather a composition of all the colours together: for Newton has demonstrated that bodies only appear white by reflecting all the kinds of coloured rays alike; and that even the light of the sun is only white, because it consists of all colours mixed together.

This may be shown mechanically in the following manner: Take seven parcels of coloured fine powders, the same as the primary colours of the rainbow, taking such quantities of these as shall be proportional to the respective breadths of these colours in the rainbow, which are of red 45 parts, orange 27, yellow 48, green 60, blue 60, indigo 40, and of violet 80; then mix intimately together these seven parcels of powders, and the mixture will be a pretty white colour: this is only similar to the uniting the prismatic colours together again, to form a white ray or pencil of light of the whole of them. The same thing is performed conveniently thus: Let the flat upper surface of a top be divided into 360 equal parts, all around its edge; then divide the same surface into seven sectors in the proportion of the numbers above, by seven radii or lines drawn from the centre; next let the respective colours be painted in a lively manner on these spaces, but so as the edge of each colour may be made nearly like the colour next adjoining, that the separation may not be well distinguished by the eye; then if the top be made to spin, the colours will thus seem to be mixed all together, and the whole surface will appear of a uniform whiteness: if a large round black spot be painted in the middle, so as there may be only a broad flat ring of colours around it, the experiment will succeed the better. See Newton's Optics, prop. 6, book 1; and Ferguson's Tracts, pa. 296.

White bodies are found to take heat slower than black ones; because the latter absorb or imbibe rays of all kinds and colours, and the former reflect them. Hence it is that black paper is sooner put in flame, by a burning-glass, than white; and hence also black clothes, hung up in the sun by the dyers, dry sooner than white ones.

WHITEHURST (John), an ingenious English philosopher, was born at Congleton in the county of Cheshire, the 10th of April 1713, being the son of a clock and watch-maker there. Of the early part of his life but little is known. On his quitting school, where it seems the education he received was very defective, he was brought up by his father to his own profession, in which he soon gave hopes of his future eminence.

It was early in life that, from his vicinity to the many stupendous phenomena in Derbyshire, which were constantly presented to his observation, his attention was excited to inquire into the various causes of them.

At about the age of 21, his eagerness after new ideas carried him to Dublin, having heard of an ingenious piece of mechanism in that city, being a clock with certain curious appendages, which he was very desirous of seeing, and no less so of conversing with the maker. On his arrival however, he could neither procure a sight of the former, nor draw the least hint from the latter, concerning it. Thus disappointed, he fell upon an expedient for accomplishing his design; and accordingly took up his residence in the house of the mechanic, paying the more liberally for his board, as he thus had hopes of more readily obtaining the indulgence wished for. He was accommodated with a room directly over that in which the favourite piece was kept carefully locked up: and he had not long to wait for his gratification; for the artist, while one day employed in examining his machine, was suddenly called down stairs; which the young inquirer happening to overhear, softly slipped into the room, inspected the machine, and, presently satisfying himself as to the secret, escaped undiscovered to his own apartment. His end thus compassed, he shortly after bade the artist farewell, and returned to his father in England.

About two or three years after his return from Ireland, he left Congleton, and entered into business for himself at Derby, where he soon procured great employment, and distinguished himself very much by several ingenious pieces of mechanism, both in his own regular line of business, and in various other respects; as, in the construction of curious thermometers, barometers, and other philosophical instruments, as well as in ingenious contrivances for water-works, and the erection of various larger machines; being consulted in almost all the undertakings in Derbyshire, and in the neighbouring counties, where the aid of superior skill in mechanics, pneumatics, and hydraulics, was requisite.

In this manner his time was fully and usefully employed in the country, till, in 1775, when the act passed for the better regulation of the gold coin, he was appointed stamper of the money-weights; an office conferred on him, altogether unexpectedly, and without solicitation. On this occasion he removed to London, where he spent the remainder of his days, in the constant habits of cultivating some useful parts of philosophy and mechanism. And here his house became also the constant resort of the ingenious and scientific at large, of whatever nation or rank, and this to such a degree, as very often to impede him in the regular prosecution of his own speculations.

In 1778, Mr. Whitehurst published his Inquiry into the Original State and Formation of the Earth; of which a second edition appeared in 1786, considerably enlarged and improved; and a third in 1792. This was the labour of many years; and the numerous investigations necessary to its completion, were in themselves also of so untoward a nature, as at times, though he was naturally of a strong constitution, not a little to prejudice his health. When he first entered on this species of research, it was not altogether with a view to investigate the formation of the earth, but in part to obtain such a competent knowledge of subterraneous geography as might become subservient to the purposes of human life, by leading mankind to the discovery of many valuable substances which lie concealed in the lower regions of the earth.

May the 13th, 1779, he was elected and admitted a Fellow of the Royal Society. He was also a member of some other philosophical societies, which appointed him of their respective bodies, without his previous knowledge; but so remote was he from any thing that might savour of ostentation, that this circumstance was known only to a very few of his most confidential friends. Before he was admitted a member of the Royal Society, three several papers of his had been inserted in the Philosophical Transactions, viz, Thermometrical Observations at Derby, in vol. 57; An Account of a Machine for raising Water, at Oulton, in Cheshire, in vol. 65; and Experiments on Ignited Substances, vol. 66: which three papers were printed afterwards in the collection of his works in 1792.

In 1783 he made a second visit to Ireland, with a view to examine the Giants' Causeway, and other northern parts of that island, which he found to be chiefly composed of volcanic matter: an account and representations of which are inserted in the latter editions of his Inquiry. During this excursion, he erected an engine, for raising water from a well, to the summit of a hill, in a bleaching ground, at Tullidoi, in the county of Tyrone: it is worked by a current of water, and for its utility is perhaps unequalled in any country.

In 1787 he published, An Attempt toward obtaining Invariable Measures of Length, Capacity, and Weight, from the Mensuration of Time. His plan is, to obtain a measure of the greatest length that conveniency will permit, from two pendulums whose vibrations are in the ratio of 2 to 1, and whose lengths coincide nearly with the English standard in whole numbers. The numbers which he has chosen show much ingenuity. On a supposition that the length of a seconds pendulum, in the latitude of London, is 39⅛ inches, the length of one vibrating 42 times in a minute, must be 80 inches; and of another vibrating 84 times in a minute must be 20 inches; their difference, 60 inches, or 5 feet, is his standard measure. By the experiments however, the difference between the lengths of the two pendulum rods, was found to be only 59·892 inches, instead of 60, owing to the error in the assumed length of the seconds pendulum, 39⅛ inches being greater than the truth, which ought to be 39⅛ very nearly. By this experiment, Mr. Whitehurst obtained a fact, as accurately as may be in a thing of this nature, viz, the difference between the lengths of two pendulum rods whose vibrations are known: a datum from which may be obtained, by calculation, the true lengths of pendulums, the spaces through which heavy bodies fall in a given time, and many other particulars relating to the doctrine of gravitation, the figure of the earth, &c, &c.

Mr. Whitehurst had been at times subject to slight attacks of the gout, and he had for several years felt himself gradually declining. By an attack of that disease in his stomach, after a struggle of two or three months, it put an end to his laborious and useful life, on the 18th of February 1788, in the 75th year of his age, at his house in Bolt-court, Fleet-street, being the same house where another eminent self-taught philosopher, Mr. James Ferguson, had just before him lived and died.

For several years before his death, Mr. Whitehurst had been at times occupied in arranging and completing some papers, for a treatise on Chimneys, Ventilation, and Garden-stoves; which have since been collected and given to the public, by Dr. Willan, in 1794.

However respectable Mr. Whitehurst may have been in mechanics, and those parts of natural science which he more immediately cultivated, he was of still higher account with his acquaintance and friends on the score of his moral qualities. To say nothing of the uprightness and punctuality of his dealings in all transactions relative to business; few men have been known to possess more benevolent affections than he, or, being possessed of such, to direct them more judiciously to their proper ends. With regard to his person, he was above the middle stature, rather thin than otherwise, and of a countenance expressive at once of penetration and mildness. His fine gray locks, unpolluted by art, gave a venerable air to his appearance. In dress he was plain, in diet temperate, in his general intercourse with mankind easy and obliging. In company he was cheerful or grave alike, according to the dictate of the occasion; with now and then a peculiar species of humour about him, delivered with such gravity of manner and utterance, that those who knew him but slightly were apt to understand him as serious, when he was merely playful. But where any desire of information on subjects in which he was conversant was expressed, he omitted no opportunity of imparting it.

WHITSUNDAY, the 50th day or seventh Sunday from Easter.—The season properly called Pentecost, is popularly called Whitsuntide; because, it is said, in the primitive church, the newly baptized persons came to church between Easter and Pentecost in white garments.

WILKINS (Dr. John), a very ingenious and learned English bishop and mathematician, was the son of a goldsmith at Oxford, and born in 1614. After being educated in Greek and Latin, in which he made a very quick progress, he was entered a student of New Inn in that university, when he was but 13 years of age; but after a short stay there, he was removed to Magdalen Hall, where he took his degrees. Having entered into holy orders, he first became chaplain to William Lord Say, and afterwards to Charles Count Palatine of the Rhine, with whom he continued some time. Adhering to the parliament during the civil wars, they made him warden of Wadham college about the year 1648. In 1656 he married the sister of Oliver Cromwell, then lord protector of England, who granted him a dispensation to hold his wardenship, notwithstanding his marriage. In 1659, he was by Richard Cromwell made master of Trinity college in Cambridge; but ejected the year following, on the restoration. He was then chosen preacher to the society of Gray's Inn, and rector of St. Lawrence Jewry, London, on the promotion of Dr. Seth Ward to the bishoprick of Exeter. He was one of the first members of the Royal Society, was chosen of their council, being indeed their first chief secretary, and proved one of their most eminent members. He was afterwards made dean of Rippon, and in 1668 bishop of Chester; but died of the stone in 1672, at 58 years of age.

Bishop Wilkins was a man who thought it prudent to submit to the powers in being; he therefore subscribed to the solemn league and covenant, while it was enforced; and was equally ready to swear allegiance to king Charles when he was restored: this, with his moderate spirit towards dissenters, rendered him not very agreeable to the churchmen; and yet several of them could not but give him one of the best of characters. Burnet writes, that "he was a man of as great a mind, as true a judgment, as eminent virtues, and of as good a soul, as any he ever knew: that though he married Cromwell's sister, yet he made no other use of that alliance, but to do good offices, and to cover the university of Oxford from the sourness of Owen and Goodwin. At Cambridge, he joined with those who studied to propagate better thoughts, to divert men from parties, or from narrow notions, from superstitious conceits, and fierceness about opinions. He was also a great observer and promoter of experimental philosophy, which was then quite a new subject, and much sought after. He was naturally ambitious, but was the wisest clergyman I ever knew. He was a lover of mankind, and had a delight in doing good." The same historian mentions afterwards another quality which Wilkins possessed in a supreme degree, and which it was well for him he did, since he had great occasion for the use of it; and that was, says he, "a courage, which could stand against a current, and against all the reproaches with which ill-natured clergymen studied to load him."

Of his publications, which are all of them very ingenious and learned, and many of them particularly curious and entertaining, the first was in 1638, when he was only 24 years of age, viz, The Discovery of a New World; or, A Discourse to prove, that it is probable there may be another Habitable World in the Moon; with a Discourse concerning the Possibility of a Passage thither.—In 1640, A Discourse concerning a New Planet, tending to prove that it is probable our earth is one of the Planets.—In 1641, Mercury; or, the Secret and Swift Messenger; showing, how a man may with Privacy and Speed communicate his Thoughts to a Friend at any Distance, 8vo.—In 1648, Mathematical Magic; or, the Wonders that may be performed by Mathematical Geometry, 8vo. All these pieces were published entire in one volume 8vo, in 1708, under the title of, The Mathematical and Philosophical Works of the Right Rev. John Wilkins, &c; with a print of the author and general title page handsomely engraven, and an account of his life and writings. To this collection is also subjoined an abstract of a larger work, printed in 1668, folio, entitled, An Essay towards a Real Character and a Philosophical Language. These were all his mathematical and philosophical works; beside which, he wrote several tracts in theology, natural religion, and civil polity, which were much esteemed for their piety and moderation, and went through several editions. He was also the inventor of the Perambulator, or Measuring-wheel.

WILSON (ALEX.) M. D. was professor of astronomy in the university of Glasgow, and also very respectably learned in other arts and sciences, and was author of some ingenious papers in the Philos. Trans. He was also remarkably eminent as a founder of printing-types, an art which he carried to a high state of excellence. Dr. Wilson died Oct. 18, 1786, and was succeeded, in both his professions, by his ingenious and learned son.

WINCH, a popular term for a windlass. Also the bent handle for turning round wheels, grind-stones, &c.

WIND, a current or stream of air, especially when it is moved by some natural cause. Winds are denominated from the point of the compass or horizon they blow from; as the east wind, north wind, south wind, &c. Winds are also divided into several kinds; as general, particular, perennial, stated, variable, &c.

Constant or *Perennial* WINDS, are those that always blow the same way; such as the remarkable one between the two tropics, blowing constantly from east to west, called also the general trade-wind.

Stated or *Periodical* WINDS, are those that constantly return at certain times. Such are the sea and land breezes, blowing from land to sea in the morning, and from sea to land in the evening. Such also are the shifting or particular trade-winds, which blow one way during certain months of the year, and the contrary way the rest of the year.

Variable or *Erratic* WINDS, are such as blow without any regularity either as to time, place, or direction. Such are the winds in the interior parts of England, &c: though some of these claim their certain times of the day; as, the north wind is most frequent in the morning, the west wind about noon, and the south wind in the night.

General WIND, is such as blows at the same time the same way, over a very large tract of ground, most part of the year; as the general trade-wind.

Particular WINDS, include all others, except the general trade winds. Those peculiar to one little canton or province, are called topical or provincial winds. The winds are also divided, with respect to the points of the compass or of the horizon, into cardinal and collateral.

Cardinal WINDS, are those blowing from the four cardinal points, east, west, north, and south.

Collateral WINDS, are the intermediate winds between any two cardinal winds, and take their names from the point of the compass or horizon they blow from.

In navigation, when the wind blows gently, it is called a breeze; when it blows harder, it is called a gale, or a stiff gale; and when it blows very hard, a storm. For a particular account of the trade-winds, monsoons, &c, see Philos. Trans. No. 183, or Abridg. vol. 1, pa. 375. Also Robertson's Navigation, book 5, sect. 6.

A wind blowing from the sea, is always moist; as bringing with it the copious evaporation and exhalations from the waters: also, in summer, it is cool; and in winter warm. On the contrary, a wind from the continent, is always dry; warm in summer, and cold in winter. Our northerly and southerly winds however, which are usually accounted the causes of cold and warm weather, Dr. Derham observes, are really rather the effect of the cold or warmth of the atmosphere. Hence it is that we often find a warm southerly wind suddenly change to the north, by the fall of snow or hail; and in a cold frosty morning, we find the wind north, which afterward shifts about to the southerly quarter, when the sun has well warmed the air; and again in the cold evening, turns northerly, or easterly.

Physical Cause of WINDS. Some philosophers, as Descartes, Rohault, &c, account for the general wind, from the diurnal rotation of the earth; and from this general wind they derive all the particular ones. Thus, as the earth turns eastward, the particles of the air near the equator, being very light, are left behind; so that, in respect of the earth's surface, they move westwards, and become a constant easterly wind, as they are found between the tropics, in those parallels of latitude where the diurnal motion is swiftest. But yet, against this hypothesis, it is urged, that the air, being kept close to the earth by the principle of gravity, would in time acquire the same degree of velocity that the earth's surface moves with, as well in respect of the diurnal rotation, as of the annual revolution about the sun, which is about 30 times swifter.

Dr. Halley therefore substitutes another cause, capable of producing a like constant effect, not liable to the same objections, but more agreeable to the known properties of the elements of air and water, and the laws of the motion of fluid bodies. And that is the action of the sun's beams, as he passes every day over the air, earth, and water, combined with the situation of the adjoining continents. Thus, the air which is less rarefied or expanded by heat, must have a motion towards those parts which are more rarefied, and less ponderous, to bring the whole to an equilibrium; and as the sun keeps continually shifting to the westward, the tendency of the whole body of the lower air is that way. Thus a general easterly wind is formed, which being impressed on the air of a vast ocean, the parts impel one another, and so keep moving till the next return of the sun, by which so much of the motion as was lost, is again restored; and thus the easterly wind is made perpetual. But as the air towards the north and south is less rarefied than in the middle, it follows that from both sides it ought to tend towards the equator.

This motion, compounded with the former easterly wind, accounts for all the phenomena of the general trade-winds, which, if the whole surface of the globe were sea, would blow quite round the world, as they are found to do in the Atlantic and the Ethiopic oceans. But the large continents of land in this middle tract, being excessively heated, communicate their heat to the air above them, by which it is exceedingly rarefied, which makes it necessary that the cooler and denser air should rush in towards it, to restore the equilibrium. This is supposed to be the cause why, near the coast of Guinea, the wind always sets in on the land, blowing westerly instead of easterly.

From the same cause it happens, that there are such constant calms in that part of the ocean called the rains; for this tract being placed in the middle, between the westerly winds blowing on the coast of Guinea, and the easterly trade-winds blowing to the westward of it; the tendency of the air here is indifferent to either, and so stands in equilibrio between both; and the weight of the incumbent atmosphere being diminished by the continual contrary winds blowing hence, is the reason that the air here retains not the copious vapour it receives, but lets it fall in so frequent rains.

It is also to be considered, that to the northward of the Indian ocean there is every where land, within the usual limits of the latitude of 30°, viz, Arabia, Persia, India, &c, which are subject to excessive heats when the sun is to the north, passing nearly vertical; but which are temperate enough when the sun is removed towards the other tropic, because of a ridge of mountains at some distance within the land, said to be often in winter covered with snow, over which the air as it passes must needs be much chilled. Hence it happens that the air coming, according to the general rule, out of the north-east, to the Indian sea, is sometimes hotter, sometimes colder, than that which, by a circulation of one current over another, is returned out of the south-west; and consequently sometimes the under current, or wind, is from the north-east, sometimes from the south-west.

That this has no other cause, appears from the times when these winds set in, viz, in April: when the sun begins to warm these countries to the north, the south-west monsoons begin, and blow during the heats till October, when the sun having retired, and all things growing cooler northward, but the heat increasing to the south, the north-east winds enter, and blow all the winter, till April again. And it is doubtless from the same principle, that to the southward of the equator, in part of the Indian ocean, the north-west winds succeed the south-east, when the sun draws near the tropic of Capricorn. Philos. Trans. No. 183.

But some philosophers, not satisfied with Dr. Halley's theory above recited, or thinking it not sufficient for explaining the various phenomena of the wind, have had recourse to another cause, viz, the gravitation of the earth and its atmosphere towards the sun and moon, to which the tides are confessedly owing. They allege that, though we cannot discover aërial tides, of ebb or flow, by means of the barometer, because columns of air of unequal height, but different density, may have the same pressure or weight; yet the protuberance in the atmosphere, which is continually following the moon, must, say they, occasion a motion in all parts, and so produce a wind more or less to every place, which conspiring with, or being counteracted by, the winds arising from other causes, makes them greater or less. Several dissertations to this purpose were published, on occasion of the subject proposed by the Academy of Sciences at Berlin, for the year 1746. But Musschenbroek will not allow that the attraction of the moon is the cause of the general wind; because the east wind does not follow the motion of the moon about the earth; for in that case there would be more than 24 changes, to which it would be subject in the course of a year, instead of two. Introd. ad Phil. Nat. vol. 2, pa. 1102.

And Mr. Henry Eeles, conceiving that the rarefaction of the air by the sun cannot simply be the cause of all the regular and irregular motions which we find in the atmosphere, ascribes them to another cause, viz, the ascent and descent of vapour and exhalation, attended by the electrical fire or fluid; and on this principle he has endeavoured to explain at large the general phenomena of the weather and barometer. Philos. Trans. vol. 49, pa. 124.

Laws of the Production of WIND.

The chief laws concerning the production of wind, may be collected under the following heads.

1. If the spring of the air be weakened in any place more than in the adjoining places, a wind will blow through the place where the diminution is; because the less elastic or forcible will give way to that which is more so, and thence induce a current of air into that place, or a wind. Hence, because the spring of the air increases, as the compressing weight increases, and compressed air is denser than that which is less compressed; all winds blow into rarer air, out of a place filled with a denser.

2. Therefore, because a denser air is specifically heavier than a rarer; an extraordinary lightness of the air in any place must be attended with extraordinary winds, or storms. Now, an extraordinary fall of the mercury in the barometer showing an extraordinary lightness of the atmosphere, it is no wonder if that foretels storms of wind and rain.

3. If the air be suddenly condensed in any place, its spring will be suddenly diminished; and hence, if this diminution be great enough to affect the barometer, a wind will blow through the condensed air. But since the air cannot be suddenly condensed, unless it has before been much rarefied, a wind will blow through the air, as it cools, after having been violently heated.

4. In like manner, if air be suddenly rarefied, its spring is suddenly increased; and it will therefore flow through the air not acted on by the rarefying force. Hence a wind will blow out of a place, in which the air is suddenly rarefied; and on this principle probably it is, that the sun, by rarefying the air, must have a great influence on the production of winds.

5. Most caves are found to emit wind, either more or less. Musschenbroek has enumerated a variety of causes that produce winds, existing in the bowels of the earth, on its surface, in the atmosphere, and above it. See Introd. ad Phil. Nat. vol. 2, pa. 1116.

6. The rising and changing of the winds are determined by weathercocks, placed on the tops of high buildings, &c. But these only indicate what passes about their own height, or near the surface of the earth. And Wolfius assures us, from observations of several years, that the higher winds, which drive the clouds, are different from the lower ones, which move the weathercocks. Indeed it is no uncommon thing to see one tier of clouds driven one way by a wind, and another tier just over the former driven the contrary way, by another current of air, and that often with very different velocities. And the late experiments with air balloons have proved the frequent existence of counter winds, or currents of air, even when it was not otherwise visible, nor at all expected; by which they have been found to take very different and unexpected courses, as they have ascended to higher elevations in the atmosphere.

Laws of the Force and Velocity of the WIND.

Wind being only air in motion, and the motion of a fluid against a body at rest, creating the same resistance as when the body moves with the same velocity through the fluid at rest; it follows, that the force of the wind, and the laws of its action on bodies, may be referred to those of their resistance when moved through it; and as these circumstances have been treated pretty fully under the article RESISTANCE *of the Air*, there is no occasion here to make a repetition of them. We there laid down both the quantity and laws of such a force, on bodies of different shapes and sizes, moving with all degrees of velocity up to 2000 feet per second, and also for planes set at all degrees of obliquity, or inclination to the direction of motion; all these circumstances having, for the first time, been determined by real experiments.

As to the Velocity of the Wind: philosophers have made use of various methods for determining it. The method employed by Dr. Derham, was by letting light downy feathers fly in the air, and nicely observing the distance to which they were carried in any number of half seconds. He says that he thus measured the velocity of the wind in the great storm of August 1705, which he found moved at the rate of 33 feet in half a second, or 45 miles per hour: whence he concludes, that the most vehement wind does not fly at the rate of above 50 or 60 miles an hour; and that at a medium the velocity of wind is at the rate of 12 or 15 miles per hour. Philos. Trans. No. 313.

Mr. Brice observes however, that experiments with feathers are liable to much uncertainty; as they hardly ever go forward in a straight direction, but spirally, or else irregularly from side to side, or up and down.

He therefore considers the motion of a cloud, by means of its shadow over the surface of the earth, as a much more accurate measure of the velocity of the wind. In this way he found that the wind, in a considerable storm, moved at the rate of near 63 miles an hour; and when it blew a fresh gale, at the rate of 21 miles per hour; and in a small breeze it was near 10 miles an hour. Philos. Trans. vol. 56, pa. 226.

In the Philos. Trans. for 1759, pa. 165, Mr. Smeaton has given a table, communicated to him by a Mr. Rouse, for showing the force of the wind, with several different velocities, which is here inserted below, as I find the numbers nearly agree with my own experiments made on the resistance of the air, when the resisting surfaces are reduced to the same size, by a due proportion for the resistance, which is in a higher degree than that of the surfaces. The table of my results is printed under the article ANEMOMETER.

A Table of the different Velocities and Forces of the Wind, according to their common appellations.

Velocity of the Wind.		Perpendicular force on 1 sq. foot, in avoirdupois pounds.	Common appellations of the Winds.
Miles in one hour.	= feet in one second.		
1	1·47	·005	Hardly perceptible.
2	2·93	·020	Just perceptible.
3	4·40	·044	
4	5·87	·079	Gentle pleasant wind.
5	7·33	·123	
10	14·67	·492	Pleasant brisk gale.
15	22·00	1·107	
20	29·34	1·968	Very brisk.
25	36·67	3·075	
30	44·01	4·429	High Winds.
35	51·34	6·027	
40	58·68	7·873	Very high.
45	66·01	9·963	
50	73·35	12·300	A storm or tempest.
60	88·02	17·715	A great storm.
80	117·36	31·490	A hurricane.
100	146·70	49·200	A hurricane that tears up trees, and carries buildings &c before it.

The velocity and force of the wind are also determined experimentally by various machines, called anemometers, wind-measurers, or wind-gages; the description of which see under these articles.

The force of the wind is nearly as the square of the velocity, or but little above it, in these velocities. But the force is much more than in the simple ratio of the surfaces, with the same velocity, and this increase of the ratio is the more, as the velocity is more. By accurate experiments with two planes, the one of 17½ square inches, the other of 32, which are nearly in the ratio of 5 to 9, I found their resistances, with a velocity of 20 feet per second, to be, the one 1·196 ounces, and the other 2·542 ounces; which are in the ratio of 8 to 17, being an increase of between $\frac{1}{5}$ and $\frac{1}{6}$ part more than the ratio of the surfaces.

WINDAGE, *of a Gun*, is the difference between the diameter of the bore of the gun, and the diameter of the ball. Formerly the windage appointed in the English service, viz, $\frac{1}{20}$ of the diameter of the bore, of long usage, has been far too much, perhaps owing to the first want of roundness in the ball, or to rust, foulness, and irregularities in the bore of the gun. But lately a beginning has been made to diminish the windage, which cannot fail to be of great advantage; as the shot will go much truer, and have less room to bounce about from side to side, to the great damage of the gun: and besides, much less powder will serve for the same effect, as in some cases $\frac{1}{3}$ or $\frac{1}{2}$ the inflamed powder escapes by the windage. The French allowance of windage is $\frac{1}{27}$ of the diameter. For more on this subject, see the experiments described in my Tracts, vols. 2 and 3.

WINDLASS, or WINDLACE, a particular machine used for raising heavy weights, as guns, stones, anchors, &c.

This is a very simple machine, consisting only of an axis or roller, supported horizontally at the two ends by two posts and a pulley: the two posts meet at top, being placed diagonally, so as to prop each other; and the axis or roller goes through the two posts, and turns in them; the pulley being fastened at top, where the posts join. Lastly, there are two staves or handspikes, which go through the roller, to turn it by; and the rope, which goes over the pulley, is wound on and off the same.

WINDLASS, in a Ship, is an instrument in small ships placed upon deck, but just abaft the foremost. It consists of a stout piece of timber, in form of an axletree, placed horizontally on two pieces of wood at the ends, on which it is turned about by means of handspikes, put into holes made for that purpose. This instrument serves for weighing anchors, or hoisting any great weight in or out of the ship; it will purchase much more than any capstan, and that without any danger to those who heave; for if, in heaving the windlass about, any of the handspikes should happen to break, the windlass would stop of itself.—See fig. 15, pl. 40.

WIND-*Gage*, in Pneumatics, an instrument serving to determine the velocity and force of the wind. See ANEMOMETER, ANEMOSCOPE, and the article just above, concerning the force and velocity of the wind.

Dr. Hales had various contrivances for this purpose. He found (Statical Essays, vol. 2, pa. 326) that the air rushed out of a smith's bellows, at the rate of 68¾ feet in a second of time, when compressed with a force of half a pound on every square inch lying on the whole upper surface of the bellows. The velocity of the air, as it passed out of the trunk of his ventilators, was found to be at the rate of 3000 feet in a minute, which is at the rate of 34 miles an hour. The same author observes, that the velocity with which impelled air passes out at any orifice, may be determined by hanging a light valve over the nose of a bellows, by pliant leathern hinges, which will be much agitated and lifted up from a perpendicular to a more than horizontal position by the force of the rushing air. There is also another more accurate way, he says, of estimating the velocity of air, viz, by holding the orifice of an inverted glass siphon full of water, opposite to the stream of air, by which the water will be depressed in one leg, and raised in the other, in proportion to the force with which the water is impelled by the air. Descrip. of Ventilators, 1743, pa. 12. And this perhaps gave Dr. Lind the idea of his wind-gage, mentioned below.

M. Bouguer contrived a simple instrument, by which may be immediately discovered the force which the wind exerts on a given surface. This is a hollow tube, AABB (fig. 14, pl. 40), in which a spiral spring CD is fixed, that may be more or less compressed by a rod FSD, passing through a hole within the tube at AA. Then having observed to what degree different forces or given weights are capable of compressing the spiral, mark divisions on the rod in such a manner, that the mark at S may indicate the weight requisite to force the spring into the situation CD: afterwards join at right angles to this rod at F, a plane surface EFE of any given area at pleasure; then let this instrument be opposed to the wind, so that it may strike the surface perpendicularly, or parallel to the rod; then will the mark at S show the weight to which the force of the wind is equivalent.

Dr. Lind has also contrived a simple and easy apparatus of this kind, nearly on the last idea of Dr. Hales mentioned above. This instrument is fully explained under the article ANEMOMETER, and a figure of it given, pl. 3, fig. 4.

Mr. Benjamin Martin, from a hint first suggested by Dr. Burton, contrived an anemoscope, or wind-gage, of a construction like a wind-mill, with four sails; but the axis which the sails turn, is not cylindrical, but conical, like the fusee of a watch; about this fusee winds a cord, having a weight at the end, which is wound always, by the force of the wind, on the sails, till the weight just balances that force, which will be at a thicker part of the fusee when the wind is strong, and at a smaller part of it when it is weaker. But though this instrument shows when a wind is stronger or weaker, it will neither show what is the actual velocity of the wind, nor yet its force upon a square foot of direct surface; because the sails are set at an uncertain oblique angle to the wind, and this acts at different distances from the axis or centre of motion. Martin's Phil. Brit. vol. 2, pa. 211. See the fig. 5. plate 3, vol. 1.

WIND-*Gun*, the same as AIR-*Gun*; which see.

WIND-*Mill*, a kind of mill which receives its motion from the impulse of the wind.—The internal structure of the windmill is much the same with that of watermills: the difference between them lying chiefly in an external apparatus, for the application of the power. This apparatus consists of an axis EF (fig. 11, pl. 41), through which pass perpendicular to it, and to each other, two arms or yards, AB and CD, usually about 32 feet long: on these yards are formed a kind of sails, vanes, or flights, in a trapezoid form, with parallel ends; the greater of which HI is about 6 feet, and the less FG are determined by radii drawn from the centre E, to I and H.

These sails are to be capable of being always turned to the wind, to receive its impulse: for which purpose there are two different contrivances, which constitute the two different kinds of windmills in common use.

In the one, the whole machine is supported upon a moveable arbor, or axis, fixed upright on a stand or foot; and turned round occasionally to suit the wind, by means of a lever.

In the other, only the cover or roof of the machine, with the axis and sails, in like manner turns round with a parallel or horizontal motion. For this purpose, the cover is built turret-wise, and encompassed with a wooden ring, having a groove, at the bottom of which are placed, at certain distances, a number of brass truckles; and within the groove is another ring, on which the whole turret stands. To the moveable ring are connected beams *ab* and *fe*; and to the beam *ab* is fastened a rope at *b*, having its other end fitted to a windlass, or axis-in-peritrochio: this rope being drawn through the iron hook G, and the windlass turned, the sails are moved round, and set fronting the wind, or with the axis pointing straight against the wind.

The internal mechanism of a windmill is exhibited in fig. 12; where AHO is the upper room, and HOZ the lower one; AB the axle-tree passing through the mill; STVW the sails covered with canvas, set obliquely to the wind, and turning round in the order of the letters; CD the cog-wheel, having about 48 cogs or teeth, *a*, *a*, *a*, &c, which carry round the lantern EF, having 8 or 9 trundles or rounds, *c*, *c*, *c*, &c, together with its upright axis GN; IK is the upper mill-stone, and LM the lower; QR is the bridge, supporting the axis or spindle GN; this bridge is supported by the beams *cd*, XY, wedged up at *c*, *d* and X; ZY is the lifting tree, which stands upright; *ab* and *ef* are levers, whose centres of motion are *z* and *e*; *fghi* is a cord, with a stone *i*, going about the pins *g* and *h*, and serving as a balance or counterpoise. The spindle *t*N is fixed to the upper millstone IK, by a piece of iron called the rynd, and fixed in the lower side of the stone, which is the only one that turns about, and its whole weight rests on a hard stone, fixed in the bridge QR at N. The trundle EF, and its axis G*t*, may be taken away; for it rests by its lower part at *t* by a square socket, and the top runs in the edge of the beam *w*. By bearing down the end *f* of the lever *fe*, *b* is raised, which also raises ZY, and this raises YX, which lifts up the bridge QR, with the axis NG, and the upper stone IK; and thus the stones are set at any distance. The lower or immoveable stone is fixed upon strong beams, and is broader than the upper one: the meal is conveyed through the tunnel *no* into a chest; P is the hopper, into which is put the corn, which runs through the spout *r* into the hole *t*, and so falls between the stones, where it is ground to meal. The axis G*t* is square, which shaking the spout *r*, as it goes round, makes the corn run out; *rs* is a string going about the pin *s*, and serving to move the spout nearer to the axis or farther from it, so as to make the corn run faster or slower, according to the velocity and force of the wind. And when the wind is strong, the sails are only covered in part, or on one side, or perhaps only one half of two opposite sails. Toward the end B of the axletree is placed another cogwheel, trundle, and millstones, with an apparatus like that just described; so that the same axis moves two stones at once;

and when only one pair is to grind, one of the trundles and its spindle are taken out: *xyl* is a girth of pliable wood, fixed at the end *x*; the other end *l* being tied to the lever *km*, moveable about *k*; and the end *m* being put down, draws the girth *xyl* close to the cogwheel, which gently and gradually stops the motion of the mill, when required: *pq* is a ladder for ascending to the higher part of the mill; and the corn is drawn up by means of a rope, rolled about the axis AB, when the mill is at work. See MILL.

Theory of the WINDMILL, *Position of the Sails, &c.*

Were the sails set square on their arms or yards, and perpendicular to the axletree, or to the wind, no motion would ensue, because the direct wind would keep them in an exact balance. But by setting them obliquely to the common axis, like the sails of a smoke-jack, or inclined like the rudder of a ship, the wind, by striking the surface of them obliquely, turns them about. Now this angle which the sails are to make with their common axis, or the degree of weathering, as the mill-wrights call it, so as that the wind may have the greatest effect, is a matter of nice inquiry, and has much occupied the thoughts of the mathematician and the artist.

In examining the compound motions of the rudder of a ship, we find that the more it approaches to the direction of the keel, or to the course of the water, the more weakly this strikes it; but, on the other hand, the greater is the power of the lever to turn the vessel about. The obliquity of the rudder therefore has, at the same time, both an advantage and a disadvantage. It has been a point of inquiry therefore to find the position of the rudder when the ratio of the advantage over the disadvantage is the greatest. And M. Renau, in his theory of the working of ships, has found, that the best situation of the rudder is when it makes an angle of about 55 degrees with the keel.

The obliquity of the sails, with regard to their axis, has precisely the same advantage, and disadvantage, with the obliquity of the rudder to the keel. And M. Parent, seeking by the new analysis the most advantageous situation of the sails on the axis, finds it the same angle of about 55 degrees. This obliquity has been determined by many other mathematicians, and found to be more accurately 54° 44′. See Maclaurin's Fluxions, pa. 733; Simpson's Fluxions, prob. 17, pa. 521; Martin's Philos. Britan. vol. 1, pa. 220, vol. 2, pa. 212; &c.

This inclination of the sails to their axis, however, is only that which gives the wind the greatest force to put the sail in motion, but not the angle which gives the force of the wind a maximum on the sail when in motion: for when the sail has a certain degree of velocity, it yields to the wind; and then that angle must be increased, to give the wind its full effect. Maclaurin, in his Fluxions, pa. 734, has shown also how to determine this angle.

It may be observed, that the increase of this angle should be different according to the different velocities from the axletree to the further extremity of the sail. At the beginning, or axis, it should be 54° 44′; and thence continually increasing, giving the vane a twist, and so causing all the ribs of the vane to lie in different planes.

It is farther observed, that the ribs of the vane or sail ought to decrease in length from the axis to the extremity, giving the vane a curvilinear form; so that no part of the force of any one rib be spent on the rest, but all move independent of each other. The twist above mentioned, and the diminution of the ribs, are exemplified in the wings of birds.

As the ends of the sail nearest the axis cannot move with the same velocity which the tips or farthest ends have, though the wind acts equally strong on them both, Mr. Ferguson (Lect. on Mech. pa. 52) suggests, that perhaps a better position than that of stretching them along the arms directly from the centre of motion, might be, to have them set perpendicularly across the farther ends of the arms, and there adjusted lengthwise to the proper angle: for in that case both ends of the sails would move with the same velocity; and being farther from the centre of motion they would have so much the more power, and in this case there would be no occasion for having them so large as they are generally made; which would render them lighter, and consequently there would be so much the less friction on the thick neck of the axle, when it turns in the wall.

Mr. Smeaton (Philos. Trans. 1759), from his experiments with windmill sails, deduces several practical maxims: as, 1. That when the wind falls on a concave surface, it is an advantage to the power of the whole, though every part, taken separately, should not be disposed to the best advantage. By several trials he has found that the curved form and position of the sails will be best regulated by the numbers in the following table:

6th Parts of the radius or sail.	Angle with the axis.	Angle with the plane of motion.
1	72°	18°
2	71	19
3	72	18 middle.
4	74	16
5	77½	12½
6	83	7 end.

2. That a broader sail requires a greater angle; and that when the sail is broader at the extremity, than near the centre, this shape is more advantageous than that of a parallelogram.

3. When the sails, made like sectors of circles, joining at the centre or axis, and filled up about 7-8ths of the whole circular space, the effect was the greatest.

4. The velocity of windmill sails, whether unloaded, or loaded so as to produce a maximum of effect, is nearly as the velocity of the wind; their shape and position being the same.

5. The load at the maximum is nearly, but somewhat less than, as the square of the velocity of the wind.

6. The effects of the same sails at a maximum, are nearly, but somewhat less than, as the cubes of the velocity of the wind.

7. In sails of a similar figure and position, the number of turns in a given time, are reciprocally as the radius or length of the sail.

8. The effects of sails of similar figure and position, are as the square of their length.

9. The velocity of the extremities of Dutch mills, as well as of the enlarged sails, in all their usual positions, is considerably greater than the velocity of the wind.

M. Parent, in considering what figure the sails of a windmill should have, to receive the greatest impulse from the wind, finds it to be a sector of an ellipsis, whose centre is that of the axletree of the mill; and the less semiaxis the height of 32 feet; as for the greater, it follows necessarily from the rule that directs the sail to be inclined to the axis in the angle of 55 degrees.

On this foundation he assumes four such sails, each being a quarter of an ellipse; which he shows will receive all the wind, and lose none, as the common ones do. These 4 surfaces, multiplied by the lever with which the wind acts on one of them, express the whole power the wind has to move the machine, or the whole power of the machine when in motion.

The same author also observes that a wind mill with 6 elliptical sails, would still have more power than one with only four. It would only have the same surface with the four; since the 4 contain the whole space of the ellipsis, as well as the 6. But the force of the 6 would be greater than that of the 4, in the ratio of 245 to 231. If it were desired to have only two sails, each being a semi-ellipsis, the surface would still be the same; but the power would be diminished by nearly 1-3d of that with 6 sails; because the greatness of the sectors would much shorten the lever on which the wind acts.

Mr. Parent has also considered which form, among the rectangular sails, will be most advantageous; i. e. that which shall have the product of the surface by the lever of the wind, the greatest. The result of this inquiry is, that the width of the rectangular sail should be nearly double its length; whereas usually the length is made almost 5 times the width.

The power of the mill, with four of these new rectangular sails, the same author shows, will be to the power of four elliptic sails, nearly as 13 to 23: which leaves a considerable advantage on the side of the elliptic ones; and yet the force of the new rectangular sails will still be considerably greater than that of the common ones.

M. Parent also considers what number of the new sails will be most advantageous; and finds that the fewer the sails, the more surface there will be, but the power the less. Farther, the power of a windmill with 6 sails is denoted by 14, that of another with 4 will be as 13, and another with 2 sails will be denoted by 9. That as to the common windmill, its power still diminishes as the breadth of the sails is smaller, in proportion to the length: and therefore the usual proportion of 5 to 1 is exceedingly disadvantageous.

WINDOW, q. d. *wind-door*, an aperture or opening in the wall of a house, to admit the air and light.

Before the use of glass became general, which was not till towards the end of the 12th century, the windows in England seem generally to have been composed of paper, oiled, both to defend it against the weather, and to make it more transparent; as now is sometimes used in workshops and unfinished buildings. Some of the better sort were furnished with lattices of wood or sheets of linen. These it seems were fixed in frames, called capsamenta, and hence our casements still so common in some of the counties.

The chief rules with regard to windows are, 1. That they be as few in number, and as moderate in dimensions, as may be consistent with other respects; inasmuch as all openings are weakenings of the structure.

2. That they be placed at a convenient distance from the angles or corners of the buildings: both for strength and beauty.

3. That they be made all equal one with another, in their rank and order; so that those on the right hand may answer to those on the left; and those above be right over those below, both on account of strength and beauty.

As to their dimensions, care is to be taken, to give them neither more nor less than is needful; regard being had to the size of the rooms, and of the building. The apertures of windows in middle-sized houses, may be from 4 to 5 feet; in the smaller ones less; and in large buildings more. And the height may be double their width at the least: but in lofty rooms, or large buildings, the height may be a 4th, or 3d, or half their breadth more than the double.

Such are the proportions for windows of the first story; and the breadth must be the same in the upper stories; but as to the height, the second story may be a 3d part lower than the first, and the third story a 4th part lower than the second.

WINDWARD, in Sea Language, denotes any thing towards that point whence the wind blows, in respect of a ship.

Sailing to WINDWARD. See SAILING.

WINDWARD *Tide*, a tide that runs against the wind.

WING (VINCENT), a considerable mathematician and astrologer of the 17th century, who died about 1668. He was author of several popular astronomical and other works: as, 1. Astronomia Instaurata, fol. 1656.—2. Celestial Harmony of the Visible World, fol. 1657.—3. Astronomia Britannica, fol. 1669, a work of merit.—4. Ephemerides for 13 years, from 1659 to 1671.—5. Computatio Catholica, &c. Mr. Wing was much connected with the Stationers' Company, in the publication of their almanacs, one of which, in a broad sheet, is still continued in his name; and another, a book almanac, was only discontinued a very few years ago.

WINGATE (EDMUND), one of the clearest writers on arithmetic &c in the English language, was the son of Roger Wingate, esq. of Bornend and Sharpenkoe, in Bedfordshire, but was born in Yorkshire in 1593. In 1610 he became a commoner of Queen's college, Oxford; but after taking a degree in arts, he removed to Gray's Inn, London, where he studied the law. But his chief inclination was to the mathematics, which he had studied with much success at college. In 1624 he was in France, where he published the Scale or Rule of Proportion, which had been invented by Edmund Gunter, of Gresham college. While in that country, he gave instructions in the English language to the princess Henrietta Maria, afterwards wife of Charles the first, and to her ladies. After his return to England, he became a bencher of Gray's Inn; and on the breaking out of the great rebellion, he joined the popular party, took the covenant, was made justice of the peace for the county of Bedford, where he resided at Woodend, in the parish of Harlington, and his name occurs in the register of Ampthill church, as a justice, in 1654, when, according to the republican custom of that period, marriages were celebrated by the civil magistrates. In 1650 he took the oath, commonly called the Engagement, became intimate with Cromwell, and was chosen into his parliament for Bedford. He was also appointed one of the commissioners, for that county, to eject from their situations, those loyal clergymen and schoolmasters who were accused as being scandalous and ignorant. He died in Gray's Inn, in 1656, and was buried in the parish church of St. Andrew, Holborn.

The works of Mr. Wingate, are,

1. The Use of the Proportional Rules in Arithmetic and Geometry. Also the Use of the Logarithms of Numbers, with those of Sines and Tangents. Printed in French, at Paris, in 1624, 8vo, and at London, in English, in 1626, 1645, and 1658.—In this book, Mr. W. speaks of having

been the first who carried the Logarithms to France; but an edition of Napier's Description and Construction of Logarithms was printed at Lyons in the year 1620, being 4 years earlier than Wingate's publication.

2. Of Natural and Artificial Arithmetic, or Arithmetic made easy; London, 1630, 8vo. It has also gone through numerous other editions, the best of which is that by Mr. Dodson.

3. Tables of Logarithms of the Sines and Tangents of all the Degrees and Minutes of the Quadrant. With the use and application of the same. London, 1633, 8vo.

4. The Construction and Use of Logarithms, with the Resolution of Triangles, &c.

5. Ludus Mathematicus; or an Explanation of the Description, Construction, and Use of the Numerical Table of Proportion. London, 1654, 8vo.

6. Tactometria, seu Tetagne-nometria, or the Geometry of Regulars, &c. 8vo.

7. The Exact Surveyor of Land, &c, 8vo.

8. An exact Abridgement of all Statutes in force and use from the Magna Charta, to 1641, 8vo.

9. The Body of the Common Law of England, &c; 8vo, 1655, &c.

10. Maxims of Reason, or the Reason of the Common Law of England; 1658, folio.

11. Statuta Pacis; or, the Table of all the Statutes which any way concern the office of a Justice of Peace, &c. 12mo.

12. An edition of Britton, a lawyer who wrote in the reign of Edward the 1st; a very useful law book, 1640, 12mo.

Mr. W. it is supposed, was also the editor of some other law books, which show equal judgment and industry; but he is now to be remembered only as a mathematician.

WINTER, one of the four seasons or quarters of the year.—Winter properly commences on the day when the sun's distance from the zenith of the place is the greatest, or when his declination is the greatest on the contrary side of the equator; and it ends on the day when that distance is a mean between the greatest and least, or when he next crosses the equinoctial.

At and near the equator, the winter, as well as the other seasons, return twice every year; but all other places have only one winter in the year; which in the northern hemisphere begins when the sun is in the tropic of Capricorn, and in the southern hemisphere when he is in the tropic of Cancer: so that all places in the same hemisphere have their winter at the same time.

Notwithstanding the coldness of this season, it is proved in astronomy, that the sun is really nearer to the earth in our winter than in summer: the reason of the defect of heat being owing to the lowness of the sun; or to the obliquity of his rays.

WITCHELL (George), F. R. S. a good astronomer and mathematician, was born in 1728. He was maternally descended from the celebrated clock and watch maker Daniel Quare, in which business he was himself brought up, and was educated in the principles of the Quakers, all his progenitors for many generations having been of that community, and whose simplicity of manners and integrity of character he practised through life. It appears that Mr. W. cultivated the study of astronomy at a very early age indeed, as he had a communication on that subject published in the Gentleman's Diary for 1741, which must have been written before he was 13 years of age. Soon after this he became a pretty constant writer in both the Diaries and the Gentleman's Magazine, a practice which he continued a long time, sometimes under his own name, but more frequently with the initials G. W. only. In 1764 Mr. W. published a map, exhibiting the passage of the moon's shadow over England in the great solar eclipse of April 1 that year; the exact correspondence of which to the observations gained him great reputation. In the following year he presented to the commissioners of longitude a plan for calculating the effects of refraction and parallax, on the moon's distance from the sun or a star, to facilitate the discovery of the longitude at sea. Having been elected F. R. S. and taught mathematics in London for many years with much reputation, he was, in 1767, appointed head master of the Royal Naval Academy at Portsmouth, on the recession of Mr. Robertson; where he died by a paralytic stroke in 1785, at 57 years of age, and was succeeded in that office by Mr. Bailey.

WOLFF, Wolfius, (Christian,) baron of the Roman empire, privy counsellor to the king of Prussia, and chancellor to the university of Halle in Saxony, as well as member of many of the literary academies in Europe, was born at Breslau in 1679. After studying philosophy and mathematics at Breslau and Jena, he obtained permission to give lectures at Leipsic; which, in 1703, he opened with a dissertation, Philosophia Practica Universalis, Methodo Mathematica conscripta, which served greatly to enhance the reputation of his talents. He published two other dissertations the same year; the first De Rotis Dentatis, the other De Algorithmo Infinitesimali Differentiali; which obtained him the honourable appellation of Assistant to the Faculty of Philosophy at Leipsic.

He now accepted the professorship of mathematics at Halle, and was elected into the society at Leipsic, at that time engaged in publishing the Acta Eruditorum. After having inserted in this work many important pieces relating to mathematics and physics, he undertook, in 1709, to teach all the various branches of philosophy, beginning with a small logical treatise in Latin, being Thoughts on the Powers of the Human Understanding. He carried himself through these great pursuits with amazing assiduity and ardour: the king of Prussia rewarded him with the office of counsellor to the court in 1721, and augmented the profits of that post by very considerable appointments: he was also chosen a member of the Royal Society of London and of Prussia.

In the midst of all this prosperity however, Wolff raised an ecclesiastical storm against himself, by a Latin oration he delivered in praise of the Chinese philosophy: every pulpit immediately resounded against his tenets; and the faculty of theology, who entered into a strict examination of his productions, resolving that the doctrine he taught was dangerous to the last degree, an order was obtained in 1723 for displacing him, and commanding him to leave Halle in 24 hours.

Wolff now retired to Cassel, where he obtained the professorship of mathematics and philosophy in the university of Marbourg, with the title of Counsellor to the Landgrave of Hesse; to which a profitable pension was annexed. Here he renewed his labours with redoubled ardour; and it was in this retreat that he published the greatest part of his numerous works.

In 1725, he was declared an honorary professor of the academy of sciences at Petersburg, and in 1733 was admitted into that of Paris. The king of Sweden also declared him one of the council of regency; but the pleasing situation of his new abode, and the multitude of honours which he had received, were too alluring to permit him to accept of many advantageous offers; among which it has been said, was the office of president of the academy at Petersburg.

The king of Prussia too, who was now recovered from the prejudices he had been made to conceive against Wolff, wanted to re-establish him in the university of Halle in 1733, and made another attempt to effect it in 1739; which Wolff for a time thought proper to decline, but at last submitted: he returned therefore in 1741, invested with the characters of privy counsellor, vice-chancellor, and professor of the law of nature and of nations. The king afterwards, on a vacancy, raised him to the dignity of chancellor of the university; and the elector of Bavaria created him also a baron of the empire. He died at Halle in Saxony, of the gout in his stomach, in 1754, in the 76th year of his age, after a life filled up with a train of actions as wise and systematical as his writings, of which he composed in Latin and German more than 60 distinct pieces. The chief of his mathematical compositions, is his Elementa Matheseos Universæ, the best edition of which is that of 1732 at Geneva, in 5 vols 4to; which does not however comprise his Mathematical Dictionary in the German language, in 1 vol. 8vo, nor many other distinct works on different branches of the mathematics, nor his System of Philosophy, in 23 vols. in 4to.

WORKING *to Windward*, in Sea Language, is the operation by which a ship endeavours to make progress against the wind.

WREN (Sir CHRISTOPHER), a great philosopher and mathematician, and one of the most learned and eminent architects of his age, was the son of the Rev. Christopher Wren, dean of Windsor, and was born at Knoyle in Wiltshire in 1632. He studied at Wadham college, Oxford; where he took the degree of master of arts in 1653, and was chosen fellow of Allsouls college there. Soon after, he became one of that ingenious and learned society, who then met at Oxford for the improvement of natural and experimental philosophy, and which at length produced the Royal Society.

When very young, he discovered a surprising genius for the mathematics, in which science he made great advances before he was 16 years of age.—In 1657 he was made professor of astronomy in Gresham college, London; and his lectures, which were much frequented, tended greatly to the promotion of real knowledge: in his inaugural oration, among other things, he proposed several methods by which to account for the shadows returning backward 10 degrees on the dial of king Ahaz, by the laws of nature. One subject of his lectures was upon telescopes, to the improvement of which he had greatly contributed; another was on certain properties of the air, and the barometer. In the year 1658 he read a description of the body and different phases of the planet Saturn; which subject he proposed to investigate while his colleague, Mr. Rooke, then professor of geometry, was prosecuting his observations on the satellites of Jupiter. The same year he communicated some demonstrations concerning cycloids to Dr. Wallis, which were afterwards published by the doctor at the end of his treatise on that subject. About that time also, he resolved the problem proposed by Pascal, under the feigned name of John de Montford, to all the English mathematicians; and returned another to the mathematicians in France, formerly proposed by Kepler, and then resolved likewise by himself, to which they never gave any solution.—In 1660, he invented a method for the construction of solar eclipses; and in the latter part of the same year, he with ten other gentlemen formed themselves into a society, to meet weekly, for the improvement of natural and experimental philosophy; being the foundation of the Royal Society.—In the beginning of 1661, he was chosen Savilian professor of astronomy at Oxford, in the room of Dr. Seth Ward; and where he was the same year created Doctor of Laws.

Among his other accomplishments, Dr. Wren had gained so considerable a skill in architecture, that he was sent for the same year, from Oxford, by order of king Charles the 2d, to assist sir John Denham, surveyor general of the works.—In 1663, he was chosen fellow of the Royal Society; being one of those who were first appointed by the Council after the grant of their charter. Not long after, it being expected that the king would make the society a visit, the lord Brounker, then president, by a letter requested the advice of Dr. Wren, concerning the experiments which might be most proper on that occasion; to whom the doctor recommended principally the Torricellian experiment, and the weather needle, as being not mere amusements, but useful, and also neat in their operation. Indeed on many occasions Dr. Wren did great honour to that illustrious body, by many curious and useful discoveries, in astronomy, natural philosophy, and other sciences, related in the History of the Royal Society, where Dr. Sprat has inserted them from the registers and other books of the society to 1665, also in Birch's history. Among others of his productions there enumerated, is a lunar globe; representing the spots and various degrees of whiteness on the moon's surface, with the hills, eminences and cavities: the whole contrived so, that by turning it round to the light, it shows all the lunar phases, with the various appearances that happen from the shadows of the mountains and valleys, &c: this lunar model was placed in the king's cabinet. Another of these productions, is a tract on the Doctrine of Motion that arises from the impact between two bodies, illustrated by experiments: also in the Philos. Trans. vol. 2, pa. 867. And a third is, The History of the Seasons, as to the temperature, weather, productions, diseases, &c, &c. For which purpose he devised also many curious machines, several of which kept their own registers, tracing out the lines of variations, so that a person might know what changes the weather had undergone in his absence: as windgages, thermometers, barometers, hygrometers, raingages, &c.—He made also great additions to the new discoveries on pendulums; and among other things showed, that there may be produced a natural standard for measure from the pendulum for common use.—He invented many ways to make astronomical observations more easy and accurate: he fitted and hung quadrants, sextants, and radii more commodiously than formerly; and also constructed two telescopes to open with a joint like a sector, by which observers may infallibly take a distance to half minutes, &c. He also made various kinds of retes, screws, and other devices, for improving telescopes to take small distances, and apparent diameters, to seconds: he made apertures to admit more or less light, as the observer pleases, by opening and shutting, the better to fit glasses for crepusculine observations.—He added much to the theory of dioptrics; and much also to the manufacture of grinding good glasses: he attempted, and not without success, the making of glasses of other forms than spherical. He exactly measured and delineated the spheres of the humours of the eye, the proportions of which to one another were only guessed at before: a discussion showing the reasons why we see objects erect, and that reflection conduces as much to vision as refraction. He displayed a natural and easy theory of refractions, which exactly answered every experiment. He fully demonstrated the whole doctrine of dioptrics in a few propositions, showing not only, as in Kepler's Dioptrics, the common properties of glasses, but the proportions by which the individual rays cut the axis, and each other, on which the charges of the telescopes, or the proportion of the eye-glasses and apertures, are clearly discovered.—He made constant observations on Saturn, and a true theory of that planet, before the printed discourse by Huygens on that subject appeared.—He also made maps of the Pleiades and other telescopic stars: and proposed methods to determine the great question as to the earth's motion or rest, by the small stars about the pole to be seen in large telescopes.—In navigation also our author made many improvements. He framed a magnetical terella, which he placed in the midst of a plane board with a hole, into which the terella is half immersed, till it be like a globe with the poles in the horizon: the plane is then dusted over with steel filings from a sieve: the dust, by the magnetical virtue, becomes immediately figured into furrows that bend like a sort of helix, proceeding as it were out at one pole, and returning in by the other; the whole plane becoming figured like the circles of a planisphere.—It being a question in his time among the problems of navigation, to what mechanical powers sailing against the wind was reducible; he showed it to be a wedge: he also demonstrated, how a transient force on an oblique plane would cause the motion of the plane against the first mover: and he made an instrument mechanically producing the same effect, and showed the reason of sailing on all winds. The geometrical mechanism of rowing, he showed to be a lever on a moving or cedent fulcrum: for this end, he made instruments and experiments, to find the resistance to motion in a liquid medium; with other circumstances that are the necessary elements for laying down the geometry of sailing, swimming, rowing, flying, and constructing of ships.—He invented a very speedy and curious way of etching. He started many things towards the emendation of water-works. He likewise made some instruments for respiration, and for straining the breath from fuliginous vapours, to try whether the same breath, so purified, will serve again.—He was the first inventor of drawing pictures by microscopical glasses. He invented perpetual, or at least long-lived lamps, for keeping a perpetual regular heat, in order to various uses, as hatching of eggs and insects, production of plants, chemical preparations, imitating nature in producing fossils and minerals, keeping the motion of watches equal, for the longitude and astronomical uses. He was also the first author of the anatomical experiment of injecting liquor into the veins of animals. By this operation, divers creatures were immediately purged, vomited, intoxicated, killed, or revived, according to the quality of the fluid injected. Hence arose many other new experiments, particularly that of transfusing blood, which has been prosecuted in many curious instances. This is a short account of the principal discoveries which Dr. Wren presented, or suggested, to the Royal Society, or were improved by him.

With respect to his architectural works: it has before been observed that he had been sent for to assist sir John Denham. In 1665 he travelled into France, to examine the most beautiful edifices and curious mechanical works there, when he made many useful observations. On his return home, he was appointed architect, and one of the commissioners for repairing St. Paul's cathedral. Within a few days after the fire of London, 1666, he drew a noble plan for a new city, and presented it to the king; but it was not approved of by the parliament. In this model, the chief streets were to cross each other at right angles, with lesser streets between them; the churches, public buildings, &c, so disposed as not to interfere with the streets, and four piazzas placed at proper distances.—On the death of sir John Denham in 1668, our author succeeded him in the office of surveyor-general of the king's works; and from this time he had the direction of a great many public edifices, by which he acquired the most distinguished reputation. He built the magnificent theatre at Oxford, St. Paul's cathedral, the Monument, the modern part of Hampton Court, Chelsea-college, one of the wings of Greenwich hospital, the churches of St. Stephen Walbrook, and St. Mary-le-bow, with upwards of 60 other churches and public works, which that dreadful fire rendered necessary. In the management of which business, he was assisted in the measurements, and laying out of private property, by the ingenious Dr. Robert Hooke. The variety of business in which he was by this means engaged, requiring his constant attendance and concern, he resigned his Savilian professorship at Oxford in 1673; and the year following he received from the king the honour of knighthood.—He was one of the commissioners who, on the motion of sir Jonas Moore, surveyor-general of the ordnance, had been appointed to select a proper place for erecting an observatory; and he proposed Greenwich, which was accordingly approved of; the foundation stone of which was laid the 10th of August 1675, and the building was presently finished under the direction of sir Jonas, with the advice and assistance of sir Christopher.

In 1680 our author was chosen president of the Royal Society; afterwards appointed architect and commissioner of Chelsea-college; and in 1684, principal officer or comptroller of the works in Windsor-castle. Sir Christopher sat twice in Parliament, as a representative for two different boroughs. While he continued surveyor-general, his residence was in Scotland-yard; but after his removal from that office, in 1718, he lived in St. James's-street, Westminster. He died the 25th of February 1723, at 91 years of age; and was interred with great solemnity in St. Paul's cathedral, in the vault under the south wing of the choir, near the east end.

The person of Sir Christopher Wren was of a low stature, and thin frame of body; but by temperance and skilful management he enjoyed a good state of health, to a very unusual length of life. He was modest, devout, strictly virtuous, and very communicative of his knowledge. Besides his peculiar eminence as an architect, his learning and knowledge were very extensive in all the arts and sciences, and especially in the mathematics.

Sir Christopher never printed any thing himself, but several of his works have been published by others; some in the Philosophical Transactions, and some by Dr. Wallis and other friends.—His posthumous works and draughts were published by his son.

WRIGHT (Edward), a distinguished English mathematician, who flourished in the latter part of the 16th century, and beginning of the 17th; dying in the year 1615. He was contemporary with Mr. Briggs, and much concerned with him in the business of the logarithms, the short time they were published before his death. He also contributed greatly to the improvement of navigation and astronomy. The following memoirs of him are translated from a Latin paper in the annals of Gonville and Caius-college in Cambridge, viz, "This year (1615) died at London, Edward Wright of Garveston in Norfolk, formerly a fellow of this college; a man respected by all for the integrity and simplicity of his manners, and also famous for his skill in the mathematical sciences: so that he was not undeservedly styled a most excellent mathematician by Richard Hackluyt, the author of an original treatise of our English navigations. What knowledge he had acquired in the science of mechanics, and how usefully he employed that knowledge to the public as well as private advantage, abundantly appear both from the writings he published, and from the many mechanical operations still extant, which are standing monuments of his great industry and ingenuity. He was the first undertaker of that difficult but useful work, by which a little river is brought from the town of Ware in a new canal, to supply the city of London with water; but by the tricks of others he was hindered from completing the work he had begun. He was excellent both in contrivance and execution, nor was he inferior to the most ingenious mechanic in the making of instruments, either of brass or any other matter. To his invention is owing whatever advantage Hondius's geographical charts have above others; for it was Wright who taught Jodocus Hondius the method of constructing them, which was till then unknown: but the ungrateful Hondius concealed the name of the true author, and arrogated the glory of the invention to himself. Of this fraudulent practice the good man could not help complaining, and justly enough, in the preface to his treatise of the Correction of Errors in the Art of Navigation; which he composed with excellent judgment, and after long experience, to the great advancement of naval affairs. For the improvement of this art he was appointed mathematical lecturer by the East-India Company, and read lectures in the house of that worthy knight sir Thomas Smith, for which he had a yearly salary of 50 pounds. This office he discharged with great reputation, and much to the satisfaction of his hearers. He published in English a book on the doctrine of the sphere, and another concerning the construction of sun dials. He also prefixed an ingenious preface to the learned Gilbert's book on the loadstone. By these and other his writings, he has transmitted his fame to latest posterity. While he was yet a fellow of this college, he could not be concealed in his private study, but was called forth to the public business of the nation, by the queen, about the year 1593. [Other accounts say 1589.] He was ordered to attend the earl of Cumberland in some maritime expeditions. One of these he has given a faithful account of, in the manner of a journal or ephemeris, to which he has prefixed an elegant hydrographical chart of his own contrivance. A little before his death he employed himself about an English translation of the book of logarithms, then lately discovered by lord Napier, a Scotchman, who had a great affection for him. This posthumous work of his was published soon after, by his only son Samuel Wright, who was also a scholar of this college. He had formed many other useful designs, but was hindered by death from bringing them to perfection. Of him it may truly be said, that he studied more to serve the public than himself; and though he was rich in fame, and in the promises of the great, yet he died poor, to the scandal of an ungrateful age." So far the memoir; other particulars concerning him, are as follow.

Mr. Wright first discovered the true method of dividing the meridian line, according to which the Mercator's charts are constructed, and upon which Mercator's sailing is founded. An account of this he sent from Caius-college, Cambridge, where he was then a fellow, to his friend Mr. Blondeville, containing a short table for that purpose, with a specimen of a chart so divided, together with the manner of dividing it. All which Blondeville published, in 1594, among his Exercises. And, in 1597, the reverend Mr. William Barlowe, in his Navigator's Supply, gave a demonstration of this division as communicated by a friend.

At length, in 1599, our author himself printed his celebrated treatise, entitled, The Correction of certain Errors in Navigation, which had been written many years before; where he shows the reason of this division of the meridian, the manner of constructing his table, and its uses in navigation, with other improvements. In 1610 a second edition of Mr. Wright's book was published, and dedicated to his royal pupil, prince Henry; in which the author inserted farther improvements; particularly, he proposed an excellent way of determining the magnitude of the earth; at the same time, recommending very judiciously, the making our common measures in some certain proportion to that of a degree on its surface, that they might not depend on the uncertain length of a barley-corn. Some of his other improvements were; The Table of Latitudes for dividing the meridian, computed as far as to minutes: An instrument, he calls the Sea-rings, by which the variation of the compass, the altitude of the sun, and the time of the day, may be readily determined at once in any place, provided the latitude be known: The correcting of the errors arising from the excentricity of the eye in observing by the cross-staff: A total amendment in the tables of the declinations and places of the sun and stars, from his own observations, made with a six-foot quadrant, in the years 1594, 95, 96, 97: A sea-quadrant, to take altitudes by a forward or backward observation; having also a contrivance for the ready finding the latitude by the height of the pole-star, when it is not on the meridian. And that this book might be the better understood by beginners, to this edition is subjoined a translation of Zamorano's Compendium; and he added a large table of the variation of the compass as observed in very different parts of the world, to show that it is not occasioned by any magnetical pole. The work has gone through several other editions since. Description and Use of the Sphere, in 1618. And, besides the books above mentioned, he published another on navigation, entitled, The Haven-finding Art, translated from the Dutch. Other accounts of our author state also, that it was in the year 1589 that he first began to attend the earl of Cumberland in his voyages. It is also said that he made, for his pupil, prince Henry, a large sphere with curious movements, which, by the help of spring-work, not only represented the motions of the whole celestial sphere, but showed also the particular systems of the sun and moon, and their circular motions, together with their places and possibilities of eclipsing each other: there are in this machine works for a motion of 17100 years, if it should not be stopt, or the materials fail. This sphere, though thus made at a great expense of money and ingenious industry, was afterwards in the time of the civil wars thrown aside, among dust and rubbish, where it was found, in the year 1646, by sir Jonas Moore, who at his own expense restored it to its first state of perfection, and deposited it at his own house in the Tower, among his other mathematical instruments and curiosities.

See Robertson's Navigation, Introd. pa. 12. Also the Philos. Magazine, vol. 21, pa. 164.

X.

XENOCRATES, an eminent philosopher among the ancient Greeks, was born at Chalcedon, and died 314 years before Christ, at about 90 years of age. He became early a disciple of Plato, studying under this great master at the same time with Aristotle, though he was not possessed of equal talents; the former wanting a spur, and the latter a bridle. He was fond of the mathematics; and permitted none of his scholars to be ignorant of them. There was something slovenly in the behaviour of Xenocrates; for which reason Plato frequently exhorted him to sacrifice to the graces. Seriousness and severity were always seen in his deportment: yet notwithstanding this severe cast of mind, he was very compassionate. There was also something very extraordinary in the rectitude of his morals: he was absolute master of his passions; and was not fond of pleasure, riches, or applause. Indeed, so great was his reputation for sincerity and probity, that he was the only person whom the magistrates of Athens dispensed from confirming his testimony with an oath: and yet he was so ill treated by them, as to be sold because he could not pay the poll-tax laid upon foreigners. Demetrius Phalereus bought Xenocrates, paid the debt to the Athenians, and immediately gave him his liberty. At Alexander's request, he composed a treatise on the Art of Reigning; 6 books on Nature; 6 books on Philosophy; one on Riches, &c; but none of them have descended to the present times.—His theology it seems was but poor stuff: Cicero refutes him in the first book of the Nature of the Gods.

XENOPHANES, a Greek philosopher, born in Colophon, was, according to some authors, the disciple of Archelaus; in which case he must have been contemporary with Socrates. Others relate that he was quite an autodidact, being entirely self-taught, and that he lived at the same time with Anaximander: according to which account he must have flourished before Socrates, and about the 60th Olympiad, as Diogenes Laertius affirms. He founded the Eleatic sect; and wrote several poems on philosophical subjects; as also a great many on the foundation of Colophon, and on that of the colony of Elea. He wrote also against Homer and Hesiod. He was banished from his country, withdrew to Sicily, and lived in Zanche and Catana. His opinion with regard to the nature of God differs not much from that of Spinoza. When he saw the Egyptians pour forth lamentations during their festivals, he thus advised them: "If the objects of your worship are Gods, do not weep: if they are men, offer not sacrifices to them." The answer he made to a man with whom he refused to play at dice, is highly worthy of a philosopher: This man calling him a coward, "Yes," replied he, "I am excessively so with regard to all shameful actions."

XENOPHON, a celebrated Greek general, philosopher, and historian, was born at Athens, and became early a disciple of Socrates, who, says Strabo, saved his life in battle. About the 50th year of his age he engaged in the expedition of Cyrus, and accomplished his immortal retreat in the space of 15 months. The jealousy of the Athenians banished him from his native city, for engaging in the service of Sparta and Cyrus. On his return therefore he retired to Scillus, a town of Elis, where he built a temple to Diana, which he mentions in his epistles, and devoted his leisure to philosophy and rural sports. But commotions arising in that country, he removed to Corinth, where it seems he wrote his Grecian History, and died at the age of 90, in the year 360 before Christ.

By his wife Philesia he had two sons, Diodorus and Gryllus. The latter rendered himself immortal by killing Epaminondas in the famous battle of Mantinea, but perished in that exploit, which his father lived to record.

The best editions of his works are those of Franckfort in 1674, and of Oxford, in Greek and Latin, in 1703, 5 vols. 8vo. Separately have been published his Cyropædia, Oxon. 1727, 4to, and 1736, 8vo. Cyri Anabasis, Oxon. 1735, 4to, and 1747, 8vo. Memorabilia Socratis, Oxon. 1741, 8vo.—His Cyri Anabasis has been admirably translated into English by Spelman.

XIPHIAS, in Astronomy, is the Dorado or Sword-fish, a constellation of the southern hemisphere; being one of the new constellations added by modern astronomers; and consisting of 6 stars only. See DORADO.

Y.

YARD, a lineal measure, or measure of length, used in England and Spain, chiefly to measure cloth, stuffs, &c. The yard was settled by Henry the 1st, from the length of his own arm.

The English yard contains 3 feet; and it is equal
- to 4-5ths of the English ell,
- to 7-9ths of the Paris ell,
- to 4-3ds of the Flemish ell,
- to 56-51sts of the Spanish vara or yard.

YARD, or *Golden* YARD, is also a popular name given to the 3 stars which compose the belt of Orion.

YEAR, in the full extent of the word, is a system or cycle of several months, usually 12. Others define year, in the general, a period or space of time, measured by the revolution of some celestial body in its orbit. Thus, the time in which the fixed stars make a revolution, is called the great year; and the times in which Jupiter, Saturn, the Sun, Moon, &c, complete their courses, and return to the same point of the zodiac, are respectively called the years of Jupiter, and Saturn, and the Solar, and Lunar years, &c.

As year denoted originally a revolution, and was not limited to that of the sun; accordingly we find by the oldest accounts, that people have, at different times, expressed other revolutions by it, particularly that of the moon; and consequently that the years of some accounts, are to be reckoned only months, and sometimes periods of 2, or 3, or 4 months. This will assist us greatly in understanding the accounts that certain nations give of their own antiquity, and perhaps also of the age of men. We read expressly, in several of the old Greek writers, that the Egyptian year, at one period, was only a month; and we are farther told that at other periods it was 3 months, or 4 months: and it is probable that the children of Israel followed the Egyptian account of their years. The Egyptians boasted, almost 2000 years ago, of having accounts of events 48 thousand years distance. A great deal must be allowed to fallacy, on the above account; but besides this, the Egyptians had, in the time of the Greeks, the same ambition which the Chinese have at present, and wanted to pass themselves on that people, as these do upon us, for the oldest inhabitants of the earth. They had recourse also to the same means, and both the present and the early impostors have pretended to ancient observations of the heavenly bodies, and recounted eclipses in particular, to vouch for the truth of their accounts. Since the time in which the solar year, or period of the earth's revolution round the sun, has been received, we may account with certainty; but for those remote ages, in which we do not precisely know what is meant by the term year, it is impossible to form any satisfactory conjecture of the duration of time in the accounts. The Babylonians pretend to an antiquity of the same romantic kind; they boast of 47 thousand years in which they had kept observations; but we may judge of these as of the others, and of the observations as of the years. The Egyptians speak of the stars having four times altered their courses in that period which they claim for their history, and that the sun set twice in the east. They were not such perfect astronomers, but, after a round-about voyage, they might perhaps mistake the east for the west, when they came in again.

YEAR, or SOLAR YEAR, properly, and by way of eminence so called, is the space of time in which the sun moves through the 12 signs of the ecliptic. This, by the observations of the best modern astronomers, contains 365 days, 5 hours, 48 min. 45¾ seconds: the quantity assumed by the authors of the Gregorian calendar is 365 days, 5 hours, 49 min. But in the civil or popular account, this year only contains 365 days; except every 4th year, which contains 366.

The vicissitude of seasons seem to have given occasion to the first institution of the year. Man, naturally curious to know the cause of that diversity, soon found it was the proximity and distance of the sun; and therefore gave the name year to the space of time in which that luminary performed his whole course, by returning to the same point of his orbit. According to the accuracy of their observations, the year of some nations was more perfect than that of others, but none of them quite exact, nor whose parts did not vary with regard to the parts of the sun's course.

Herodotus informs us that it was the Egyptians who first formed the year, making it to contain 360 days, which they subdivided into 12 months, of 30 days each. Mercury Trismegistus added 5 days more to the account. And on this footing it is said that Thales instituted the year among the Greeks; though that form of the year did not obtain through all Greece. Also, the Jewish, Syrian, Roman, Persian, Ethiopic, Arabic, &c years, were all different. In fact, considering the imperfect state of astronomy in those ages, it is no wonder that different people should disagree in the calculation of the sun's course. We are even assured by Diod. Siculus, lib. 1. Plutarch, in Numa, and Pliny, lib. 7, cap. 48, that the Egyptian year itself was at first very different from that now represented.

The solar year is either astronomical or civil.

The *Astronomical Solar* YEAR, is that which is determined precisely by astronomical observations; and is of two kinds, tropical, and sidereal or astral.

Tropical, or *Natural* YEAR, is the time the sun takes in passing through the zodiac; which, as before observed, is 365d. 5h. 48m. 45¾ sec. This is the only proper or natural year, because it always keeps the same seasons to the same months.

Sidereal or *Astral* YEAR, is the space of time the sun takes in passing from any fixed star, till his return to it again. This consists of 365d. 6h. 9m. 17 sec.; being 20m. 21½ sec. longer than the true solar year.

Lunar YEAR, is the space of 12 lunar months. Hence, from the two kinds of synodical lunar months, there arise two kinds of lunar years; the one astronomical, the other civil.

Lunar Astronomical YEAR, consists of 12 lunar synodical months; and contains 354d. 8h. 48m. 38 sec. and is therefore 10d. 21h. 0m. 7s. shorter than the solar year. A difference which is the foundation of the epact.

Lunar Civil YEAR, is either common or embolismic.

The *Common Lunar* YEAR consists of 12 lunar civil months; and therefore contains 354 days. And

The *Embolismic* or *Intercalary Lunar* YEAR, consists of 13 lunar civil months, and therefore contains 384 days.

Thus far we have considered years and months, with regard to astronomical principles, upon which the division is founded. By this, the various forms of civil years that have formerly obtained, or that do still obtain, in divers nations, are to be examined.

Civil YEAR, is that form of year which every nation has contrived or adopted, for computing their time by. Or the civil is the tropical year, considered as only consisting of a certain number of whole days: the odd hours and minutes being set aside, to render the computation of time, in the common occasions of life, more easy. As the tropical year is 365d. 5h. 49m. or almost 365d. 6h. which is 365 days and a quarter; therefore if the civil year be made 365 days, every 4th year it must be 366 days, to keep nearly to the course of the sun. And hence the civil year is either common or bissextile. The

Common Civil YEAR, is that consisting of 365 days; having seven months of 31 days each, four of 30 days, and one of 28 days; as indicated by the following well known memorial verses:

Thirty days hath September,
April, June, and November;
February twenty-eight alone,
And all the rest have thirty-one.

Bissextile or *Leap* YEAR, consists of 366 days; having one day extraordinary; called the intercalary, or bissextile day; and takes place every 4th year. This additional day to every 4th year, was first introduced by Julius Cæsar; who, to make the civil years keep pace with the tropical ones, contrived that the 6 hours which the latter exceeded the former, should make one day in 4 years, and be added between the 22d and 23d of February, which was their 6th of the calends of March; and as they then counted this day twice over, or had bis sexto calendas, hence the year itself came to be called bis sextus, and bissextile.

However, among us, the intercalary day is not introduced by counting the 23d of February twice over, but by adding a day at the end of that month, which therefore in that year contains 29 days.—A farther reformation was made in this year by Pope Gregory. See *Gregorian* YEAR, CALENDAR, BISSEXTILE, and LEAP-*Year*.

The civil or legal year, in England, formerly commenced on the day of the Annunciation, or 25th of March; though the historical year began on the day of the Circumcision, or 1st of January; on which day the German and Italian year also commences. The part of the year between these two terms was usually expressed both ways: as 1745-6, or 174$\frac{5}{6}$. But by the act for altering the stile, the civil year now commences with the 1st of January.

Ancient Roman YEAR. This was the lunar year, which, as first settled by Romulus, contained only ten months, of unequal numbers of days in the following order: viz, March 31; April 30; May 31; June 30; Quintilis 31; Sextilis 30; September 30; October 31; November 30; December 30; in all 304 days; which came short of the true lunar year by 50 days; and of the solar by 61 days. Hence, the beginning of Romulus's year was vague, and unfixed with regard to any precise season; to remove which inconvenience, that prince ordered so many days to be added yearly as would make the state of the heavens correspond to the first month, without calling them by the name of any month.

Numa Pompilius corrected this irregular constitution of the year, composing two new months, January and February, of the days that were used to be added to the former year. Thus Numa's year consisted of 12 months, of different days, as follow; viz,

January - 29;	February - 28;	March - - 31;
April - - 29;	May - - - - 31;	June - - - 29;
Quintilis 31;	Sextilis - - - 29;	September 29;
October - 31;	November - 29;	December 29;

in all 355 days; therefore exceeding the quantity of a lunar civil year by one day; that of a lunar astronomical year by $15^h\ 11^m\ 22^s$; but falling short of the common solar year by 10 days; so that its beginning was still vague and unstable.

Numa, however, desiring to have it begin at the winter solstice, ordered 22 days to be intercalated in February every 2d year, 23 every 4th, 22 every 6th, and 23 every 8th year. But this rule failing to keep matters even, recourse was had to a new way of intercalating; and instead of 23 days every 8th year, only 15 were to be added. The care of the whole was committed to the pontifex maximus; who however, neglecting the trust, suffered things to run to great confusion. And thus the Roman year stood till Julius Cæsar reformed it. See CALENDAR. And for the manner of reckoning the days of the Roman months, see CALENDS, NONES, and IDES.

Julian YEAR. This is in effect a solar year, commonly containing 365 days; though every 4th year, called bissextile, it contains 366. The months of the Julian year, with the number of their days, stood thus:

January - - 31;	February - 28;	March - - 31;
April - - - 30;	May - - - 31;	June - - 30;
July - - - 31;	August - - 31;	September 30;
October - 31;	November 30;	December 31.

But every bissextile year had a day added in February, making it then to contain 29 days.

The mean quantity therefore of the Julian year is 365$\frac{1}{4}$ days, or $365^d\ 6^h$; exceeding the true solar year by somewhat more than 11 minutes; an excess which amounts to a whole day in almost 131 years. Hence the times of the equinoxes go backward, and fall earlier by one day in about 130 or 131 years. And thus the Roman year stood, till it was farther corrected by pope Gregory.

For settling this year, Julius Cæsar brought over from Egypt, Sosigenes, a celebrated mathematician; who, to supply the defect of 67 days, which had been lost through the neglect of the priests, and to bring the beginning of the year to the winter solstice, made one year to consist of 15 months, or 445 days; on which account that year was used to be called annus confusionis, the year of confusion. See *Julian* CALENDAR.

Gregorian YEAR. This is the Julian year corrected by this rule, viz, that instead of every secular or 100th year being a bissextile, as it would be in the former mode, in the new way three of them are common years, and only the 4th is bissextile.

The error of 11 minutes in the Julian year, by continual repetition, had accumulated to an error of 13 days from the time when Cæsar made his correction; by which means the equinoxes were greatly disturbed. In the year 1582, the equinoxes were fallen back 10 days, and the full moons 4 days, more backward than they were in the time of the Nicene council, which was in the year 325; viz, the former from the 20th of March to the 10th, and the latter from the 5th to the 1st of April. To remedy this increasing irregularity, pope Gregory the 13th, in the year 1582, called together the chief astronomers of his time, and concerted this correction, omitting the 10 days above mentioned. He exchanged the lunar cycle for that of the epacts, and made the 5th of October of that year to be the 15th; by that means restoring the vernal equinox to the 21st of March. It was also provided, by the omission of 3 intercalary days, in 400 years, to make the civil year keep pace nearly with the solar year, for the time to come. See CALENDAR.

In the year 1700, the error of 10 days was increased to 11; upon which, the protestant states of Germany, to prevent farther confusion, adopted the Gregorian correction. And the same was accepted also in England in the year 1752, when 11 days were thrown out after the 2d of September that year, by accounting the 3d to be the 14th day of the month: calling this the new style, and the former the old style. And the Gregorian, or new style, is now in like manner used in most countries of Europe.

Yet this last correction is still not quite perfect; for as it has been shown that, in 4 centuries, the Julian year gains $3^d\ 2^h\ 40^m$; and as it is only the 3 days that are kept out in the Gregorian year; there is still an excess of $2^h\ 40^m$ in 4 centuries, which amounts to a whole day in 36 centuries, or in 3600 years. See CALENDAR, *New* or *Gregorian* STILE, &c.

Egyptian YEAR, called also the year of Nabonassar, on account of the epoch of Nabonassar, is the solar year of 365 days, divided into 12 months, of 30 days each, beside 5 intercalary days, added at the end. The order and names of these months are as follow:

1. Thoth;	2. Paophi;	3. Athyr;
4. Chojac;	5. Tybi;	6. Mecheir;
7. Phamenoth;	8. Pharmuthi;	9. Pachon;
10. Pauni;	11. Epiphi;	12. Mesori.

As the Egyptian year, by neglecting the 6 hours, in every 4 years loses a whole day of the Julian year, its beginning runs through every part of the Julian year in the space of 1460 years; after which, they meet again; for which reason it is called the erratic year. And because this return to the same day of the Julian year, is performed in the space of 1460 Julian years, this circle is called the Sothic period.

This year was applied by the Egyptians to civil uses, till Anthony and Cleopatra were defeated; but the mathematicians and astronomers used it till the time of Ptolemy, who made use of it in his Almagest; so that the knowledge of it is of great service in astronomy, for comparing the ancient observations with the modern.

The ancient Egyptians, we are informed by Diodorus Siculus, (Plutarch, lib. 1, in the life of Numa; and Pliny, lib. 7, cap. 48) measured their years by the course of the moon. At first they were only one month, then 3, then 4, like that of the Arcadians; and then 6, like that of the people of Acarnania. Those authors add, that it is on this account that they reckon such a vast number of years from the beginning of the world; and that in the history of their kings, we meet with some who lived 1000, or 1200 years. The same thing is maintained by Kircher; Oedip. Egypt. tom. 2, pa. 252. And a late author observes, that Varro has affirmed the same of all nations, that has been quoted of the Egyptians. By which means many account for the great ages of the more ancient patriarchs; expounding the gradual decrease in their ages, by the successive increase of the number of months in their years.

On the Egyptians being subdued by the Romans, they received the Julian year, though with some alteration; for they still retained their ancient months, with the five additional days, and every 4th year they intercalated another day, for the 6 hours, at the end of the year, or between the 28th and 29th of August. Also, the beginning of their year, or the first day of the month Thoth, answered to the 29th of August of the Julian year, or to the 30th if it happened to be leap year.

The Ancient Greek YEAR.—This was a lunar year, consisting of 12 months, which at first had each 30 days, then alternately 29 and 30 days, computed from the first appearance of the new moon; with the addition of an embolismic month of 30 days, every 3d, 5th, 8th, 11th, 14th, 16th, and 19th year of a cycle of 19 years; in order to keep the new and full moons to the same terms or seasons of the year.

Their year commenced with that new moon which was nearest to the summer solstice. And the order of the months, with the number of their days, were as follow: 1. Εκατομβαιων, of 29 days; 2. Μηταγειτνιων 30; 3. Βοηδρομιων 29; 4. Μαιμακτηριων 30; 5. Πυανεψιων 29; 6. Ποσειδεων 30; 7. Γαμηλιων 29; 8. Ανθεστηριων 30; 9. Ελαφηβολιων 29; 10. Μουνυχιων 30; 11. Θαργηλιων 29; 12. Σκιροφοριων 30.—But many of the Greek nations had other names for their months.

The Ancient Jewish YEAR.—This is a lunar year, usually consisting of 11 months, containing alternately 30 and 29 days. And it was made to agree with the solar year, by adding 11, and sometimes 12 days, at the end of the year, or by an embolismic month. The order and quantities of the months were as follow: 1. Nisan or Abib 30 days; 2. Jiar or Zius 29; 3. Siban or Sievan 30; 4. Thamuz or Tamuz 29; 5. Ab 30; 6. Elul 29; 7. Tifri or Ethanim 30; 8. Marchesvan or Bul 29; 9. Cisleu 30; 10. Tebeth 29; 11. Sabat or Schebeth 30; 12. Adar 30 in the embolismic year, but 29 in the common year.—In the defective year, Cisleu was only 29 days; and in the redundant year, Marchesvan was 30.

The Modern Jewish YEAR is likewise lunar, consisting of 12 months in common years, but of 13 in embolismic years; which, in a cycle of 19 years, are the 3d, 6th, 8th, 11th, 14th, 17th, and 19th. Its beginning is fixed to the new moon next after the autumnal equinox. The names and order of the months, with the number of the days, are as follow: 1. Tisri 30 days; 2. Marchesvan 29; 3. Cisleu 30; 4. Tebeth 29; 5. Schebeth 30; 6. Adar 29; 7. Veadar, in the embolismic year, 30; 8. Nisan 30; 9. Ilar 29; 10. Sivan 30; 11. Thamuz 29; 12. Ab 30; 13. Elul 29.

The Syrian YEAR, is a solar one, having its commencement fixed to the beginning of October in the Julian year; from which it only differs in the names of the months, the quantities being the same; as follow: 1. Tishrin, answering to our October, and containing 31 days; 2. Latter Tishrin, containing, like November, 30 days; 3. Canun 31; 4. Latter Canun 31; 5. Shabat 28, or 29 in a leap-year; 6. Adar 31; 7. Nisan 30; 8. Aiyar 31; 9. Haziram 30; 10. Thamuz 31; 11. Ab 31; 12. Elul 30.

The Persian YEAR, is also a solar one, of 365 days, consisting of 12 months of 30 days each, with 5 intercalary days added at the end. The months are as follow: 1. Asrudia meh; 2. Ardibascht meh; 3. Cardi meh; 4. Thir meh; 5. Merded meh; 6. Schabarir meh; 7. Mehar meh; 8. Aben meh; 9. Adar meh; 10. Di Meh; 11. Behen meh; 12. Assirer meh. This year is the same as the Egyptian Nabonassarean, and is called the Yezdegerdic year, to distinguish it from the fixed solar year, called the Gelalean year, which the Persians began to use in the year 1079, and which was formed by an intercalation, made six or seven times in 4 years, and then once every 5th year.

The Arabic, Mahometan, and Turkish YEAR, called also the year of the Hegira, is a lunar year, equal to 354^d 8^h 48^m, and consists of 12 months, containing alternately 30 and 29 days. Though sometimes it contains 13 months; the names &c being as follow: 1. Muharram of 30 days; 2. Saphar 29; 3. Rabia 30; 4. Latter Rabia 29; 5. Jomada 30; 6. Latter Jomada 29; 7. Rajab 30; 8. Shaaban 29; 9. Ramadan 30; 10. Shawal 29; 11. Dulkaadah 30; 12. Dulheggia 29, but in the embolismic year 30. An intercalary day is added every 2d, 5th, 7th, 10th, 13th, 15th, 18th, 21st, 24th, 26th, 29th, in a cycle of 29 years. The months commence with the first appearance of the new moons after the conjunction.

Ethiopic YEAR, is a solar year perfectly agreeing with the Actiac, except in the names of the months, which are; 1. Mascaram; 2. Tykympt; 3. Hydar; 4. Tyshas; 5. Tyr; 6. Jacatil; 7. Magabit; 8. Mijazia; 9. Ginbat; 10. Syne; 11. Hamel; 12. Hahase. Intercalary days 5. It commences with the Egyptian year, on the 29th of August of the Julian year.

The Year of the Native Americans.—In Humboldt's Researches, concerning the institutions and monuments of the ancient inhabitants of America, among many other things concerning the Mexican nation, &c, we find several particulars relating to their year and computation of time. It seems that the Mexican calendar possesses a degree of accuracy and refinement, that rises considerably above all the other marks of their civilization. It appears that a stone of porphyry, of an enormous bulk, dug up in the year 1790, and covered with sculpture, evidently relative to the calendar, has thrown considerable light on this curious subject. The sculpture is in relievo, and well polished; the concentric circles, with their numerous divisions and subdivisions, are traced with mathematical exactness. In the centre of the stone is sculptured the hieroglyphic of the sun, surrounded by eight triangular radii. The god Tonatiuh is figured, opening his large mouth, armed with teeth, which reminds us of a figure of a divinity in Hindustan, the image of Kala, or Time.

It appears that the civil year of the Mexicans, was a solar year of 365 days, and divided into 18 months, of 20 days each, with 5 days added at the end. The beginning of the day was reckoned, like that of the Persians and Egyptians, from sun-rising. It was divided into 4 intervals, determined by the rising and setting of the sun, and its two passages over the meridian circle. The hieroglyphic of the day was a circle divided into 4 equal parts. Each month, of 20 days, was divided into 4 weeks, or periods of 5 days. The Muescas, a nation south of the Isthmus, had weeks of 3 days; but it does not appear that any nation of the new continent was acquainted with the week or cycle of 7 days; which, with a few exceptions, is found all over the old world.

Thirteen Mexican years formed a cycle, to which they gave a particular name; and 4 of these, constituting a period of 52 years, was denoted by another term; and two of these periods of 52 years formed what they called an old age. At the end of 52 years, 13 days were added, which makes the Mexican year agree with the Julian, of 365¼ days. But Gama, an astronomer very learned in the chronology and history of the Mexicans, is of opinion that they intercalated only 25 days in 104 years; and this would give the length of the year = 365·24 days, which is very near the truth; being more accurate than that of Hipparchus, and is nearly the same as that which was determined by the astronomers of the caliph Almamoun.

The Mexicans were in possession of annals which went back 8½ centuries before the arrival of Cortes in the country of Anahuac. The reckoning of time was according to periods of 52 or 104 years; and along with the series of years and days, expressed by hieroglyphics, the migrations of the nations, the battles and remarkable events of each reign, were represented in the paintings of which these annals were composed. In the reckoning of time, however, a particular artifice was employed; for though the numbering of the years and months, from a given era, would have sufficiently ascertained the date of any event, just as with us, this simple method was rejected, and in its stead was substituted a contrivance, by which the name of the year determined its relative situation. This device, M. Humboldt thinks, was the work of the priests, and was effected by dividing the cycle of 13 years into smaller cycles of 4 years each, and distinguishing these years by particular names.

The symbolical writing of the Mexican nations exhibited simple signs for the number 20, and for its 2d and 3d powers, 400 and 8000. A small standard, or flag, represented 20 units; 400, the square of 20, was figured by a feather, because grains of gold, inclosed in a quill, were used in some places as money, or a sign for the purposes of exchange. The figure of a sack indicated 8000, or the cube of 20, and had the name that was given to a kind of purse that contained 8000 grains of cocoa. A flag, divided by two cross lines, and half coloured, denoted 10; and when three quarters were coloured, it denoted 15. The Mexican vocabulary afforded names for numbers as far as 48 millions, and derived, according to the strictest rules of analogy, from the decimal mode of reckoning. The units, as far as 10, or 20 sometimes, were marked by dots or points; thus, 23 was expressed by a flag followed by 3 dots, &c.

M. Humboldt remarks, that several of the names by which the Mexicans denoted the 20 days of their month, are those of the signs of a zodiac, in use from the remotest antiquity among the nations of eastern Asia. He compares the names of the Mexican symbols for the days, with the Tartarean, Japanese, and Tibetan names of the 12 signs, and also with the names of the lunar houses of the Hindus. In 8 of the hieroglyphics the analogy is very striking. Thus, Atl, the name of the first day, as also of water, is indicated by an hieroglyphic, the parallel or undulating lines of which remind us of the sign Aquarius. In the Tibetan zodiac this sign is marked by a rat, which is also used as an emblem of water. The rat is likewise an asterism in the Chinese zodiac. Seven other of the names or characters stand related nearly in the same manner. M. Humboldt also justly considers it a remarkable circumstance, that the ape is a character used in the Mexican calendar, as it is in the Tibetan zodiac, and in the lunar houses of the Hindus, though this animal does not exist in the high country of the Andes.

It appears that the Mexicans made astronomical observations by means of the gnomon; and knew from them, that in the first year of the cycle, the equinoxes fell on certain days of the 4th and 13th month. The Peruvians and Cousko regulated their intercalation, not by the shadow of the gnomons, which they however very assiduously measured, but, by marks placed in the horizon, to denote where the sun rose and set on the days of the solstices and equinoxes.

For the Hindu year, see the Philos. Trans. Abridg. vol. 16, pa. 742, &c, and vol. 17, pa. 250, &c; also our article CHRONOLOGY.

YELLOW, one of the primary or original colours of light.

YESDEGERDIC YEAR. See *Persian* YEAR.

YOUNG (MATTHEW) D. D., the very learned bishop of Clonfert and Kilmacduach, was of a respectable family in the county of Roscommon, was born in 1750, and died Nov. 28, 1800, at Whitworth in Lancashire, of a lingering and painful malady, a cancer in the tongue. He was admitted into the university of Dublin in 1766, and elected fellow of the college in 1775. In the prosecution of that object, his attention was necessarily directed to the Newtonian philosophy, of which he early became an enthusiastic admirer; and displayed, at the examination for his fellowship, an unexampled knowledge and comprehension of it. It continued to be his favourite study, but not his only one. His active mind embraced in rapid succession the most dissimilar objects; and these he pursued with unceasing ardour, amidst his various duties as a fellow and tutor, and the freest intercourse with society, which he was formed at once to delight and instruct. His love of literary conversation, and the advantages he experienced from it in the pursuit of science, led him early to engage in forming a society whose chief object was the improvement of its members in theological learning. It consisted of a small number of his most intimate college friends, and continued to exist for a series of years, with equal reputation and advantage. Out of this association grew another, somewhat more extensive, whose labours were directed to philosophical researches, and in the formation of which Mr. Young was also actively engaged: and this itself became the germ of the Royal Irish Academy; which owes its existence to the zeal and exertions of the members of that society, among whom Mr. Young was particularly distinguished. In the intervals of his severer studies, he applied himself to modern languages; and the result of his labours may be seen in the Transactions of the R. I. A., to which he also contributed largely on mathematical and philosophical subjects.

In the first volume of their Transactions; A Synthetical Demonstration of the Rule for the Quadrature of Simple Curves per æquationes terminorum numero infinitas; On the Extraction of Cubic and other Roots; Ancient Gaelic poems respecting the race of the Frians collected in the Highlands. In vol. 2nd; An Enquiry into the different modes of Demonstration by which the Velocity of Spouting Fluids has been investigated a priori. In vol. 3rd; The Origin and Theory of the Gothic Arch. In vol. 4th; Demonstration of Newton's Theorems for the Correction of spherical Errors in the Object-glasses of Telescopes. In the 5th and 6th volumes, nothing. Besides these, Dr. Young published the following learned and ingenious works: The Phenomena of Sounds and Musical Strings, 8vo, 1784: The Force of Testimony, &c, 4to: The Number of Primitive Colours in Solar Light: On the Precession of the Equinoxes: Principles of Natural Philosophy, 8vo, 1800, being his last publication, and containing the substance of his lectures in the college.

In 1786, when the professorship of philosophy in Trinity-college became vacant, he had attained so high reputation in that branch of science, that he was elected to the office without opposition. His Essay on Sounds had been published some years; and it was known he was engaged in the arduous task of illustrating the Principia of Newton. He now devoted himself to the duties of his professorship; and the college having been enriched with the excellent apparatus of Mr. Atwood, Dr. Y. improved the fortunate occasion of carrying his lectures to a degree of perfection unknown in the university of Dublin, and never perhaps exceeded in any other. He proceeded in the mean time in his great work, "The Method of Prime and Ultimate Ratios, illustrated by a Commentary on the first two books of the Principia," and had nearly completed it in English, when he was advised by his friends to publish it in Latin. He readily acquiesced, and thus had an opportunity, while translating it, of revising the whole, and rendering it fuller and more perfect. It was finished a year or two before his appointment to the see of Clonfert, at which time he was engaged in preparing for its publication. His attention was unavoidably diverted from it by the occupations attending so important a change; and, before he could return to it, the dreadful malady had commenced, under which he languished for 15 months, before its fatal termination; though in the midst of his sufferings his ardour for science was not abated.

The circumstances of his promotion to the episcopal bench reflect equal honour on himself and the noble person (lord Cornwallis) who conferred it. It was a favour as unsolicited as unexpected, unless the report made to his Excellency by his principal secretary, on being consulted as to the properest person to fill the vacant see, may be called solicitation. His report was, that "he believed Dr. Young to be the most distinguished literary character in the kingdom;" and he was recommended accordingly.

Z.

ZAMORANO (Rerico), a good Spanish mathematician, in the 16th century, being the royal lecturer on that science, at Seville, where he published an excellent compendium of navigation, in 1585; being a treatise written clearly and with brevity, not being encumbered with such idle speculations as abound in Medina and Cortes. Zamorano, it seems, contributed much to the reforming the sea charts, as we are informed by his successor, Anares Garcia de Cespedes, who himself also published a treatise on navigation at Madrid, in 1606.

ZENITH, in Astronomy, the vertical point, or point in the heavens directly overhead. Or, the zenith is a point in the surface of the sphere, from which a right line drawn through the place of any spectator, passes through the centre of the earth. The zenith of any place, is also the pole of the horizon, being 90 degrees distant from every point of it. And through the zenith pass all the azimuths, or vertical circles.

The point diametrically opposite to the zenith, is called the nadir, being the point in the sphere directly under our feet: and it is the zenith to our antipodes, as our zenith is their nadir.

Zenith *Distance*, is the distance of the sun or star from our zenith; and is the complement of the altitude, or what it wants of 90 degrees.

ZENO, Eleates, or of *Elea*, one of the greatest philosophers among the ancients, flourished about 500 years before the Christian æra. He was the disciple of Parmenides, and even, according to some writers, his adopted son. Aristotle asserts that he was the inventor of logic: but his logic seems to have been calculated and employed to perplex rather than to illustrate and decide any thing; for Zeno employed it only to dispute against all comers, and to silence his opponents, whether they argued right or wrong. Among many other subtleties and embarrassing arguments, he proposed some with regard to motion, denying that there was any such thing in nature; and Aristotle, in the 6th book of his physics, has preserved some of them, which are extremely subtile, especially the famous argument named Achilles; which was to prove this proposition; that the swiftest animal could never overtake the slowest, as a greyhound a tortoise, if the latter set out a little before the former: for suppose the tortoise to be 100 yards before the dog, and that this runs 100 times as fast as the other; then while the dog runs the first 100 yards, the tortoise runs 1, and is therefore 1 yard before the dog; again, while the dog runs over this yard, the tortoise will run the 100th part of a yard, and will be so much before the dog; and again, while the dog runs over this 100th part of a yard, the tortoise will have got the 100th part of that 100th part before him; and so on continually, says he, the dog will always be some small part behind the tortoise. But the fallacy will soon be detected, by considering where the tortoise will be when the dog has run over 200 yards; for as the former can have run only two yards in the same time, and therefore must then be 98 yards behind the dog, he consequently must have overtaken and passed the tortoise. It has been said that, to prove to him, or some disciple of his, that there is such a thing as motion, Diogenes the Cynic rose up and walked over the floor.—Zeno showed great courage in suffering pain; for having joined with others to endeavour to restore liberty to his country, which groaned under the oppression of a tyrant, and the enterprise being discovered, he supported with extraordinary firmness the sharpest tortures. It is even said that he had the courage to bite off his tongue, and spit it in the tyrant's face, for fear of being forced, by the violence of his torments, to discover his accomplices. Some relate that he was pounded to death in a mortar.

Zeno, a celebrated Greek philosopher, was born at Citium, in the Isle of Cyprus, and was the founder of the Stoics; a sect which had its name from that of a portico at Athens, where this philosopher chose to hold his discourses. He was cast on that coast by shipwreck; and he ever after regarded this as a great happiness, praising the winds for having so happily driven him into the port of Piræum.—Zeno was the disciple of Crates, and had a great number of followers. He made the sovereign good to consist in dying in conformity to nature, guided by the dictates of right reason. He acknowledged but one God; and admitted an inevitable destiny over all events. His servant taking advantage of this last opinion, cried, while he was beating him for dishonesty, "I was destined to steal;" to which Zeno replied, "Yes, and to be beaten too." This philosopher used to say, "That if a wise man ought not to be in love, as some pretended, none would be more miserable than beautiful and virtuous women, since they would have none for their admirers but fools." He also said, "That a part of knowledge consists in being ignorant of such things as ought not to be known: that a friend is another self: that a little matter gives perfection to a work, though perfection is not a little matter." He compared those who spoke well and lived ill, to the money of Alexandria, which was beautiful, but composed of bad metal.—It is said that being hurt by a fall, he took that as a sign he was then to quit this life, and laid violent hands on himself, about 264 years before Christ.

Cleanthes, Crysippus, and the other successors of Zeno maintained, that with virtue we might be happy in the midst even of disgrace and the most dreadful torments. They admitted the existence of but one God, the soul of the world, which they considered as his body, and both together forming a perfect being. It is remarked that, of all the sects of the ancient philosophers, this was one of those which produced the greatest men. We ought not to confound the two Zenos above mentioned, with

Zeno, a celebrated Epicurean philosopher, born at Sidon, who had Cicero and Pomponius Atticus for his disciples, and who wrote a book against the mathematics, which, as well as that of Possidonius's refutation of it, is lost: nor yet with several other Zenos mentioned in history.

ZENSUS, or Zenzus, in Arithmetic and Algebra, a name used by some of the older authors, especially in Germany, for a square number, or the 2d power: being a corruption from the Italic *censi*, of Pacioli, Tartalea, &c, or the Latin *census*, which signified the same thing.

ZETETICE, or Zetetic *Method*, in Mathematics, was the method made use of to investigate, or find out the solution of a problem; and was much the same thing as analytics, or the analytic method. Vieta has an ingenious work of this kind in 5 books; Zeteticorum libri quinque.

ZOCCO, Zoccolo, Zocle, or Socle, in Architecture, a square body, less in height than in breadth, placed under the bases of pedestals, statues, vases, &c. See Socle and Plinth.

ZODIAC, in Astronomy, an imaginary ring or broad circle, in the heavens, in form of a belt or girdle, within which the planets all make their excursions. In the very middle of it runs the ecliptic, or path of the sun in his annual course; and its breadth, comprehending the deviations or latitudes of the planets, is by some authors accounted 16°, some 18, and others 20 degrees.

The zodiac, cutting the equator obliquely, makes with it the same angle as the ecliptic, which is its middle line, which angle, continually varying, is now nearly equal to 23° 27′ 46″; which is called the obliquity of the zodiac or ecliptic, and is also the sun's greatest declination.

The zodiac is divided into 12 equal parts, of 30 degrees each, called the signs of the zodiac, being so named from the constellations which anciently passed through them. But, the stars having an apparent motion from west to east, arising from the precession of the equinoxes, those constellations do not now correspond to their proper signs. And therefore, when a star is said to be in such a sign of the zodiac, it is not to be understood of that constellation, but only of that dodecatemory or 12th part of it.

The zodiac appears to be very ancient, and to have passed from the ancient Hindus, successively westward, through Persia, Arabia, Assyria, Egypt, &c, to Europe; as specimens of the same kind of zodiac have been found in all those countries, with only some small variation in the figures of some of the constellations; accompanied also with appropriate emblematical figures of the sun and moon, with those of the planets, in their order.

Cassini has also observed a tract in the heavens, within whose bounds most of the comets, though not all of them, are observed to keep, and which he therefore calls the Zodiac of the comets. This he makes as broad as the other zodiac, and marks it with signs or constellations, like that; as Antinous, Pegasus, Andromeda, Taurus, Orion, the Lesser Dog, Hydra, the Centaur, Scorpion, and Sagittary.

ZODIACAL *Light*, a brightness sometimes observed in the zodiac, resembling that of the galaxy or milky way. It appears at certain seasons, viz, towards the end of winter and in spring, after sunset, or before his rising, in autumn and beginning of winter, resembling the form of a pyramid, lying lengthwise with its axis along the zodiac, its base being placed obliquely with respect to the horizon. This phenomenon was first described and named by the elder Cassini, in 1683. It was afterwards observed by Fatio, in 1684, 1685, and 1686; also by Kirch and Eimmart, in 1688, 1689, 1691, 1693, and 1694. See Mairan, Suite des Mem. de l'Acad. Royale des Sciences 1731, pa. 3.

The zodiacal light, according to Mairan, is the solar atmosphere, a rare and subtile fluid, either luminous by itself, or made so by the rays of the sun surrounding its globe; but in a greater quantity, and more extensively, about his equator, than any other part. Mairan observes also that it may be proved from many observations, that the sun's atmosphere sometimes reaches as far as the earth's orbit, and there meeting with our atmosphere, produces the appearance of an aurora borealis. The length of the zodiacal light varies sometimes in reality; and sometimes in appearance only, from various causes.

Cassini often mentions the great resemblance between the zodiacal light and the tails of comets. The same observation has been made by Fatio: and Euler endeavoured to prove that they were owing to similar causes. See Découverte de la Lumière Celeste que paroit dans le Zodiaque, art. 41. Lettre à M. Cassini, printed at Amsterdam in 1686. Euler, in Mem. de l'Acad. de Berlin, tom. 2.

This light seems to have no other motion than that of the sun itself: and its extent from the sun to its point, is seldom less than 50 or 60 degrees in length, and more than 20 degrees in breadth: but it has been known to extend to 100 or 103°, and from 8 to 9° broad.

It is now generally acknowledged, that the electric fluid is the cause of the aurora borealis, ascribed by Mairan to the solar atmosphere, which produces the zodiacal light, and which is thrown off chiefly and to the greatest distance from the equatorial parts of the sun, by means of the rotation on his axis, and extending visibly as far as the orbit of the earth, where it falls into the upper regions of our atmosphere, and is collected chiefly towards the polar parts of the earth, in consequence of the diurnal revolution, where it forms the aurora borealis. And hence it has been suggested, as a probable conjecture, that the sun may be the fountain of the electrical fluid, and that the zodiacal light, and the tails of comets, as well as the aurora borealis, the lightning, and artificial electricity, are its various and not very dissimilar modifications.

ZONE, in Geography and Astronomy, a division of the earth's surface, by means of parallel circles, chiefly with respect to the degree of heat in the different parts of that surface.

The ancient astronomers used the term Zone, to explain the different appearances of the sun and other heavenly bodies, with the length of the days and nights; and the geographers, as they used the climates, to mark the situation of places; using the term climate when they were able to be more exact, and the term zone when less so.

The zones were commonly accounted five in number; one a broad belt round the middle of the earth, having the equator in the very middle of it, and bounded, towards the north and south, by parallel circles passing through the tropics of Cancer and Capricorn. This they called the torrid zone, which they supposed not habitable, on account of its extreme heat. Though sometimes they divided this into two equal torrid zones, by the equator, one to the north, and the other south; and then the whole number of zones was accounted 6.

Next, from the tropics of Cancer and Capricorn to the two polar circles, were two other spaces called temperate zones, as being moderately warm; and these they supposed to be the only habitable parts of the earth.

Lastly, the two spaces beyond the temperate zones, about either pole, bounded within the polar circles, and having the poles in the middle of them, are the two frigid or frozen zones, and which they supposed not habitable, on account of the extreme cold there.

Hence, the breadth of the torrid zone is equal to twice the greatest declination of the sun, or obliquity of the ecliptic, equal to 46° 56′, or twice 23° 28′. Each frigid zone is also of the same breadth, the distance from the pole to the polar circle being equal to the same obliquity 23° 28′. And the breadth of each temperate zone is equal to 43° 4′, the complement of twice the same obliquity. See these zones exhibited in plate 40, fig. 16.

The difference of zones is attended with a great diversity of phenomena. 1. In the torrid zone, the sun passes through the zenith of every place in it twice a year; making as it were two summers in the year; and the inhabitants of this zone are called amphiscians, because they have their noon-day shadows projected different ways in different times of the year, northward at one season, and southward at the other.

2. In the temperate and frigid zones, the sun rises and sets every natural day of 24 hours. Yet every where, but under the equator, the artificial days are of unequal lengths, and the inequality is the greater, as the place is farther from the equator. The inhabitants of the temperate zones are called heteroscians, because their noon-day shadow is cast the same way all the year round, viz, those in the north zone toward the north pole, and those in the south zone toward the south pole.

3. Within the frigid zones, the inhabitants have their artificial days and nights extended to a great length; the sun sometimes skirting round a little above the horizon for many days together: and at another season never rising above the horizon at all, but making continual night for a considerable time. The inhabitants of these zones are called periscians, because sometimes they have their shadows going quite round them in the space of 24 hours.
